P R E F A C E.

THE present SUPPLEMENT brings the Record of Chemical Discovery down to the end of the year 1869, including also several additions to, and corrections of, former results which have appeared in 1870 and 1871.

The author has been fortunate in obtaining the assistance of some of the former Contributors to the Dictionary, to whom he begs to tender his best thanks. The following is a list of their names and contributions:—

G. C. FOSTER, B.A., F.R.S.	Electricity.—Heat.
MICHAEL FOSTER, M.D.	Proteids.
BENJAMIN H. PAUL, PH.D.	Beer.—Iron, Metallurgy of.
H. E. ROSCOE, PH.D., F.R.S.	Light, Chemical Action of.—Spectral Analysis.
J. A. WANKLYN, <i>Corresponding Member of the Royal Bavarian Academy of Sciences</i>	Acetic Ether (in part).—Butyl Alcohols.—Butyric acid (in part).—Ethyl, Acetylinated.—Ketones.

CONTENTS

OF

THE LONGER ARTICLES.

	PAGE
ACETIC ACID	5-20
Formation by oxidation of alcohol	6
Physical properties.	6
Oxidation by Potassium-permanganate	6
Aqueous acetic acid, density of	6
Metallic acetates	9-13
Acetic ethers	13
Action of alkali-metals on ethyl acetate	15
Sodium-triacetyl	15
Ethyl- and methyl-triacetyl	16
Ethylene-sodium acetate	16
Methyl-acetate	17
Phenyl-acetate	18
Bromacetic and Chloracetic acids	18
Cyanacetic acid	19
Iodacetic acid	20
Thiacetic acid	20
ACETYLENE	30-37
Formation	30
Action of Electricity, Heat, Hydrogen, Hydrocarbons, Oxidising agents, Chlorine and Antimonic Chloride	32
Action of Bromine and Hydrobromic acid.	33
Action of Iodine and Hydriodic acid	34
Action of metals; Sodium- and Potassium-acetylene	35
Action of salts: Cuproso-vinyl oxide	35
Argento-vinyl oxide and chloride — Argentic Bromacetylde — Mercurovinyl acetate	36
Action of Sulphuric acid: Vinyl-sulphuric acid	37

	PAGE
ACIDS, ORGANIC	37-54
General relations and constitution	37
Basicity	38
Classification	39
1. Monatomic acids:	
Fatty or adipic series $C^nH^{2n}O^2$	39
Acrylic series $C^nH^{2n-4}O^2$	40
Series $C^nH^{2n-4}O^2$	43
Aromatic series $C^nH^{2n-8}O^2$	43
Series $C^nH^{2n-10}O^2$	43
2. Diatomic acids.	
<i>Diatomic and Monobasic:</i>	
Lactic series $C^nH^{2n}O^3$	44
Pyruvic series $C^nH^{2n-2}O^3$	45
Series $C^nH^{2n-4}O^3$ and $C^nH^{2n-8}O^3$	45
Series $C^nH^{2n-10}O^3$ and $C^nH^{2n-14}O^3$	46
<i>Diatomic and Dibasic:</i>	
Oxalic or succinic series $C^nH^{2n-2}O^4$	47
Fumaric series $C^nH^{2n-4}O^4$	47
Series $C^nH^{2n-6}O^4$, $C^nH^{2n-8}O^4$ and $C^nH^{2n-10}O^4$	50
3. Triatomic acids	50
4. Tetraatomic acids	51
5. Pentaatomic acids	52
6. Hexatomic acids	52
7. Sulpho-acids	52
ALCOHOLS	60-74
Monatomic alcohols:	
Series $C^nH^{2n+2}O$	61
Primary alcohols	62
Secondary alcohols	64
Tertiary alcohols	66
Series $C^nH^{2n}O$	66
Series $C^nH^{2n-2}O$, $C^nH^{2n-4}O$ and $C^nH^{2n-6}O$	67
Diatomic alcohols:	
1. Glycols, $C^nH^{2n+2}O^2$	67
2. Diatomic phenols, $C^nH^{2n-4}O^2$	70

	PAGE		PAGE
Alcohols (cont.)		Salts of organic acids	149
Triatomic alcohols:		Mercury-compounds	149
1. Glycerin	70	Proximate analysis of organic compounds by limited oxidation	149
2. Triatomic phenols	71	Proximate analysis of vegetable tissues	153
Tetratomic alcohols	71		
Pentatomic alcohols	72	ANALYSIS, VOLUMETRIC	153-155
Hexatomic alcohols:		Acidimetry and alkalimetry	153
Sugars	72	Titration of compound ethers	154
ANALYSIS, INORGANIC 123-125		Titration of alkaloids	155
Disintegration of insoluble substances	123	Volumetric analysis depending on absorption of oxygen	155
Qualitative analysis of solutions containing only the more ordinary metals, without the use of hydrogen sulphide or ammonium sulphide	124	Volumetric analysis without weighing	155
Influence of fixed organic substances on the precipitation of metallic oxides from saline solutions by alkalis	125		
ANALYSIS, INORGANIC by FLAME REACTIONS (Bunsen)	125-155	ANILINE COLOURS	159-170
I. The structure of the non-luminous gas-flame	125	Aniline black	159
II. Method of examination in the various parts of the flame:		Aniline blue	160
A. Behaviour of the elements at high temperatures	128	Aniline greens	161
B. Oxidation and reduction	128	Aldehyde green	161
III. Reactions of the elements	132-137	Iodine green	162
Examples of the method	137	Perkin's green	164
Tables of volatile elements which can be reduced as films	138	Aniline maroons and browns	164
ANALYSIS OF GASES:		Aniline pink	165
Williamson and Russell's apparatus	140	Aniline red	165
Russell's apparatus	140	Aniline violets:	
Application of the latter to the exact determination of the volume of gas given off in any chemical reaction	142	1. Mauve or aniline purple	167
ANALYSIS, ORGANIC	142-153	2. Methylaniline violets	167
Clooz' apparatus	142	3. Mauvaniline and violaniline	168
Schulze's method	143	4. Violets derived from rosaniline	168
Ladenburg's method	143	Aniline yellows:	
Wheeler's process for the simultaneous determination of C, H, and N	144	Chrysotoluidine	169
Baumhauer's apparatus for the simultaneous determination of C, H, and O	144	Diazo-amidobenzene and amido-diphenylanilide	169
A. Mitscherlich's new method of organic analysis: direct determination of oxygen	145	Zinaline	169
Estimation of nitrogen	146	Uses of aniline colours	169
Analysis of compounds containing chlorine or bromine	148		
Estimation of sulphur and phosphorus	148	AROMATIC SERIES	193-215
		Constitution of benzene	193
		Substitution-derivatives of benzene	194
		Additive compounds of the aromatic hydrocarbons	196
		Isomerism in the aromatic series	196
		1. Isomerism depending on the relative position of the substituted radicles in the benzene-ring or principal chain: <i>ortho</i> , <i>meta</i> , and <i>para</i> compounds	196
		2. Isomerism or metamerism depending on the position of the substituted radicles in the principal or in the lateral chains	199
		Aromatic hydrocarbons	199
		Haloid derivatives of the hydrocarbons	200

	PAGE
Aromatic Series (cont.)	
Phenols	201
Quinones	202
Aromatic bases	203
Aromatic acids	203
Formation of aromatic compounds	204
Azo- and diazo-compounds of the Aromatic Series	207
Appendix to the Aromatic Series :	
1. Cinnamic acid	211
2. Diphenyl	211
3. Naphthalene	212
4. Anthracene and alizarin	213

ARSENIC	215-226
Physical properties of metallic arsenic	215
Detection	215
Arsenious bromide	217
Arsenious chloride	217
Fluorides	218
Hydrides	218
Arsenious oxide	218
Arsenites	220
Arsenic oxide, acid, and salts	222
Sulphides	226

ATOMICITY	237-248
Definition of atomicity : monads, dyads, &c.	237
Artiads and perissads	238
Variation of atomicity	238
Saturated and unsaturated molecules	240
Closed and open chains	241
Compound radicles	242
Classification of elements according to their atomicities	243
Table of elementary bodies with their atomic weights	247

BENZENE	259-278
Formation, purification, and density	259, 260
Reactions	261
Detection of benzene in a mixture of volatile oils	262
Benzene hexbromide and bromobenzenes	263
Benzene hexchloride	263
Chlorides of chlorinated benzenes	264
Chlorobenzenes	264
Iodobenzenes	267
Nitrobenzenes	268
Nitrobromobenzenes	268
Nitrochlorobenzenes	269
Nitro-iodobenzene	269
Azobenzene	269
Amidazobenzene or Amidodiphenylimide	270
Hydrazobenzene	271
Azobenzene	272

Sulpho-derivatives of benzene :	
Benzene-sulphamide or sulphobenzolamide	273
Benzene-sulphuric or sulphobenzolic acid and its derivatives	273
Benzene-sulphurous acid	275
Chlorobenzene-sulphurous acid	276
Sulphobenzide	276
Dichlorosulphobenzide	277
Nitrosulphobenzide	277
Amidsulphobenzide	277
Diamidosulphobenzide	278

BENZENE, HOMOLOGUES OF	278-304
Densities and specific volumes of the aromatic hydrocarbons	278
Methyl-benzene or Toluene, C^7H^8	279
Bromotoluenes	280
Chlorotoluenes	281
Iodotoluene	282
Nitrotoluenes	282
Azotoluene	283
Azoxyluene	284
Toluene-sulphuric acid and derivatives	286
Toluene-sulphurous acid	288
Sulphotoluide	289
Tolyl bisulphoxide	289
Tolyl sulphide and sulphhydrate	290
Hydrocarbons, C^8H^{10} : Xylenes	291
Ethyl-benzene	292
Dimethyl-benzene or xylene	292
Bromo, chloro, and nitroxylenes	294
Azoxylene	295
Xylene-sulphurous acid	295
Xylol oxysulphide	295
Hydrocarbons C^8H^{12} , Cumenes	295
Propyl-benzene	295
Pseudocumene	296
Bromocumenes	296
Nitrocumenes	297
Pseudocumene sulphuric acid	297
Mesitylene	298
Bromomesitylenes	298
Chloromesitylenes	298
Hydroxyl-mesitylene	299
Nitromesitylene	299
Amido-mesitylene or mesidine	300
Diamidomesitylene or mesitylene-diamine	300
Mesitylene-sulphuric or sulphomesitylic acid	300
Mesitylene-sulphochloride	301
" sulphosamide	301

	PAGE
Benzene, Homologues of (<i>cont.</i>)	
Mesityl sulphhydrate	301
Mesitylene-sulphurous acid	301
Hydrocarbons, $C^{10}H^{14}$:	
Propyl-methyl-benzene or propyl-toluene	301
Diethyl-benzene	301
Ethyl-dimethyl-benzene or ethyl-xylene	302
Cymene	302
Hydrocarbons, $C^{11}H^{16}$:	
Amyl-benzene	303
Diethyl-methyl-benzene or diethyl-toluene	303
Propyl-dimethyl-benzene, propyl-xylene, or laurene	304
Amyl-methyl-benzene or amyl-toluene, $C^{12}H^{18}$	304
Amyl-dimethyl-benzene or amyl-xylene, $C^{13}H^{20}$	304
BENZOIC ACID	306-327
Formation. Decompositions	306, 307
Metallic benzoates	308
Benzoic ethers	308
Bromobenzoic acids	309
Chlorobenzoic acids	311
Iodobenzoic acids	313
Nitrobenzoic acids	313
Nitrobromobenzoic acid	315
Nitrochlorobenzoic acid	316
Nitro-iodobenzoic acid	316
Amidobenzoic acid	316
Bromamidobenzoic acid	317
Chloramidobenzoic acid	318
Hemicyan-amidobenzoic acid	318
Mota-amidobenzoic, amidosulylie, or anthranilic acid	319
Para-amidobenzoic or amido-draeylic acid	320
Azobenzoic acid	320
Para-azobenzoic or azo-draeylic acid	321
Hydrazobenzoic acid	321
Hydrazodraeylic acid	321
Azo-amidobenzoic or diazobenzo-amidobenzoic acid	322
Azo-amidodraeylic acid	322
Azoxybenzoic acid	322
Diazoxybenzoic acid	322
Sulphobenzoic acid	323
Thiobenzoic acid	324
Benzoyl sulphide or thio-benzoic anhydride	325
Benzoyl bisulphide	325
Thiobenzoyl sulphhydrate or dithiobenzoic acid	326

	PAGE
BLOOD	351-357
Proportions of various constituents of the blood: iron, cholesterin, protagon and fat, sugar and alcohol, urea, trimethylamine	351
Hæmoglobin, hæmatoglobine, or hæmatocrystallin	352
Compounds of hæmoglobin with CO, NO, HCy and KCy	354
Hæmatin	355
Hæmatin hydrochlorides; Teichmann's hæmin crystals	356
Detection of blood-stains	357
BORON	358-366
Graphitoid boron, identical with boride of aluminium	358
Boron chloride	358
Boron nitride	359
Boric oxide and acid	359
Metallic borates	360
Boric ethers	360

CHEMICAL ACTION . 422-429

Laws of connection between the condition of a chemical change and its amount	422
Influence of the relative quantities of the reacting substances	423
Influence of pressure on chemical action: dissociation	424

COMBUSTION . 483-488

Temperature of flame	483
Luminosity of flame	485
Conditions of explosion	486

CYANIDES, ALCOHOLIC 522-531

1. Normal hydrocyanic ethers or Nitriles	523
Methyl cyanide or acetonitrile	523
Ethyl cyanide or propionitrile	524
Propyl cyanide or butyronitrile	525
Isobutyronitrile	525
Amyl, heptyl, octyl and cetyl cyanides	525
Allyl cyanide or crotonitrile	525
Phenyl cyanide or benzonitrile	526
Nitrobenzonitrile	526
Amidobenzonitrile	526
Naphthyl cyanide	527
2. Isocyanides or Carbamines:	
Methyl-carbamine	528
Ethyl-carbamine	529
Isopropyl-, butyl-, amyl-, and phenyl-carbamines	530

DICTIONARY OF CHEMISTRY.

SUPPLEMENT.

A

ABIES. The needles of *Abies pectinata* contain a sugar called abietite, very much like mannite, but differing therefrom by its relations to solvents, and by its composition, which is represented by the formula $C^9H^{10}O^3$: it contains, therefore, $3H^2O$ less than mannite, $2H^2O$ less than quercite, and H^2 more than phloroglucin.

To separate the proximate principles contained in the needles, they were first exhausted with boiling alcohol, then with water; the aqueous decoction was precipitated by neutral lead acetate, and the precipitate, after washing with water, was treated with acetic acid, in which it is only partially soluble. The soluble portion was neutralised with ammonia, and re-precipitated by basic lead acetate; and this last precipitate, decomposed by hydrogen sulphide, yielded a tannin identical with the soluble tannin of the horse-chestnut, $C^{12}H^{12}O^4$. This tannin is transformed into an insoluble modification by adding hydrochloric acid to its solution, then agitating the liquid with six or eight volumes of ether, and leaving the whole to itself for ten or twelve hours. The precipitate thus obtained forms, after washing and drying, a chamois-coloured powder, insoluble in water, ether, and acetic acid, slightly soluble in boiling alcohol and in potash, which latter colours it red-brown. This insoluble tannin dissolves, however, in boiling potash, and when it is boiled with water and alcohol, a small quantity dissolves, forming a red liquid. The conversion of the soluble into the insoluble tannin is attended with loss of water; the latter has the composition $C^{12}H^{10}O^{11}$. (Rochleder, *J. pr. Chem.* cv. 63, 123.)

The fruits of *Abies Regina Amaliae*, indigenous in Arcadia, yield, by distillation with water, about 18 per cent. of a colourless volatile oil, $C^{10}H^{16}$, having a fragrant odour of lemons, a specific gravity of 0.868, boiling at $156-159^\circ$, slightly levo-gyrate. It resinises quickly in the air, exerting at the same time a stronger ozonising action than common turpentine oil. It dissolves iodine without rise of temperature, and absorbs hydrochloric acid gas, forming a liquid compound, $C^{10}H^{16}.HCl$. (Buchner & Thiel, *J. pr. Chem.* xcii. 109.)

ABIETIC ACID. See **SILVIC ACID**.

ABIETITE. See **ABIES**.

ABSINTHIN or **ABSYNTHIN.** This substance, the bitter principle of wormwood (*Artemisia Absinthium*), has been re-investigated by A. Kromayer (*Arch. Pharm.* [2] cviii. 129; *Jahresb.* 1861, p. 745). The mode of preparation adopted consists mainly in exhausting the dry herb of the plant with hot water; treating the concentrated extract with animal charcoal, which absorbs the bitter principle; then extracting it with alcohol, partially purifying it by treatment with lead-acetate, &c., as described at p. 2, vol. i.; then dissolving it in alcohol, precipitating it with tannic acid, washing the precipitate with water and weak spirit; dissolving it in strong alcohol; mixing it with levigated lead-oxide; evaporating the mixture after addition of a little water; boiling out the dry residue with alcohol; and leaving the colourless filtered liquid to evaporate slowly, in a moderately warm place. Absinthin then remains as a yellowish pulverulent mass, neutral, having an intensely bitter taste, and an aromatic odour like that of wormwood, nearly insoluble in cold, somewhat more

Sup.

B

soluble in hot water, easily in alcohol and ether. From the alcoholic solution it is gradually precipitated by water in white flocks. It melts between 120° and 125° , and decomposes at a stronger heat, giving off pungent vapours. Strong sulphuric acid dissolves it with brownish, afterwards greenish-blue colour, changing, on addition of a few drops of water, to a splendid blue, which disappears on further addition of water. When an alcoholic solution of absinthin is mixed with an equal volume of strong sulphuric acid, a brown-red mixture is formed which, on addition of a few drops of water, assumes a beautiful violet colour. Absinthin boiled with dilute sulphuric acid is converted into a brown resin, and the supernatant red-brown solution exhibits a beautiful yellow-green iridescence by reflected light. This solution does not contain sugar; neither is sugar produced by treating absinthin with strong hydrochloric acid. Strong nitric acid attacks absinthin only when heated; on mixing an alcoholic solution of absinthin with water till it begins to show turbidity, and then with solution of tannic acid, a pure white precipitate of tannate of absinthin is obtained, which assumes the consistence of a plaster when stirred, and after washing and drying at 100° , forms a greyish, easily pulverised mass. Absinthin does not reduce an alkaline solution of cupric oxide, but when warmed with ammoniacal silver nitrate forms a speculum of metallic silver. Solutions of absinthin are not precipitated by metallic salts.

The analysis of pure absinthin yielded numbers answering to the formula $C^{16}H^{22}O^8$, or $2C^{10}H^{11}O^4.H^2O$. Kromayer regards it as an aldehyde.

ACANTHITE. A rhombic or trimetric variety of silver sulphide Ag_2S (v. 304), occurring at Freiberg and Joachimsthal (Koenigott, *Pogg. Ann.* xcv. 462; Dauber, *Jahresb.* 1860, p. 747). According to Breilhaupt (*ibid.* 1863, p. 796), it mostly occurs in twins very much like those of diopside.

ACARÖID RESIN. This resin yields, by oxidation with melting potash, so large a quantity of paraoxybenzoic acid (36 grms. from 9 ounces) that it may be conveniently used as a source of that acid. The mother-liquor of the ethereal extract contains also resorcin and pyrocatechin, as well as the double compound of protocatechuic and paraoxybenzoic acids, $(C^8H^4O^7.H^2O)$, first obtained from benzoin (Hlasiwetz a. Barth, *Jahresb.* 1866, p. 630).

ACECONITIC ACID. $C^6H^3O^8 - \left(\begin{smallmatrix} C^6H^3O^8 \\ H^3 \end{smallmatrix} \right) O^8 = (C^6H^3)^{'''}(COHO)^2 \cdot *$ (A. Baeyer, *Berl. Akad. Ber.* 1864, p. 584; more fully, *Ann. Ch. Pharm.* cxxxv. 306; *Jahresb.* 1864, p. 397; 1865, p. 394.)

A tribasic acid produced, together with citracetic acid—an acid of nearly the same composition, and likewise tribasic—by heating ethylic bromacetate with sodium. The product of the reaction is a smoary brown mass, which by evaporation in a vacuum yields a non-separable mixture of the ethers of the two acids just mentioned, boiling above 200° . The solution of this crude ether in baryta-water yields, by evaporation, sparingly soluble barium aceconitate and easily soluble barium citracetate. The aceconitate was deposited in crystals, which, however, did not yield definite results on analysis, but the silver-salt prepared by decomposing them with sulphuric acid, neutralising with ammonia, and precipitating with silver nitrate, gave numbers agreeing with the formula $C^6H^3Ag^3O^8 + 2 aq.$; showing that aceconitic acid is represented by the formula $C^6H^3O^8$, and is isomeric with acconitic acid. The formation of the ether probably takes place by two stages, the sodium first taking the place of an atom of hydrogen in the acetyl molecule of the bromacetate acid, and sodium bromide being afterwards eliminated:

Free aceconitic acid crystallises in warty groups of needles like acconitic acid, but more easily and in better defined forms than the latter; it is likewise easily soluble in water. When heated it melts and burns, leaving a small quantity of charcoal; when warmed in a test-tube it does not yield any crystalline sublimes. The barium salt crystallises in small sparingly soluble crystals; the solution of the calcium salt becomes turbid when heated, like that of the citrate; with neutral lead acetate and mercurous nitrate the acid forms white precipitates.

Citracetic acid and its salts are in crystallisable, and therefore very difficult to purify; they give, however, by analysis numbers agreeing nearly with those of the corresponding acconitates, so that citracetic acid is probably another isomer of acconitic acid.

* In Baeyer's preliminary notice, aceconitic acid was represented by the formula $C^6H^3O^8$, the same as that of carballic acid.

ACENAPHTHENE or **ACENAPHTHALENE**. $C^{12}H^{10} = C^6H^5 \cdot C^6H^5$ (Berthelot, *Bull. Soc. Chim.* [2] viii. 222; *Jahresb.* 1867, p. 594).—A hydrocarbon occurring in the portion of heavy coal-tar oil which distils between 260° and 340° . When the portion distilling between 270° and 290° is separated by fractional distillation and left at rest, acenaphthene separates in large transparent prisms, and a further quantity may be obtained from the mother-liquor by repeated distillation and cooling. It is purified by pressing the crystals between paper, dissolving them in ten to fifteen times their weight of boiling alcohol, and leaving the solution to cool very slowly. Acenaphthene is also contained in the solid hydrocarbons which crystallise gradually from the tar-oils distilling between 300° and 400° , and passes over in the distillation of these oils, together with fluorene. If the solid distillate thus obtained be re-crystallised, the fluorene separates out first, while the acenaphthene accumulates in the mother-liquors, and may be separated therefrom by careful evaporation. It may also be isolated from the solid mixture above mentioned by sublimation in a flask, the bottom of which is heated to 100° . Lastly, it is formed when a mixture of naphthalene vapour and ethylene gas is passed through a heated porcelain tube, and may be separated from the products by re-crystallising the portion which distils between 270° and 300° from alcohol.

Acenaphthene crystallises from alcoholic solution in colourless shining needle-shaped prisms, sometimes a decimetre long, and from solution in heavy tar-oils, in bulky hard brittle crystals. Its odour is like that of naphthalene, but fainter. It is heavier than water, melts at a little above 100° , solidifies at 93° , and boils at 284° – 285° (corr.). It dissolves easily in boiling alcohol, and separates almost completely on cooling. From a mixture of the alcoholic solutions of acenaphthene and picric acid, the picrate, $C^{12}H^{10} \cdot C^6H^3(NO^2)_3O$, crystallises quickly in orange-yellow needles; from a solution of equivalent proportions of the two substances in boiling alcohol, it crystallises in laminae. Evaporated with Fritzsche's re-agent (nitranthracene), acenaphthene forms red needles, partly curved and branching like a fan. In *sulphuric acid*, either fuming or ordinary, it dissolves with formation of acenaphthene sulphuric acid, which is coloured green by small quantities of nitric acid, and forms easily soluble salts. Nitric acid acts violently on acenaphthene. If the hydrocarbon be triturated with the acid in a cooled vessel till the acid is saturated, the solution solidifies, after a while, to a crystalline mass of dinitro-acenaphthene, $C^{12}H^8(NO^2)_2$, which is nearly insoluble in alcohol even at the boiling heat, sparingly soluble in ether, but dissolves abundantly in boiling light tar-oils, and crystallises from this solution in brown-yellow pointed needles. The mother-liquor of these crystals leaves, on spontaneous evaporation, brown granules of a compound of mono- and di-nitroacenaphthene, $C^{12}H^9(NO^2) \cdot C^{12}H^8(NO^2)_2$. Sodium does not act upon acenaphthene. Potassium eliminates hydrogen, and forms the compound $C^{12}H^8K$, as a black insoluble mass, decomposed by water, with reproduction of acenaphthene. Bromine likewise acts strongly upon acenaphthene. On adding it to an ethereal solution of the hydrocarbon till the liquid acquires a yellow colour, and leaving the solution to evaporate, there remains a thickish oil in which a few laminar crystals form, probably consisting of monobromacenaphthene, $C^{12}H^9Br$. A solution of acenaphthene in the most volatile portion of American petroleum, mixed in a cooled vessel with a slight excess of bromine (4 pts. bromine to 1 pt. of the hydrocarbon), yields the hexbromide, $C^{12}H^6Br_6$, which crystallises out in small grains, while a liquid substitution-product remains in solution; by re-crystallisation from boiling alcohol the hexbromide is obtained in slender white needles. Acenaphthene heated to its boiling point with *sodium*, is decomposed, with evolution of hydriodic acid and formation of a carbonaceous substance; at 100° it appears to be converted by iodine into a polymeric compound. Hydrochloric and hydrobromic acids in aqueous solution do not act upon acenaphthene. Heated to 100° with saturated *hydriodic acid*, it forms a liquid hydride, probably $C^{12}H^{14}$, boiling at about 270° , together with the above-mentioned polymeric modification produced by the separated iodine. With 20 pts. hydriodic acid at 280° , it forms, as chief products, naphthalene-hydride and ethyl-hydride:

and in smaller quantities, acenaphthene-hydride. With 80 pts. hydriodic acid at the same temperature, it yields decyl-hydride, $C^{12}H^{22}$ (boiling at 180°), as principal products; further octyl-hydride, C^8H^{18} (boiling between 115° and 120°), ethyl-hydride, traces of hexyl-hydride, and a substance not volatile at 360° , probably a polymer.

ACETAL. $C^{12}H^{14}O_2$.—This compound contains the elements of 1 molecule of aldehyde and 1 molecule of ethyl-oxide, $C^6H^8O \cdot (C^2H^5)_2O$; moreover, its several modes of formation from aldehyde, and its re-actions with hydrochloric acid, phosphorus-

pentachloride, and acetic acid (i. 4), show that it is an ethyl-compound, and may be represented by the formula $(C^2H^4)^n \left\{ \begin{smallmatrix} OC^2H^3 \\ OC^2H^3 \end{smallmatrix} \right\}$ or $(C^2H^4)^n \left\{ \begin{smallmatrix} C^2H^3 \\ C^2H^3 \end{smallmatrix} \right\} O^2$. The bivalent radicle

C^2H^4 occurring in it is, however, not ethylene $\begin{array}{c} CH^3 \\ | \\ CH^2 \end{array}$ (as in the isomeric compound ethylene diethylate), but ethylidene, $\begin{array}{c} CH^3 \\ | \\ CH \end{array}$.

The constitutional formulæ of the two isomeric compounds are in fact:

The three chlorinated derivatives of acetal are represented in like manner by the formulæ:

Dichloroacetal, $C^2H^4Cl^2O^2$, is decomposed by zinc-ethyl at 140° , giving off a gaseous mixture of ethyl chloride, ethylene, and propylene, together with gases not absorbed by bromine (doubtless arising from the action of the ethyl chloride on the zinc-ethyl), and leaving ethyl oxide mixed with oxide and chloride of zinc. Neglecting the ethylene, which is formed as a secondary product in almost all re-actions of zinc-ethyl, the action may be represented by the equation:

(Paterno, *Compt. rend.* lxvii. 458.)

Trichloroacetal, $C^2H^4Cl^3O^2$, is formed, together with dichloroacetal, by the action of chlorine on alcohol at 80° . On treating the product with water, distilling the oil which collects at the bottom, redistilling the portion which boils above 185° in a current of steam, collecting apart the last fourth of the distillate, redistilling this in the same manner, and repeating these operations several times, a distillate of trichloroacetal is at length obtained, which crystallises immediately in the receiver, and may be completely purified by pressure and recrystallisation from alcohol or ether. Trichloroacetal crystallises in light shining needles, very much like caffeine. It melts at 72° , boils with slight decomposition at 230° , dissolves easily in alcohol and ether, and when heated with sulphuric acid to 150° yields chloral. (Paterno, *Compt. rend.* lxvii. 785.)

Methyl-acetal, $C^2H^4O^2 = (C^2H^4)^n \left\{ \begin{smallmatrix} OC^2H^3 \\ OCH^3 \end{smallmatrix} \right\}$, is produced, together with dimethyl-acetal (*infra*), by mixing in a capacious retort 300 pts. of sulphuric acid, 300 pts. of water, and 200 of manganese dioxide, then adding a mixture of 100 pts. alcohol and 90 pts. wood-spirit, and as soon as the first re-action is over, distilling till a quantity of liquid has passed over equal to that of the alcoholic mixture employed. The distillate is then rectified, the portions which distil above and below 68° being collected apart, and the distillation stopped at 85° . Each of the products thus obtained is purified by treating it with aqueous potash and with calcium chloride, as described under acetal (i. 3), and then rectified, the portions which pass over towards 68° in the one case and 85° in the other being collected apart.

Methyl-acetal is a very mobile colourless liquid having an odour like that of acetal, a specific gravity = 0.8535, and boiling at 85° . It burns with a brilliant flame, dissolves in all proportions of alcohol, in 15 parts of water, and is precipitated by water from its alcoholic solution. It is not decomposed by caustic potash.

The same or an isomeric compound has been found by Dancer in crude wood-spirit (iii. 1002).

Dimethyl-acetal, $C^2H^6O^2 = (C^2H^4)^n \left\{ \begin{smallmatrix} OCH^3 \\ OCH^3 \end{smallmatrix} \right\}$ is a colourless ethereal liquid, having an odour like that of methyl-compounds in general. Specific gravity = 0.8555. It boils at 65° , and burns with a luminous white blue-edged flame. (Wurtz, *Ann. Ch. Phys.* [3] xlviii. 373.)

ACETAMIDE. C^2H^3NO .—This compound, heated in a sealed tube with an alkaline solution of *potassium permanganate*, yields no free nitrogen, and only a trace of ammonia, by far the greater portion of the nitrogen being oxidised to nitric or nitrous acid. (Wanklyn & Gamgee, *Chem. Soc. J.* [2] vi. 25.)

Acetamide, heated in sealed tubes with saturated aqueous *hydriodic acid*, yields ammonia, acetic acid, and ethane or ethyl-hydride:

(Berthelot, *Bull. Soc. Chim.* [2] ix. 183.)

Acetamide, heated to about 210° with *carbon bisulphide*, gives off a number of gaseous products, among which are, hydrogen sulphide, carbon oxysulphide, carbon monoxide, and a combustible gas not absorbed by baryta or cuprous chloride, probably ethane, and leaves a residue of ammonium sulphocyanate mixed with undecomposed acetamide. The principal reaction appears to be:

(Ladenburg, *Zeitschr. f. Chem.* [2] v. 478.)

Acetamide forms a crystalline compound with *bitter almond oil*. (Strecker, *Zeitschr. f. Chem.* [2] iv. 651.) (See ALDEHYDES.)

ACETANILIDE. (See iv. 418; v. 1087.)

ACETENYL-BENZENE. $\text{C}^6\text{H}^5 - (\text{C}^2\text{H}^3) - \text{C} \equiv \text{CH}$. — *Phenyl-acetylene* $\text{C}^2(\text{C}^2\text{H}^3)\text{H}$. (Glaser, *Zeitschr. f. Chem.* v. 97.)—This hydrocarbon, related to acetylene in the same manner as cinnamene (styrol) to ethylene, is produced: 1. By heating phenyl-propionic acid with water to 120° in a sealed tube:

more easily by heating barium phenyl-propionate mixed with sand to about 200° :

The copious yellow distillate thereby obtained is easily purified by a few distillations. The hydrocarbon is also formed in small quantity when phenyl-propionic acid or either of its salts is simply boiled with water.

2. By the action of alcoholic potash on cinnamene dibromide, just as ethylene-dibromide similarly treated, yields acetylene as the final product:

The cinnamene dibromide is first converted by alcoholic potash into bromocinnamene, $\text{C}^6\text{H}^5\text{Br}$; and the latter is heated with the same re-agent to 120° in sealed tubes. The product distilled with water yields a distillate still containing alcohol, from which the acetenyl-benzene may be separated by water, and purified by drying with calcium chloride and rectification.

3. By heating methyl-benzylal chloride (produced by the action of phosphorus-pentachloride on methyl-benzoyl, $\text{C}^6\text{H}^5.\text{COCH}^3$) with very concentrated alcoholic potash to 120° in a sealed tube (Friedel, *Zeitschr. f. Chem.* [2] v. 123):

Acetenyl-benzene is a frequent product of the decomposition of other hydrocarbons of the benzene series; thus it occurs in cinnamene which has been heated to redness in a stream of hydrogen; in that produced by the mutual action of benzene and ethylene at a red heat, or by the decomposition of ethyl-benzene; but not in the hydrocarbons of coal-tar. (Berthelot, *Compt. rend.* lxvii. 552.)

Acetenyl-benzene is a colourless strongly refracting liquid, having a peculiar aromatic odour, boiling constantly at 139° – 140° , and having a vapour-density of 8.70 (calc. 8.53). It unites directly with bromine, forming a pungent oily liquid, and is quickly decomposed by nitric acid of specific gravity 1.35 and by sulphuric acid. With metallic solutions it forms precipitates analogous in composition to those of the other hydrocarbons of the acetylene series. Its alcoholic solution, mixed with an ammoniacal solution of cuprous chloride largely diluted with alcohol, forms a yellow precipitate of the compound $(\text{C}^6\text{H}^5.\text{C}^2\text{H}^3)_2\text{O}.\text{CuO}$; the silver compound obtained in like manner is a light grey powder composed of $2(\text{C}^6\text{H}^5.\text{C}^2\text{H}^3).\text{Ag}^2\text{O}$. (Glaser.)

ACETIC ACID. *Hydrogen Acetate. Hydric Acetate.* $\text{C}^2\text{H}^3\text{O}^2 = \begin{array}{l} \text{CH}^3 \\ | \\ \text{COOH} \end{array}$

Formation.—The chloride $\text{C}^2\text{H}^3\text{OCl}$ corresponding to this acid is produced syntheti-

cally by passing a mixture of carbonyl chloride (phosgene gas) and marsh-gas through a retort heated to 120° :

and this chloride is converted by water into hydrochloric and acetic acids. (Harnitz-Harnitzky, *Ann. Ch. Pharm.* cxxxvi. 121.)

Acetic acid may be formed synthetically from acetylene (i.e. from carbon and hydrogen) by converting the latter into ethylene by direct addition of hydrogen, the ethylene into alcohol, and oxidising the alcohol. The transformation may, however, be more simply effected by heating acetylene dichloride with aqueous potash to 230° or with alcoholic potash to 100° for ten hours (Berthelot, *Zeitschr. f. Chem.* [2] v. 683):

Acetic acid is also produced, together with other products, by the fermentation of mucic acid in contact with yeast, white of egg, vegetable albumin, or most easily with muscular flesh:

Formation by oxidation of Alcohol.—Pasteur has shown by conclusive experiments that the formation of acetic acid from alcohol by atmospheric oxidation, in the ordinary process of vinegar making, depends essentially on the presence of a peculiar fungus, the *Mycoderma aceti*. The formation of vinegar from wine or beer is invariably preceded by the development of this fungus at the surface of the liquid. It appears to act by absorbing the oxygen of the air within its pores, like platinum-black, and thus bringing it into close contact with the particles of the alcohol. The plant may be sown on the surface of the liquid by introducing a small portion of it from another vinous liquid already in a state of acetous fermentation; or it may be introduced by simply exposing the liquid to the air, in which the germs of this fungus, as of many others, are always floating. But, like all other plants, it requires food for its development, and this it finds in the albuminous matter and mineral salts contained in ordinary vinous liquors. If these are absent the plant cannot grow, and acetification cannot take place. Thus, pure aqueous alcohol may be exposed to the air for any length of time without turning acid, because the germs of the mycoderm which fall into it from the air remain barren for want of nutriment; but as soon as any albuminous matter is introduced into the liquid, the plant begins to grow and the alcohol is oxidised. The albuminous matter is not, however, itself the active agent in the change, and is quite incapable of inducing it in the absence of the fungus. If a bottle, partly filled with wine and containing air in its ordinary state, be hermetically closed and then heated to a temperature of 55° or upwards, the germs of the mycoderm present in the air or in the liquid will be killed, and under these conditions the wine may be kept for years without exhibiting the slightest degree of acetification, although it contains an abundance of albuminous matter; but if it be opened, and the liquid exposed to the air, so that the germs of the fungus may have access to it, the formation of acetic acid will take place. Moreover, pure aqueous alcohol may be acetified without the aid of any albuminous matter, provided the mycoderm have access to it, and be supplied with the nitrogen and saline matters necessary for its growth. Pasteur has in fact shown that this nutriment may be supplied in the form of alkaline and earthy phosphates and ammonium phosphate, the latter furnishing the nitrogen. Under these circumstances the mycoderm grows, though less quickly than in ordinary vinous liquids, and the alcohol is slowly converted into acetic acid.

The acetification goes on most quickly and favourably when the mycoderm grows only at the surface of the liquid; if it sinks to the bottom or diffuses itself through the mass of the liquid, the oxygen contained in its pores acts upon the acetic acid already formed, and burns it completely to carbonic acid and water: in this way, if the mycoderm be allowed to remain in the liquid after the acetification is complete, the whole of the acetic acid may be destroyed and the liquid rendered perfectly neutral. (Pasteur, *Études sur le Vinaigre*, Paris, 1868; also *Annales scientifiques de l'École normale supérieure*, tome i. 1864; *Bull. Soc. Chim.* 1861, p. 94; *Jahresb.* 1861, p. 786.)

On the formation of acetic acid in alcoholic fermentation, see also Béchamp (*Rép. Chim. pure*, v. 575; *Jahresb.* 1863, p. 778); Blondesau (*Compt. rend.* lvii. 963; *Jahresb.* 1864, p. 312).

Physical Properties.—According to Mendelejeff (*Jahresb.* 1863, p. 7), the sp. gr. of glacial acetic acid at 15° (referred to water at 4° as unity) is 1.0607. According to Regnault (*Relation des Expériences*, &c., p. 751, *Jahresb.* 1863, p. 74), glacial acetic

acid may remain solid at $+16^{\circ}$, but, when once liquefied, is very difficult to re-solidify, sustaining without change a temperature of -8° or even -10° , in spite of brisk agitation; but contact with a pointed piece of glass, or better, with a crystal of the glacial acid, causes it to solidify immediately. Oudemans (*Zeitschr. f. Chem.* 1866, p. 750; *Jahresb.* 1866, p. 300) prepared pure acetic acid by rectifying the commercial glacial acid over manganese peroxide and sodium acetate, then subjecting it to fractional distillation and crystallisation, till it exhibited a constant specific gravity. This sp. gr. was 1.05533 at 15° . The acid melted at 16.45° , and boiled at 117° (bar. at 763 mm.); after a fourth of the liquid had passed over, the boiling point rose to 117.6° , and finally (in the last $\frac{1}{4}$ th of the distillate) to 118.2° .

From determinations of the sp. gr. of mixtures of acetic acid vapour and hydrogen gas at various temperatures, Playfair and Wanklyn (*Chem. Soc. J.* xv. 153) infer that the vapour of acetic acid probably has, at comparatively high temperatures, a density of 2.073 referred to air, or 30 referred to hydrogen, corresponding to a condensation of 2 volumes for the molecule $C^2H^4O^2$, and at lower temperatures, the density 60 (referred to hydrogen), corresponding to a similar condensation for the molecule $C^2H^4O^4$; further, that the constitution of the molecule is probably different at these different temperatures. Cahours had formerly shown (i. 10) that the vapour of acetic acid begins to exhibit its normal density at about 240° . From recent experiments he concludes that it still retains this density at 350° , and begins to exhibit a lower density only at 440° , being then partially decomposed into marsh gas and carbon dioxide: hence the normal density remains constant for an interval of about 200° .

Oxidation by Potassium Permanganate.—Acetic acid appears at first to have no action on a solution of the permanganate, either acid or alkaline. Nevertheless, on heating acetic acid with a dilute neutral solution of the permanganate to 100° in a long-necked flask, a reaction is soon set up and becomes considerable after 15 or 20 hours: the only products are water and carbonic acid. Sodium acetate, left in contact in the cold with a neutral solution of the permanganate, does not exhibit any reaction for the first few days, but at the end of three months a visible reduction takes place, attended with formation of carbonate. At the boiling heat the reduction becomes visible after a few hours, especially in presence of a small quantity of potash, resulting in the formation of oxalic acid: $C^2H^4O^2 + O = C^2H^2O^4 + H^2O$. (Berthelot, *Bull. Soc. Chim.* [2] viii. 392.)

According to F. Lossen (*Ann. Ch. Pharm.* cxiv. 174), acetic acid may be converted into oxalic acid by dissolving 1 pt. sodium acetate, 1 pt. sodium hydrate, and 2 pts. potassium permanganate in a small quantity of water, boiling the solution to dryness, and heating the dry mass to a temperature not sufficient to decompose potassium oxalate, till a sample no longer forms a green solution with water.

Aqueous Acetic Acid.—It was formerly supposed that a mixture of glacial acetic acid and water exhibits a maximum amount of condensation when the proportions are such as to form the hydrate $C^2H^4O^2.H^2O$, containing 77 per cent. of the glacial acid to 23 of water; and that this hydrate boils without decomposition at a constant temperature. Results tending to confirm this statement have been published by Bussy and Buignet (*Jahresb.* 1865, p. 69). On the other hand, Roscoe has shown (*Chem. Soc. J.* xv. 270) that aqueous acetic acid of this, as well of any other strength, suffers decomposition by boiling, and that, in whatever proportions glacial acetic acid and water may be mixed, the mixture may be decomposed by distillation, under either ordinary or increased pressure, in such a manner as ultimately to leave a residue of glacial acetic acid;—in short, that there is no such thing as a definite hydrate of acetic acid. From Roscoe's determinations, which agree very nearly with those of Van Toorn (*J. für Chem.* vi. 171), of the density of aqueous acetic acid of strengths a little above and below that of the supposed hydrate $C^2H^4O^2.H^2O$, it further appears that there is no maximum density corresponding to a definite strength, but that aqueous acids of strengths varying from 76.5 to 80 per cent. exhibit the same density:

Percentage of acid	76.5°	77.5°	79°	80°	98.5°	100°
Sp. gr. at 15.5°	1.0762	1.0754	1.0764	1.0754	1.0597	1.0564

The recent experiments of Oudemans, made with acetic acid purified in the manner above described, likewise show that the maximum density of mixtures of acetic acid and water bears no relation whatever to a fixed equivalent proportion of the acid and water, but corresponds to a different proportion for each particular temperature. Oudemans' results for the temperatures 0° , 15° , and 40° , are given in the following table: they agree nearly with the older determinations by Van Toorn, but not with those of Mohr (i. 11), which, according to Oudemans, appear to have been made, not with pure glacial acetic acid, but with an acid containing 5 per cent. of water.

Density of Aqueous Acetic Acid (Oudemans).

CH ₃ CO ₂ H p. c.	Density			CH ₃ CO ₂ H p. c.	Density		
	at 0°	at 15°	at 40°		at 0°	at 15°	at 40°

ACETATES (METALLIC).—These salts are represented by the following formulae, according to the equivalent value of the metal which they contain :

For monatomic or univalent metals (sodium) $\text{Na}^+(\text{C}^2\text{H}^3\text{O}^2)^- \text{ or } \left\{ \begin{smallmatrix} \text{C}^2\text{H}^3\text{O}^2 \\ \text{Na} \end{smallmatrix} \right\} \text{O}^+$

For diatomic or bivalent metals (barium) $\text{Ba}^{++}(\text{C}^2\text{H}^3\text{O}^2)^- \text{ or } \left\{ \begin{smallmatrix} \text{C}^2\text{H}^3\text{O}^2 \\ \text{Ba} \end{smallmatrix} \right\} \text{O}^+$

For trivalent metals (thallium in thallic salts) $\text{Th}^{+++}(\text{C}^2\text{H}^3\text{O}^2)^- \text{ or } \left\{ \begin{smallmatrix} \text{C}^2\text{H}^3\text{O}^2 \\ \text{Th} \end{smallmatrix} \right\} \text{O}^+$

For (apparently) trivalent metals (iron) $(\text{Fe}^+)^+ (\text{C}^2\text{H}^3\text{O}^2)^- \text{ or } \left\{ \begin{smallmatrix} \text{C}^2\text{H}^3\text{O}^2 \\ (\text{Fe}^+)^+ \end{smallmatrix} \right\} \text{O}^+$

In the last case the metal is really tetratomic (iron, chromium, aluminium), but when two of its atoms are associated together, one unit of equivalence in each of them is neutralised by combination with the other, so that the group is really sexvalent like the group C^2 in ethyl hydride, C^2H^4 ; thus the formula of neutral ferric acetate may be written thus :

In acetates containing bivalent or multivalent metals, one or more equivalents of the radicle, $\text{C}^2\text{H}^3\text{O}$, may be replaced by chlorine or bromine, or by other acid radicles or residues, such as NO^+ , $(\text{SO}^+)^-$, &c., e.g.,

Barium aceto-nitrate * $\text{Ba}^{++} \left\{ \begin{smallmatrix} \text{C}^2\text{H}^3\text{O}^2 \\ \text{NO}^+ \end{smallmatrix} \right\}$

Chromic diaceto-tetrachloride $(\text{Cr}^+)^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ \text{Cl}^+ \end{smallmatrix} \right\}$

Ferric tetraceto-dinitrate $(\text{Fe}^+)^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ (\text{NO}^+)^- \end{smallmatrix} \right\}$

partly also, in some cases, by hydroxyl, HO, forming basic salts, e.g.,

Ferric tetracetate $(\text{Fe}^+)^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ (\text{HO})^+ \end{smallmatrix} \right\}$

Ferric triaceto-dinitrate $(\text{Fe}^+)^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ (\text{NO}^+)^- \\ \text{HO} \end{smallmatrix} \right\}$

Cerous Acetate, $\text{Ce}^{++}(\text{C}^2\text{H}^3\text{O}^2)^- + \text{aq.}$, obtained by dissolving cerous oxide or carbonate in acetic acid, or by decomposing cerous sulphate with barium acetate, crystallises in radiate groups of small needles, which give off their water in dry air without losing their crystalline form; after drying at 115° , they become carbonised at a higher temperature, without fusing, and when ignited leave a residue of cerous ceric oxide (Lange, *J. pr. Chem.* lxxxii. 129). According to Czudnowicz (*ibid.* lxxxii. 217; *Jahresb.* 1861, p. 190), the water of crystallisation cannot be expelled without decomposition of the salt, which in fact begins at a temperature a little above 100° , the salt caking together, and ultimately leaving cerous ceric oxide.

Chromic Acetates. The normal salt, $\text{Cr}^+(\text{C}^2\text{H}^3\text{O}^2)^- + 2\text{aq.}$, is obtained as a green crystalline mass, by evaporating a solution of chromic hydrate in acetic acid. It is insoluble in alcohol. Its aqueous solution, which is green by reflected, red by transmitted light, is not decomposed, either by ebullition or by addition of lime-water; but ammonia throws down from it a green precipitate of chromic hydrate, soluble in excess of the reagent. (H. Schiff, *Ann. Ch. Phys.* [3] lxxi. 140; Schützenberger, *Bull. Soc. Chim.* 1865, iv. 86.)

The solution of the normal acetate heated for several days with excess of chromic hydrate, loses its acid reaction and yields by evaporation a green powder soluble in water, consisting of a basic acetate, $\text{Cr}^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ (\text{HO})^+ \end{smallmatrix} \right\}$ (Schiff.)

Chromic Diacetotetrachloride, $\text{Cr}^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ \text{Cl}^+ \end{smallmatrix} \right\} + 4\text{aq.}$, is obtained by dissolving chromic dioxytetrachloride (chlorochromic acid), $\text{Cr}^+\text{O}^+\text{Cl}^2$, in strong acetic acid. It is an unstable salt, which gives off acetic acid when heated above 100° . The chlorine is but very slowly precipitated from it by silver nitrate at ordinary temperatures, but, on the other hand, the salt easily yields acetic ether when heated with sulphuric acid and alcohol. (Schiff.)

Chromic Diaceto-sulphate, $\text{Cr}^+ \left\{ \begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^- \\ (\text{SO}^+)^- \end{smallmatrix} \right\}$, obtained by dissolving chromic disulphate in acetic acid, is a crystalline salt which becomes anhydrous at 100° , and gives off acetic acid at a higher temperature. (Schiff.)

* Described vol. iv. p. 80.

Chromic Pentaceto-nitrate, $\text{Cr}^2\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^3 \\ \text{NO}^2\end{smallmatrix}\right\} + 2\text{aq.}$, is obtained by mixing a solution of chromic hydrate in a slight excess of acetic acid with a solution of the same quantity of chromic hydrate in the exact quantity of nitric acid required to dissolve it. The concentrated solution, when left to itself, deposits an abundant crystallisation of a dark green salt, which may be purified by recrystallisation from water or from glacial acetic acid. It forms dark green bulky laminae, which give off nitrous fumes at 100° , the chromium being at the same time converted into trioxide (Schützenberger).

Ferric Acetates. The normal salt, $(\text{Fe}^2)^1(\text{C}^2\text{H}^3\text{O}^2)^3$ or $\left(\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^6 \\ (\text{Fe}^2)^1\end{smallmatrix}\right)\text{O}^6$, is described at p. 16, vol. i. The following basic acetates are known:—

Ferric Tetracetate, $\text{Fe}^2\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^4 \\ (\text{HO})^2\end{smallmatrix}\right\}$, is obtained by dissolving at 50° the ferric hydrate produced from 1 part of iron, in 10 parts of acetic acid of 30 per cent., and evaporating the solution at 70° . It is an amorphous mass, soluble in alcohol and in water. (Oudemans, *Jahresber.* 1858, p. 282.)

Ferric Triacetate, $\text{Fe}^2\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^3 \\ (\text{HO})^3\end{smallmatrix}\right\}$, is probably contained in the red solution obtained by treating ferric dichlorotriacetate (*infra*) with silver oxide. This solution, evaporated in a vacuum, becomes syrupy, but does not crystallise. It quickly decomposes at ordinary temperatures, forming an ochreous jelly. (Scheurer-Kestner.)

Triferric Diacetate, $\text{Fe}^2\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^2 \\ (\text{HO})^4\end{smallmatrix}\right\} \cdot 2\text{Fe}^2\text{O}^3$.—This is the ochreous deposit formed when a solution of ferrous acetate is exposed to the air.

Other basic salts appear to be formed in the decomposition of the normal salt by heat or otherwise, but they have not been analysed.

Ferric Aceto-nitrates. (Scheurer-Kestner, *Ann. Ch. Phys.* [3] lxxiii. 422; lxxviii. 472; *Jahresber.* 1861, p. 307.)—These salts, which may be produced by mixing the solutions of ferric nitrate and acetate in various proportions, or by dissolving ferric hydrate in various mixtures of nitric and acetic acids, are mostly very unstable: on boiling them with water, ferric oxide is precipitated, and the acids are set free.

The **tetraceto-dinitrate**, $\text{Fe}^2\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^4 \\ (\text{NO}^2)^2\end{smallmatrix}\right\} + 6\text{aq.}$, is prepared: *a.* By heating a solution of ferrous acetate (sp. gr. 1.250) mixed with excess of acetic acid to 80° , then adding nitric acid by drops, and leaving the solution to cool:

B. By dissolving ferric dinitrate in acetic acid:

The reaction is terminated when the mixture no longer yields a precipitate with nitric acid.

γ. By dissolving 1 molecule of ferric hydrate in 4 mol. acetic acid and 2 mol. nitric acid.—*δ.* By mixing 1 mol. ferric nitrate with 2 mol. ferric acetate.—*ε.* By treating ferric dichloro-tetracetate (*infra*) with silver nitrate.

This salt crystallises in well-defined right rhombic prisms, having a blood-red colour, very soluble in water, soluble in all proportions of alcohol, insoluble in ether, which may therefore be used for washing the crystals. It is decomposed by the slightest elevation of temperature, and when treated with nitric acid, yields ferric tetraceto-nitrate (*infra*).

The **diaceto-tetranitrate**, $\text{Fe}^2\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^2 \\ (\text{NO}^2)^4\end{smallmatrix}\right\} + 8\text{aq.}$, is obtained: *a.* By leaving a solution of ferric tetranitrate, $\text{Fe}^2(\text{NO}^2)^4(\text{HO})^2$ (sp. gr. 1.250), mixed with excess of strong acetic acid to evaporate in a vacuum, and washing the resulting crystals with ether containing alcohol.—*β.* By dissolving 1 mol. ferric hydrate in 2 mol. acetic and 4 mol. nitric acid.—*γ.* By mixing 1 mol. normal ferric acetate with 2 mol. ferric nitrate. It crystallises in small oblique rhombic prisms, often united in crosses.

The **triaceto-dinitrate**, $(\text{Fe}^2)^1\left\{\begin{smallmatrix}(\text{C}^2\text{H}^3\text{O}^2)^3 \\ \text{HO}\end{smallmatrix}\right\} + 8\text{aq.}$, is prepared by treating ferric hydrate with proportional quantities of the two acids; or by treating ferric triaceto-dichloride (*infra*) with silver nitrate. It forms dark-coloured, almost black; rhomboidal crystals or crystalline plates, soluble in alcohol.

The *tetraceto-nitrate*, $\text{Fe}^2 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^4 \\ \text{NO}^3 \\ \text{HO} \end{array} \right\} + 4\text{aq.}$, is obtained by digesting a mixture of 1 mol. ferric hydrate, 4 mol. acetic acid, and 1 mol. nitric acid at 40° for several days, and evaporating in a vacuum; the same result is obtained with a mixture of 1 mol. ferric acetate, 1 mol. ferric dinitrate, and 1 mol. acetic acid. It forms right rhombic prisms, of red-brown colour; hard, shining, less deliquescent than the other ferric aceto-nitrates, very soluble in water and in alcohol, decomposable by slight rise of temperature.

The *triaceto-nitrate*, $\text{Fe}^2 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^3 \\ \text{NO}^3 \\ (\text{HO})^1 \end{array} \right\} + \text{aq.}$, is prepared by digesting a mixture of ferric hydrate and the two acids in the required proportions at about 30° ; or by frequently agitating a mixture of 2 mol. acetic acid and 1 mol. ferric dinitrate; the product in the latter case is a mixture of triaceto-nitrate and tetra-nitrate. The triaceto-nitrate forms flattened monoclinic prisms of deep-red colour, very soluble in water and in alcohol, insoluble in ether.

Ferric Diortho-diaceto-nitrate. $\text{Fe}^2 \left\{ \begin{array}{c} (\text{CHO}^2)^2 \\ (\text{C}^2\text{H}^3\text{O}^2)^2 \\ \text{NO}^1 \\ \text{HO} \end{array} \right\} + 5\text{aq.}$ —This salt may be prepared by the direct action of the three acids in proportional quantities on ferric hydrate; but more advantageously by the slow action of nitric acid (sp. gr. = 1.38) on a mixture of ferrous acetate and formate at the heat of the water-bath. When the oxidation is complete, a red liquid is obtained, which is very unstable, but crystallises when evaporated to a syrup over oil of vitriol. It is very soluble in water and in alcohol, insoluble in ether; very unstable, depositing ferric oxide on boiling, and decomposing if the evaporation of the solution be carried too far, even in a vacuum.

The quantity of nitric acid required to effect the oxidation of the ferrous salt in the process of preparation just described, is double of that required by the formula

of the salt: hence it is probable that the salt $\text{Fe}^2 \left\{ \begin{array}{c} (\text{CHO}^2)^2 \\ (\text{C}^2\text{H}^3\text{O}^2)^2 \\ (\text{NO})^2 \end{array} \right\}$ is first formed and afterwards converted into the basic salt just described by loss of nitric peroxide; red vapours are in fact disengaged during the evaporation of the mixture.

Ferric Aceto-chlorides.—The *triaceto-chloride*, $(\text{Fe}^2)^1 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^3 \\ \text{Cl}^2 \\ \text{HO} \end{array} \right\} + 3\text{aq.}$, is obtained by cautiously treating with nitric acid a solution of ferrous chloride in acetic acid heated to 80° .

$12\text{Fe}^2\text{Cl}^2 + 9\text{C}^2\text{H}^3\text{O}^2 + 4\text{NO}^3\text{H} - 3(\text{Fe}^2)^1 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^3 \\ \text{Cl}^2 \\ \text{HO} \end{array} \right\} + 3\text{Fe}^2\text{Cl}^6 + 4\text{NO} + 5\text{H}^2\text{O}.$

The same salt is formed when a mixture of 1 mol. ferric hydrate, 2 mol. acetic acid, and 1 mol. hydrochloric acid is digested at 40° for two or three days. It forms very hard crystals, black by reflected, red by transmitted light, very soluble in alcohol and in water. When treated with silver oxide, they yield ferric triacetate. (Scheurer-Kestner, *Ann. Ch. Phys.* [3] lxxviii. 472; *Jahresh.* 1863, p. 257.)

The *tetraceto-dichloride*, $(\text{Fe}^2)^1 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^4 \\ \text{Cl}^2 \end{array} \right\} + 3\text{aq.}$, is obtained by dissolving 1 mol. ferric hydrate in a mixture of 2 mol. hydrochloric and 4 mol. acetic acid; or by oxidising ferrous chloride dissolved in very strong acetic acid with nitric acid. It forms yellowish-red crystals, soluble in alcohol and in water, easily resolved into acetic acid and ferric triaceto-dichloride. When treated with silver nitrate, it decomposes after 12 hours at 50° , forming ferric tetraceto-dinitrate:

Lead Acetates, or Plumbic Acetates. According to J. Löwe (*J. pr. Chem.* xcviii. 385; *Jahresh.* 1866, p. 235), there are only three definite plumbic acetates, viz.,

The normal or monoplumbic salt . . . $\text{Pb}^2(\text{C}^2\text{H}^3\text{O}^2)^2$
 The bibasic or biplumbic salt . . . $\text{Pb}^2 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^2 \\ \text{O}^2 \end{array} \right\}$ or $\text{Pb}^2(\text{C}^2\text{H}^3\text{O}^2)^2.\text{Pb}^2\text{O}$
 The tribasic or triplumbic salt . . . $\text{Pb}^2 \left\{ \begin{array}{c} (\text{C}^2\text{H}^3\text{O}^2)^2 \\ \text{O}^3 \end{array} \right\}$ or $\text{Pb}^2(\text{C}^2\text{H}^3\text{O}^2)^2.2\text{Pb}^2\text{O}$.

When bromine is added to a solution of the monoplumbic salt, a brown precipitate

of lead dioxide is produced, and if the liquid be warmed, the formation of this precipitate goes on till the bromine has been added in the proportion of 2 at. Br to 2 mol. $(C^2H^3O^2)^2Pb$. The solution contains lead bromide and acetic acid :

(Chapman a. Smith, *Chem. Soc. J.* [2] vii. 185.)

The *biplumbic salt*, which dissolves easily in water and in alcohol of 90 p. c., is produced by treating 1 mol. lead-oxide with a solution of at least 1 mol., or an excess, of the normal salt; also when the triplumbic salt is dissolved in the solution of the monoplumbic salt; and by the incomplete decomposition of the monoplumbic salt with aqueous ammonia, potash, or soda. Ammonia added in excess to its aqueous solution, throws down a mixture of triplumbic acetate and plumbic hydrate :

The *triplumbic salt* is also produced : *a.* When a solution of the normal salt (1 mol.) is digested with at least 2 mol. of pure plumbic oxide (of crude litharge, about 3 mol. are required). By prolonged digestion of 6 pts. normal acetate (1 mol.) with 30 pts. water and 7 pts. (2 mol.) of good finely pulverised litharge, till the undissolved residue appeared perfectly white, Löwe obtained a solution containing chiefly the biplumbic salt, while the spongy residue consisted chiefly of the triplumbic acetate and plumbic carbonate. When 6 pts. of the normal salt were digested with 14 pts. (4 mol.) of litharge, the solution contained the triplumbic salt; and the crystalline deposit, which dissolved partially in boiling water, leaving a considerable quantity of plumbic oxide and carbonate, was likewise found to contain the triplumbic, but no sesquiplumbic salt.—*β.* The triplumbic salt is further produced by cautious addition of potash to the solution of the normal salt, and by mixing the solution of the latter with excess of ammonia. It is obtained in silky needles when 100 cc. of the cold saturated solution of the normal salt are mixed with 100 cc. water, the mixture poured into 40 to 50 cc. of aqueous ammonia (of what strength?), and the whole warmed over the water-bath in a vessel which protects it from the air. If the solution of the normal salt be mixed with only $\frac{1}{3}$ th of its volume of aqueous ammonia, the biplumbic salt is formed in solution, together with a precipitate of triplumbic salt; with less than $\frac{1}{3}$ th volume of aqueous ammonia, only the biplumbic salt is formed. The triplumbic salt treated with ammonia, either at ordinary or at higher temperatures, is not converted into a sexbasic salt, but partially decomposed, with separation of crystalline plumbic hydrate, or yellow plumbic oxide; neither is it converted into a more basic compound by digesting it with plumbic oxide (which in fact is not at all attacked by it). In its aqueous solution, caustic potash forms a precipitate of plumbic hydrate $(Pb^2H^2O^2)$ dried at 100°.

From all these results, Löwe concludes that the sexbasic salt commonly said to be formed by agitating a solution of the diplumbic or triplumbic salt with lead oxide, has no existence. Neither did he succeed in preparing the sesquibasic salt (i. 16). When the dehydrated normal salt is heated to 200°, till the fused mass resolidifies, the residue dissolves easily in cold water, leaving a mixture of plumbic oxide and carbonate, and the solution contains biplumbic acetate, together with more or less of the triplumbic salt (precipitable by strong alcohol), according to the duration of the heating.

The composition of the basic lead acetates above described was inferred from the mode of their decomposition with potassium nitrate, whereby the corresponding basic nitrates are supposed to be formed, which by their sparing solubility and permanence are well adapted for quantitative estimation. Thus a basic lead acetate was inferred to be biplumbic or triplumbic when its solution gave with potassium nitrate a precipitate of biplumbic or triplumbic nitrate.

For the preparation of official sub-acetate of lead, or lead-vinegar (if it is to contain the biplumbic salt), Löwe recommends that 2 pts. of the triplumbic salt precipitated by ammonia, and well pressed, be dissolved at a gentle heat in a solution of 1 pt. of the crystallised normal salt in 4 or 5 pts. of water thoroughly de-aerated by boiling.

Acetates of Mercury. The formulæ of these salts, according to the atomic weight of mercury now adopted, are :

Mercuric acetosulphide, $\text{Hg}(\text{C}^2\text{H}^3\text{O}^2)^2.\text{Hg}^2\text{S}$, is produced by passing hydrogen sulphide into a concentrated solution of mercuric acetate. The mercuric sulphide thereby produced dissolves at first in the mercuric acetate, but on passing the gas in excess the acetosulphide is precipitated as a white crystalline powder, and ultimately the whole is converted into black mercuric sulphide. The crystalline acetosulphide may be obtained in extremely thin, flexible, nacreous, translucent, rectangular plates, by adding recently precipitated mercuric sulphide to a warm concentrated solution of mercuric acetate, as long as it continues to turn white and assumes a crystalline aspect,—mixing the filtered solution with an equal volume of alcohol of 90° and a little strong acetic acid, and leaving it for two or three days in a cool dark place. The compound dissolves in 12 parts of warm water, and decomposes on boiling, with deposition of mercuric sulphide and basic mercuric acetate. Alcohol and ether, at the boiling heat, dissolve out almost all the acetic acid. A solution of recently precipitated mercuric sulphide in mercuric acetate yields with soluble chlorides a white precipitate of the sulphochloride $\text{Hg}^2\text{S}^2\text{Cl}^2$ or $2\text{HgS}.\text{HgCl}^2$, and precipitates of analogous composition with soluble bromides and iodides and alkaline nitrates; with alkaline sulphates a precipitate of sulphato-sulphide, containing $\text{HgS}.2\text{HgSO}^4$; with chromic acid and alkaline chromates, an ochre-coloured precipitate of the chromato-sulphide, $\text{HgS}.2\text{HgCrO}^4$. (R. Palm, *Chem. Centralb.* 1863, pp. 118, 121, 175, 227; *Jahresb.* 1862, p. 220.)

Potassium Acetate. $\text{C}^2\text{H}^3\text{O}^2\text{K}$.—When this salt is heated for some hours in a sealed tube with bromine and water in the proportion of 2 at. bromine to 1 mol. $\text{C}^2\text{H}^3\text{O}^2\text{K}$, potassium bromide is formed, and on opening the tube, carbon dioxide escapes, together with a gas which burns with a green flame: probably methyl-bromide:

Traces of a heavy liquid insoluble in water, probably brominated methyl-bromide, are also formed. The same reaction takes place very quickly under the influence of direct sunshine. Chlorine acts in a similar manner, one of the products formed by it being methylene dichloride CH^2Cl^2 . (Chapman a. Smith, *Chem. Soc. J.* [2] vii. 185.)

Silver Acetate. This salt is resolved by heat into crystalline hydrogen acetate, carbon dioxide, marsh gas, and a residue of metallic silver and charcoal:

Heated with iodine, in the proportion of 2 mol. to 1 mol. iodine (I^2), it is resolved into silver iodide, methyl acetate, hydrogen acetate, carbon dioxide, acetylene, and hydrogen: probably thus:

In this second reaction, the methyl in one molecule of silver-acetate appears to split up into methylene and hydrogen, the latter taking the place of the silver in another molecule of the acetate, while the methylene is resolved into acetylene and hydrogen.

With iodine in presence of water, silver acetate yields hydrogen acetate, together with iodide and iodate of silver:

(Birnbaum, *Zeitschr. f. Chem.* [2] v. 452.)

ACETATES (ALCOHOLIC); ACETIC ETHERS.—*a. Monatomic.*—**Amyl Acetate**. $\text{C}^5\text{H}^{11}.\text{C}^2\text{H}^3\text{O}^2$. The sp. gr. of this ether, according to Mendeleef (*Jahresb.* 1860, p. 7), is 0.8763 at 16° (that of water at 4° being taken as unity). Boiling point 140° (Wanklyn, *Chem. Soc. J.* [2] iii. 30; Schorlemmer, *Jahresb.* 1866, p. 627); 138° (Friedel and Crafts, *ibid.* 1864, p. 460). When heated to 240° with ethyl-alcohol, it is partly converted into ethyl acetate. This is the general mode of reaction between alcohols and compound ethers of organic acids, which, in fact, consists in the simple substitution of one alcohol-radicle for another, without formation of water or of acid. (Friedel and Crafts.) Heated in closed vessels in the oil-bath, with phosphorous chloride, it yields phosphorous oxide, acetyl chloride, and amyl chloride (Schlagdenhauffen):

By oxidation with *dilute chromic acid*, it is converted into valeric and acetic acids:

(Chapman a. Thorp, *Chem. Soc. J.* [2] lv. 77.) See *ETHERS*.

Cetyl Acetate. $\text{C}^{18}\text{H}^{35}\text{.C}^2\text{H}^2\text{O}^2$ (i. 840). Sp. gr. 0.858 at 20°. Melting point 18.5°; solidifying point 14°; boiling point 222°–225° (E. Dollfus, *Ann. Ch. Pharm.* cxxxi. 283).

Diallyl Acetates. See *DIALLYL*.

Ethyl Acetate. $\text{C}^2\text{H}^3\text{.C}^2\text{H}^2\text{O}^2$.—To obtain this ether quite pure, it has been recommended by Engelhardt (*J. Pharm.* [3] xxxix. 159), and more recently by Berthelot (*Ann. Ch. Phys.* [3] lxx. 398), to wash the crude product with a weak alkaline solution; then, after rectification, to agitate it several times with a weak solution of common salt; dry it with pulverulent potassium carbonate (not with calcium chloride, which, being soluble in the ether, gives rise to percussive ebullition in the subsequent rectification); and finally distil at a constant temperature. Frankland and Duppa (*Chem. Soc. J.* [2] iv. 396) prepare acetic ether by gradually pouring a mixture of 3.6 kilogr. of 97 p.c. alcohol and 9 kilogr. strong sulphuric acid on 6 kilogr. sodium acetate previously fused and dried, leaving the mixture to stand for 12 hours, then distilling, and rectifying the distillate (which is free from alcohol and amounts to 6 kilogr.) over fused and pulverised calcium chloride. The best mode of mixing the alcohol and sulphuric acid is to pour the alcohol through a narrow glass tube, and with continual stirring (by means of this tube), to the bottom of the vessel containing the acid; it is advisable also to leave the ethyl-sulphuric acid thus formed for 24 hours, before pouring it upon the sodium acetate.

Sp. gr. 0.8981 at 15° (Mendeleef). Latent heat of liquid, 105.796 heat-units (Favre and Silbermann); of vapour, 154.49 heat-units (Regnault, *Jahresh.* 1863, p. 77). Specific heat of liquid, 0.4314; of vapour referred to constant weight, 0.4008; to constant volume, 1.2184 (Regnault, *Jahresh.* 1863, p. 86).

Reactions.—1. By oxidation with *dilute chromic acid*, it yields nothing but acetic acid: $\text{C}^2\text{H}^3\text{.C}^2\text{H}^2\text{O}^2 + \text{O}^2 = 2\text{C}^2\text{H}^2\text{O}^2$ (Chapman a. Thorp).—2. The action of *chlorine* on this ether has been further examined by Schillerup (*Ann. Ch. Pharm.* cxi. 128). When *chlorine* gas is passed into ethyl acetate in the shade (the liquid being first at the temperature of the air, afterwards heated in the water-bath till it boils) and the passage of the gas being continued till it is no longer absorbed at the latter temperature, a product is obtained which distils without decomposition, but does not yield any compound of constant boiling point by fractional distillation. The portions which distil between 100° and 140° are regarded by Schillerup as mixtures of three chlorinated substitution-products of acetic ether, viz. $\text{C}^2\text{H}^3\text{Cl}\text{O}^2$, $\text{C}^2\text{H}^2\text{Cl}^2\text{O}^2$ and $\text{C}^2\text{H}\text{Cl}^3\text{O}^2$. On treating these portions with a pasty mixture of barium hydrate and baryta-water, decomposition takes place, and on distilling the product, chloroform and ethyl acetate pass over, leaving a residue of barium chloride and barium formate, mixed with a large quantity of black tarry matter.

3. With *bromine*, acetic ether does not form any substitution-products analogous to those which it yields with chlorine. When 1 molecule of acetic ether is heated to 150° in a close vessel with 2 at. bromine, ethyl bromide and bromoacetic acid are produced:

Bromoacetic acid heated to 180° for three hours with ethyl acetate yields acetic acid and ethyl bromoacetate:

(Crafts, *Bull. Soc. Chim.* 1863, p. 117.)

4. Acetic ether distilled with a mixture of lime-water and chloride of lime yields chloroform. (Schlagdenhauffen, *J. Pharm.* [3] xxxvi. 190.)

5. Acetic ether (like compound ethers in general) is decomposed by *anhydrous bases* in the same manner as by the corresponding hydrates, excepting that a metallic derivative of the alcohol (an alcoholate) is formed instead of the alcohol itself; thus:

(Berthelot a. Fleuriou, *Ann. Ch. Phys.* [3] xvii. 80.)

6. With *sodium-ethylate*, acetic ether forms a compound decomposable by water,

with formation of alcohol and sodium acetate (Beilstein, *Ann. Ch. Pharm.* cxii. 121):

(See Wanklyn's observations, *infra*.)

7. Ethyl acetate may be heated to 200° with *potassium sulphhydrate* without formation of mercaptan (Wanklyn, *Chem. Soc. J.* [2] ii. 418).

*Action of the Alkali-metals on Ethyl Acetate.**

About thirty years ago this subject was investigated by Löwig and Weidmann, whose paper will be found in the *Journal für praktische Chemie*, Bd. xx. 1840, p. 414 *et seq.* In the same journal there is also an account of the action of potassium on methyl acetate by Weidmann and Schweitzer (*ibid.* p. 386). An analogous result was arrived at in both instances, viz. that the alkali-metal acts on the ether *without evolving any gas*, and gives a solid mass, consisting of ethylate or methylate of the metal, together with a salt of a *reduced acetic acid* (acetylous or hypo-acetylous acid). The equations by which these chemists expressed this reaction are not very intelligible at the present time, but the experimental facts are given with great clearness. A parallel result was obtained with benzoic ether. These researches appear to have been almost forgotten, but they are nevertheless in accordance with the most recent investigations.

A few years ago, Geuther in Germany (*Arch. Pharm.* [2] cxvi. 97; cxv. 29, 201; *Jahresh.* 1865, p. 304), and Frankland and Duppa in England, experimented on the action of sodium on acetic ether; according to the latter, the action is very complicated (see *Phil. Trans.* 1866, vol. clvi. Part I. p. 37; *Chem. Soc. J.* [2] iv. 396). From the account of this reaction given by Geuther, and the account given by Frankland and Duppa, it would appear that for every equivalent of sodium used up by the ether an equivalent of hydrogen is given off. But the most recent investigations by Wanklyn (*Ann. Ch. Pharm.* 1869, xlix. 43; cl. 21) have shown that sodium is completely taken up by pure ethyl acetate and by pure amyl acetate, without the slightest evolution of hydrogen, and also that valerianic, butyric, and benzoic ethers do not evolve any gas when they are acted upon by sodium: that, in short, hydrogen is never evolved by the action of the alkali-metals on ethers.†

The action of sodium on acetic ether has been shown to be simple, and somewhat analogous to that on the other ethers. It consists in displacement of acetyl by the metal and formation of sodium ethylate and sodium-triacetyl; thus:

No other direct action takes place between the metal and the ether, it having been shown that just one-fourth of the quantity of metal employed is to be found in the state of sodium-triacetyl subsequently to the termination of the reaction.

A little secondary action, however, takes place between the sodium ethylate and the excess of acetic ether; thus:

Of course, the exact conditions under which the experiment is made will determine the extent to which this secondary action proceeds.

The products therefore are:

Direct	{ Sodium ethylate. Sodium-triacetyl.
Indirect	{ Ethylene-sodium acetate. Alcohol.

Sodium triacetyl. $C^2H^{\cdot}NaO^3 = Na(C^2H^{\cdot}O)^3$.—No doubt the hypoacetylite of soda of the older experimenters was sodium-triacetyl. By Geuther, who first succeeded in obtaining it tolerably pure, and arrived at the true empirical formula $C^2H^{\cdot}NaO^3$, it was called 'äthylen-dimethylen-carbonsäures-natron,' and was supposed to be derived in a complicated way from acetic ether, its formation being accompanied by the evolution of a quantity of hydrogen equivalent to the sodium reacting on the ether. Frankland and Duppa, whose account of its origin involves the same supposition, termed it 'Ethylic sodacetone-carbonate.'

* Communicated by Professor Wanklyn.

† Since the above was written, the non-evolution of hydrogen has been confirmed by Lefebvre (*Dew. Chem. Gesellsch. Ber.* 1870).

Preparation.—The slightly yellow wax-like mass, resulting from the action of sodium on acetic ether (1 part of sodium to 8 parts of acetic ether should be taken, and the materials heated in the water-bath, or even a little higher, until the metal has disappeared), is dissolved in perfectly dry ether mixed with a little absolute alcohol, the solution filtered or decanted, and the filtrate set aside to crystallise. Crystals of sodium-triacetyl separate. This compound is soluble in water, and apparently cannot be recovered from its aqueous solution. By treatment with an equivalent of acetic acid and common ether, it is resolved into the corresponding hydrogen compound, viz. $\text{H}(\text{C}^2\text{H}^3\text{O})^3$, hydrogen-triacetyl, which is an oil, rather heavier than water (sp. gr. at $5^\circ = 1.03$), and boils at 181° . It was called '*Æthyldiacetsaure*' by its discoverer Geuther. It shows an acid reaction with litmus only in presence of water. With neutral ferric chloride it gives a characteristic dark violet-red colour. It may be distilled unchanged in contact with steam, but undergoes decomposition in presence of strong acids or alkalis, or even in contact with water alone at a temperature of 150° . A number of its metallic derivatives have been obtained. The decomposition effected by water in presence of acids or alkalis is very interesting, viz.,

wherein, as will be seen, alcohol is produced by a substance derived from acetic acid, inasmuch as the triacetyl is derived solely from the acetyl present in acetic ether.

Hydrogen triacetyl has also been obtained by Lippmann (*Zeitschr. f. Chem.* [2] v. 28)—who, however, calls it *ethylic acetone carbonate*—by the action of acetyl chloride on the product of the action of sodium on acetic ether (doubtless on the ethylene-sodium acetate contained therein):

He finds that it is violently attacked by sodium, with evolution of hydrogen and formation of sodium-triacetyl; and that this compound heated with a solution of mercuric chloride in acetic ether yields a precipitate of *mercuric triacetyl*, $\text{C}^2\text{H}^3\text{Hg}^2\text{O}^3$. Both hydrogen-triacetyl and mercuric triacetyl unite directly with *bromine*, forming the compounds $\text{C}^2\text{H}^3\text{O}^3\text{Br}^2$ and $\text{C}^2\text{H}^3\text{HgO}^3\text{Br}^2$, both of which are heavy, pungent, oily liquids.

Noeldecke (*ibid.* iv. 681), by treating the product of the action of sodium on ethyl-acetate with ethyl-chloracetate, has obtained an acid, $\text{C}^2\text{H}^3\text{O}^3$, homologous with $\text{C}^2\text{H}^3\text{O}^3$, together with succinic acid. The ethylic ethers of the two acids resulting from the reaction were converted into sodium salts by treatment with caustic soda, and these salts were separated by absolute alcohol, which dissolved the salt $\text{C}^2\text{H}^3\text{NaO}^3$, leaving the succinate undissolved. The formation of ethyl-succinate is represented by the equation:

For the equations representing the formation of the ethylic ether of the acid $\text{C}^2\text{H}^3\text{O}^3$, regarded by Noeldecke as acetyl-propionic acid, $\text{C}^2\text{H}^3(\text{C}^2\text{H}^3\text{O})\text{O}^2$, we must refer to his memoir. This acid is monobasic, and forms crystallisable salts with calcium, copper, and zinc.

Ethylic and methylic derivatives have been obtained by the action of iodide of ethyl or methyl on sodium-triacetyl. Both of them were first described by Geuther, and the ethylic compound has also been specially examined by Frankland and Dugga.

Ethyl-triacetyl, $\text{C}^2\text{H}^3(\text{C}^2\text{H}^3\text{O})^2$, boils at 198° ; sp. gr. at $12^\circ = 0.998$ (Geuther). Frankland and Dugga give the boiling point 195° , and the sp. gr. at $16.6^\circ = 0.9834$.

Methyl-triacetyl, $\text{CH}^3(\text{C}^2\text{H}^3\text{O})^2$, boils at 187° ; sp. gr. at $6^\circ = 1.009$ (Geuther).

Just as hydrogen-triacetyl yields acetone, alcohol, and water, by the action of alkalis upon it, so also do these derivatives, ethyl- and methyl-triacetyl, suffer an analogous decomposition. Thus ethyl-triacetyl, under the influence of alkalis, as when boiled with potash, or when treated with baryta-water, yields a ketone $\text{C}^2\text{H}^3\text{O}$, together with alcohol:

In addition to sodium-triacetyl, produced by the direct action of sodium on acetic ether, it has been explained that another new organic product, viz.,

Ethylene-sodium acetate, is produced by a secondary action of acetic ether on some of the sodium-ethylate, resulting as the complement to the sodium-triacetyl.

When, therefore, the crude mass, obtained by the prolonged action of acetic ether on sodium, is treated with ethyl-iodide, the following products will be formed:

From sodium-ethylate	common ethylic ether.
From sodium-triacetyl	ethyl-triacetyl.
From ethylene-sodium acetate	$\text{C}^2\text{H}^3\text{O}^3$ (new body).

The formation of the new body $C^10H^{18}O^8$, which was obtained by Frankland and Duppa, and named 'ethyl-ethyldiacetone-carbonate,' is explained by its discoverers on the assumption that hydrogen is evolved during the reaction. Unpublished researches by Wanklyn have shown, however, that ethylene-sodium acetate prepared by the action of acetic ether on sodium ethylate yields the oily liquid $C^10H^{18}O^8$, thus:

The new body $C^10H^{18}O^8$ boils at 210° to 212° without decomposition; sp. gr. at $20^\circ = 0.9738$. It possesses the property of being resolved by baryta or lime-water into carbon dioxide, alcohol, and a ketone, thus:

It has thus been stated that, by the action of ethyl iodide on the crude wax-like product of the action of sodium on acetic ether, there is produced ethyl-triacetyl, $C^8H^{14}O^6$, and a new body, $C^10H^{18}O^8$. Now both of these oily products have high boiling points, and are capable of reacting on the undecomposed sodium ethylate produced by the direct action of sodium on acetic ether. By this reaction it has recently been shown by Geuther that butyric ether is produced. Geuther made ethyl-triacetyl, and then exposed sodium ethylate to its action, and obtained a very large quantity of butyric ether thus:

By a similar reaction no doubt $C^10H^{18}O^8$ will be found to give rise to caproic ether, thus:

Such is, then, the true chemical history of the butyric ether (and probably of the caproic ether) obtained by Frankland and Duppa by the successive action of sodium and ethyl-iodide on acetic ether. The butyric ether is a product of ethyl-triacetyl and sodium-ethylate. Frankland and Duppa explained the production of both butyric and caproic ether, by assuming the evolution of hydrogen gas, and the production of the so-called sod-acetic ether and disod-acetic ether, which, by action of ethyl-iodide were supposed to give butyric and caproic ether respectively. J. A. W.

by oxidation with dilute chromic acid into acetic acid, carbon dioxide and water $C^2H^4O^2 + O^2 = C^2H^4O^2 + CO^2 + H^2O$ (Chapman and Thorpe). The action of sodium upon it is analogous to that which the same metal exerts upon ethyl acetate (p. 15), the direct products being sodium-methylate and sodium-triacetyl.

Methyl acetate subjected to the action of chlorine under various circumstances yields the four chlorinated derivatives, $C^2H^3ClO^2$, $C^2H^2Cl^2O^2$, $C^2HCl^3O^2$ and $C^2Cl^4O^2$. The first, third and fourth are described in vol. i. pp. 23, 24.

Pentachlorinated methyl acetate, $C^2HCl^5O^2$, is formed by the action of chlorine on alkaline citrates, and is also the final product of the action of chlorine on methyl acetate in the shade. It is converted by caustic alkalis into dichloracetate, chloric acid and carbonate:

Aqueous ammonia yields similar products; with alcoholic ammonia, dichloracetamide, $C^2H^2Cl^2NO$, is produced, instead of ammonium dichloracetate (Cloeze, *Ann. C. Phys.* [3] xvii. 297, 311; *Jahresb.* 1861, p. 369).

Pentabrominated methyl acetate, $C^2HBr^5O^2$, is produced by the action of bromine on the citrates of potassium, sodium and barium. Cahours, who obtained it in this manner, together with bromoform, designated it as bromoxaform (see *Citric Acid* i. 906); Cloeze (*Rép. Chim. pure*, 1862, p. 127) obtains it also by the action of bromine on methylic alcohol or methyl acetate. It is a solid body, insoluble in water, soluble in alcohol, which deposits it by spontaneous evaporation in plates, melting at 75° , decomposed by distillation, and transformed by hot caustic

Sup.

9015

potash-solution into potassium bromide, bromoform and potassium oxalate (Cahours, i. 707). According to Cloez, aqueous potash and ammonia decompose it, with formation of carbonate and formate, whereas with alcoholic ammonia it yields dibromacetamide.

Phenyl Acetate. $C^6H^5.C^2H^3O^2$.—This compound, discovered by Scrugham (i. 24), may be prepared in the pure state by heating 20 pts. of dehydrated lead acetate, 3 pts. of phenol, and an excess of carbon bisulphide to 170° , in sealed tubes, which must be opened from time to time, to prevent explosion. The portion of the product which boils above 190° yields phenyl acetate by fractional distillation, as a colourless liquid, having a peculiarly pungent odour, a sp. gr. of 1.074, vapour-density, obs. = 4.727, calc. 4.69, and boiling at 200° . It becomes yellowish by keeping, dissolves in water, reacts neutral, and is scarcely decomposed by water even at 180° . Boiled with potash-ley it yields phenol and potassium acetate. It has the same index of refraction as easily fusible German glass, inasmuch as tubes of this glass become invisible when immersed in it (J. Broughton, *Chem. Soc. J.* [2] iii. 21). Heated with an equal weight of *aniline* in a flask with upright condensing tube, or in a sealed tube to 250° , it yields phenol and acetanilide (Lauth, *Bull. Soc. Chim.* [2] ii. 164).

Acetates of Diatomic Alcohol-radicles: Amylene, Butylene, Ethylene, &c.—The recent additions to the chemical history of these ethers will be given in connection with the respective diatomic alcohols.

SUBSTITUTION-DERIVATIVES OF ACETIC ACID.

Bromacetic Acid, $C^2H^3BrO^2$, described at p. 664, vol. i., as formed by the action of bromine on acetic acid, is likewise produced: α . Together with dibromhydrin and other products, by the action of bromine on anhydrous glycerin (L. Barth, *Ann. Ch. Pharm.* cxxiv. 341).— β . Together with ethylic bromide, by the action of bromine on ethylic acetate: in sealed tubes at 150° :

Part of the bromacetic acid is further converted into dibromacetic acid (Crofts, *ibid.* cxxix. 50).— γ . By the action of hydrobromic acid on glycollic acid: $C^2H^4O^3 + HBr = H^2O + C^2H^3BrO^2$ (Kekulé, *ibid.* cxxx. 11).— δ . By oxidation of an alcoholic solution of monobromacetylene exposed to the air: $C^2HBr + O + H^2O = C^2H^3BrO^2$ (Glöckner, *Ann. Ch. Pharm. Suppl.* vii. 107).

This acid acts on *silver benzoate* in such a manner as to form glycollide, benzoic acid and silver bromide:

With *sodium salicylate*, it forms glycollide and salicylic acid.

The *lead-salt*, $Pb^{II}(C^2H^3BrO^2)^2$, crystallises, according to A. Naumann (*Jahresb.* 1864, p. 322), not in needles, as stated by Perkin and Duppa, but in white shining laminae, and is decomposed by prolonged boiling of its aqueous solution into bromide and glycollate of lead. The sodium salt is decomposed in a similar manner.

The ethylic ether heated with sodium is converted, as already observed (p. 2), into the ethylic ethers of acconitic acid and citracetic acid.

Tribromacetic Acid, $C^2HBr^3O^2$, is produced by the action of water on tribromacetic bromide (p. 21). It forms crystals which melt at 135° , boil at 250° , and yield with potash decomposition-products analogous to those obtained from trichloracetic acid; namely, a salt of formic acid and bromoform.

Chloracetic Acid, $C^2H^3ClO^2$, and **Dichloracetic Acid,** $C^2H^2Cl^2O^2$, may be advantageously prepared by treating boiling acetic acid (diluted to sp. gr. 1.065) with chlorine in presence of iodine. Half a litre of the acid is heated to boiling with 40 to 60 grams of iodine in a flask-retort, having a long upright neck, and dry chlorine gas is passed in a moderate stream through a tube dipping into the liquid; a side tube serves for the escape of hydrochloric acid gas, while the vapours condensed in the long neck flow back again into the flask. The chlorine begins to act strongly only when the iodine is converted into perchloride; if the current of chlorine is too slow, free iodine sublimes; but on accelerating the stream of chlorine, this iodine flows back in the form of monochloride, which is subsequently

converted into trichloride, and then acts upon the acetic acid. After the passage of the chlorine has been continued for several days, the liquid is boiled till vapours of iodine make their appearance, then left to cool, and the decanted liquid is distilled. The portion boiling below 180° (which contains the unaltered acetic acid and the greater part of the iodine) is again subjected to the action of chlorine. The distillate which passes over crystallises on cooling, and yields by repeated distillation and crystallisation, pure monochloroacetic acid. The iodine-vapours given off during the distillations arise from a small quantity of iodoacetic acid, which is always produced in a certain quantity, but may be removed by repeated distillation or by treatment with a small quantity of concentrated hydriodic acid. The portion of the product boiling above 188° (which does not amount to so much as the monochlorinated acid, except in favourable cases, and after at least sixty hours' action of the chlorine), consists chiefly of dichloroacetic acid, which must be freed from a little iodoacetic acid in the manner above described, and then purified by fractional distillation. Lastly, the portion of the crude distillate boiling between 195° and 210° , appears to contain trichloroacetic acid (Hugo Müller, *Chem. Soc. J.* [2] ii. 398).

Monochloroacetic acid, $C^2H^3ClO^2$, is described at p. 875, vol. i., together with several of its salts. The sodium salt, prepared by saturating the aqueous acid in the cold with sodium carbonate, does not yield any distinct crystals by evaporation in a vacuum. A specimen dried in this way remained unaltered when heated to a little below 100° ; above that temperature it melted, turned brown and swelled up (Heintz, *Jahresb.* 1861, p. 444).

Ethyl chloroacetate, $C^2H^5.C^2H^3ClO^2$, is easily prepared by passing hydrochloric acid gas into an alcoholic solution of the acid, and precipitating with water. Heated to 130° – 150° , with rather more than an equivalent quantity of sodium glycolate, it is converted into ethyl glycolate, $C^2H^5.C^2H^3O^2$ (Heintz).

Dichloroacetic acid, $C^2H^2Cl^2O^2$ or $H.C^2HCl^2O^2$, may be prepared as above, or, according to Maumené (*Bull. Soc. Chim.* [2] i. 417), by leaving 5 at. dry chlorine to act upon 3 molecules of pure monochloroacetic acid, in large flasks, for twenty-four hours. By heating the very corrosive product in the water-bath to remove hydrochloric acid, and then distilling it, without the use of corks, pure dichloroacetic acid is obtained as the last portion of the distillate.

Dichloroacetic acid is, at ordinary temperatures, a liquid of sp. gr. 1.526 at 15° , boiling at 195° , very corrosive, and emitting suffocating vapours when heated. According to H. Müller, it does not solidify in the cold; according to Maumené, it crystallises in distorted rhombohedral plates. It appears to be easily decomposed by water, with formation of hydrochloric acid (Müller). Its salts are mostly soluble in water; those of the alkali metals crystallise with difficulty. The lead-salt is amorphous, soluble in water, but insoluble in alcohol. The silver-salt, $AgC^2HCl^2O^2$, crystallises indistinctly, and decomposes in aqueous solution, with separation of silver chloride and metallic silver (Müller). According to Maumené, it is obtained by digesting the acid with silver oxide suspended in water at 40° , as a sparingly soluble crystalline precipitate, which, when warmed, is very easily resolved, like the trichloroacetate, into monochloroacetic and hydrochloric acids, together with carbon dioxide, carbon monoxide, water and silver chloride. The solution, heated to 75° – 80° with silver oxide, is decomposed in the manner shown by the equation:

Ethyl dichloroacetate, $C^2H^5.C^2HCl^2O^2$, is formed, together with other products, by heating carbon dichloride C^2Cl^4 with sodium ethylate to 100° – 150° for twelve or eighteen hours. The portion of the product which is soluble in water consists of sodium ethyl-glyoxylate. (See GLYOXYLATES.) The oily portion separable by water consists mainly of ethyl dichloroacetate (with a small quantity of dichloroacetic chloride, p. 22). This ether has a density of 1.29, and boils at 153° (at 156° , Müller). Heated with water to 120° , it is resolved into glyoxylic acid, $C^2H^3O^4$, hydrochloric acid and alcohol; on keeping it, oxalic acid is produced, together with alcohol (Fischer and Geuther, *Jahresb.* 1864, p. 316). The methylic ether exhibits similar properties, and has a sweet taste and aromatic odour (Müller).

Cyanoacetic Acid, $C^2H^4(CN)O^2$, or its ethylic ether, is produced by boiling ethyl-monochloroacetate with aqueous potassium cyanide. The ether treated with strong potash-ley gives off ammonia, and is converted into malonic acid, $C^3H^4O^4$ (Kolbe, *Ann. Ch. Pharm.* cxxxi. 221; H. Müller, *ibid.* cxxxi. 350).

Th. Meves (*Ann. Ch. Pharm.* cxliiii. 201) prepares cyanoacetic acid by heating 250 grms. ethyl monochloroacetate with a solution of 300 grms. potassium cyanide in 1,200 grms. water in an oil-bath till the odour of prussic acid is no longer perceptible.

evaporating the exactly neutralised dark brown liquid to half its bulk, acidulating the filtered liquid with sulphuric acid, evaporating, and repeatedly treating the residue with ether. The united ethereal solutions when evaporated leave the crude cyanacetic acid as a dark brown liquid, which must be treated with lead carbonate (to remove malonic acid), filtered, and, after precipitation of the lead by hydrogen sulphide, evaporated first over the water-bath, then in a vacuum over sulphuric acid. The crystallised and only slightly coloured cyanacetic acid thus obtained forms salts which, excepting those of silver and mercury, are very soluble in water:

Potassium cyanacetate,	$C^2H^2(CN)O^2K$,	is deliquescent.
Silver	"	$C^2H^2(CN)O^2Ag$, sulphur-yellow precipitate.
Barium	"	$[C^2H^2(CN)O^2]^2Ba$, does not crystallise well.
Copper	"	$[C^2H^2(CN)O^2]^2Cu$, green needles.
Lead	"	$C^2H^2(CN)O^2 \cdot \frac{1}{2}Pb.H^2O$, spicular crystals.
Mercuric	"	$[C^2H^2(CN)O^2]^2Hg.2HgO$, white powder.
Zinc	"	$[C^2H^2(CN)O^2]^2Zn.2H^2O$, indistinctly crystalline.

Iodacetic Acid. $C^2H^3IO^2$.—*Preparation and Properties* (iii. 279). Resolved by concentrated hydriodic acid, even in the cold, into acetic acid and free iodine: $C^2H^3IO^2 + HI = C^2H^3O^2 + I^2$ (Kekulé, *Chem. Soc. J.* [2] ii. 365).

Thiaacetic Acid. $\begin{matrix} C^2H^3O \\ H \end{matrix} \left\{ S \right.$ (v. 771).—Formed by the action of potassium sulphurate in alcoholic solution on phenyl acetate.

On adding water, the phenol separates and the potassium thiaacetate dissolves (Kekulé, *Zeitschr. f. Chem.* [2] iii. 196). According to Fröhde (*Jahresb.* 1866, p. 167), sodium thiaacetate is formed by heating lead acetate with sodium hyposulphite.

Ethyl Thiaacetate, $C^2H^4OS.C^2H^5$, may be prepared by dropping acetyl chloride on sodium mercaptide, the reaction being assisted towards the end by the application of a gentle heat. It is a colourless liquid, having an alliaceous odour, and boiling at 117° . When dropped into cooled nitric acid of sp. gr. 1.2, diluted with an equal bulk of water, it is oxidised to sulphethylic acid (Saytzeff, *Zeitschr. f. Chem.* [2] iv. 642).

Thiaacetic Anhydride, or Acetic Sulphide, $(C^2H^3O)^2S$, may be prepared by adding acetyl chloride by small portions to crystallised potassium sulphide contained in a well-cooled flask, provided with a condenser. On distilling the liquid at the end of the reaction, pure thiaacetic anhydride passes over, as a yellowish liquid boiling at 121° . It is not attacked by dilute nitric acid, but fuming nitric acid oxidises it to acetic and sulphuric acids. Not decomposed by heating with acetyl iodide or ethyl iodide (Saytzeff).

ACETIC BROMIDE, or ACETYL BROMIDE. $C^2H^3O.Br$.—H. Gal (*Bull. Soc. Chim.* v. 172) prepares this compound by introducing 6 at. bromine through a drawn-out tube into a retort containing 3 mols. of glacial acetic acid, and 2 at. red phosphorus. A violent reaction then takes place, resulting in the formation of hydrobromic acid, phosphorous acid, and acetic bromide, which is separated by distillation:

According to this equation, half the bromine is employed in the formation of the acetic bromide, whereas according to the ordinary method with phosphorus pentabromide (i. 34) only $\frac{1}{3}$ th of the bromine is converted into that compound; 240 grms. bromine, 90 grms. glacial acetic acid, and 33 grms. phosphorus, yield 140 grms. acetic bromide boiling at 81° .

Monobromacetic Bromide. $C^2H^2BrO.Br$.—Produced: 1. By heating 6 grms. acetic bromide with 8 grms. bromine in sealed tubes placed in a water-bath heated to 50° or 60° (the tubes being opened from time to time to allow of the escape of hydrobromic acid); by collecting the portion of the product which distils over at 151° – 153° , it is obtained as a yellowish liquid, which may be rendered colourless by agitation with mercury. 2. By heating acetic bromide with an equivalent quantity of phosphorus pentabromide at 140° – 150° in a sealed tube: $C^2H^3O.Br + PBr_5 = PBr_3 + HBr + C^2H^2BrO.Br$ (Samosadsky, *Zeitschr. f. Chem.* [3] vi. 105).—

8. Hübner (*Ann. Ch. Pharm.* cxxiv. 315) and Naumann (*ibid.* cxxix. 257) prepare it by the action of bromine on acetic chloride. When these substances are heated together in equivalent proportions (120 pts. bromine to 64 pts. acetic chloride) to 100° in a retort connected with an upright condensing tube, the reaction takes place chiefly in the manner represented by the equation $C^2H^2OCl + Br^2 = C^2H^2BrO.Br + HCl$. By repeatedly rectifying the red liquid which remains in the retort, and collecting the portion which boils above 148°, the monobromacetic bromide is obtained as a colourless or light yellow liquid boiling at 149°–150°. It fumes in the air, strongly attacks the mucous membranes of the nose and bronchial tubes, and produces deep wounds when placed upon the skin; its vapour instantly destroys cork and caoutchouc. It is not decomposed by sodium even with aid of heat. It mixes in all proportions with anhydrous ether (Naumann, Hübner). It dissolves slowly in water, forming hydrobromic and bromacetic acids, the latter of which may be obtained in fine crystals by leaving the bromide exposed to the acid. With alcohol it yields ethyl bromide and ethylic monobromacetate boiling at 159°. By heating with bromine, it is converted into dibromacetic bromide (Gal). Neutralised with sodium carbonate, and evaporated, it leaves a saline mass, containing a small quantity of sodium bromacetate, together with sodium bromide and glycolic acid. Distilled with an equivalent quantity of dry sodium acetate, it yields up to 100° chiefly acetic oxide, $(C^2H^2O)^O$; between 178° and 195°, bromacetic oxide, $(C^2H^2BrO)^O$; and above 200° bromacetic acid, as a decomposition-product of the latter. With 1 mol. bromacetic bromide and 2 mols. sodium acetate (equal weights), the reaction takes place as shown by the equation:

Dibromacetic Bromide, $C^2HBr^2O.Br$, is formed by heating 1 mol. bromacetic bromide with 2 at. bromine to 150° for several days, and distilling the contents of the tube. It is colourless, fumes in the air, boils at 194°, dissolves slowly in water, yields no crystals on exposure to the air, is easily decomposed by potash, and when treated with alcohol yields ethylic dibromacetate, $C^2H^2C^2HBr^2O^2$, boiling at 194° (?) (Gal, *loc. cit.*).

Tribromacetic Bromide, $C^3Br^3O.Br$, is produced by heating dibromacetic bromide with excess of bromine to 200°, as long as hydrobromic acid continues to be evolved, and may be obtained pure by distillation, between 220° and 226°. It is a liquid which fumes in the air, and is converted by prolonged contact with water into tribromacetic acid; by alcohol into ethylic tribromacetate, $C^3H^2C^3Br^3O^2$, boiling at 226° (Gal).

Chloracetic Bromide, $C^2H^2ClO.Br$ or $CH^2Cl.COBr$ (P. de Wilde, *Ann. Ch. Pharm.* cxxx. 372; *Jahresb.* 1864, p. 320; Gal, *loc. cit.*).—Prepared by adding 6 at. bromine, by drops, or in a thin stream, to a mixture of 3 at. monochloracetic acid, and 2 at. amorphous phosphorus:

By distillation, the chloracetic bromide is obtained as a colourless liquid, turning red or yellow after a few days, fuming in the air, and exciting lachrymation. Sp. gr. 1.913 at 9°; B. P. 127° (De Wilde); 133° to 135° (Gal). In contact with water it yields hydrobromic and monochloracetic acids, and with alcohol, ethylic bromide and ethylic monochloracetate.

Cyanacetic Bromide, $C^2H^2(CN)O.Br$ or $CH^2Cy.COBr$, is produced, together with its isomer, bromacetic cyanide, $C^2H^2BrO.CN$, by heating silver cyanide for an hour in the water-bath, with a mixture of bromacetic bromide and chloroform. The liquid extracted by hot ether from the resulting silver bromide deposits, first, long, very sparingly soluble needles of cyanacetic bromide, and some time afterwards large transparent plates of bromacetic cyanide. The sparingly soluble cyanacetic bromide crystallises from boiling chloroform or ether in needles, but from a mixture of chloroform and glacial acetic acid in small cubes. When decomposed by water or potash it does not yield hydrocyanic acid, but, together with ammonium bromide (or ammonia and potassium bromide), the acids which result from the mutual action of ethylic chloracetate and potassium cyanide, viz. cyanacetic and malonic acids (p. 19) (Hübner, *Jahresb.* 1862, p. 243; 1864, p. 323).

ACETIC CHLORIDE, or ACETYL CHLORIDE, $CH^3.COCl$ or $CH^3.COCl$ (i. 35).—This compound is contained in the more volatile portion of the product obtained by the action of chlorine on anhydrous aldehyde. By the action of chlorine it is converted into monochloroacetic chloride (Wurtz, *Ann. Chim. Phys.* [3] xlix. 58).

With *potassium sulphhydrate*, it yields acetic sulphhydrate or thiactic acid (v. 771), and with *potassium monosulphide*, it yields acetic sulphide or thiactic anhydride:

and

(Jacquemin a. Vosselmann, *Compt. rend.* xlix. 371). With *zinc-methyl*, it forms acetone or dimethyl ketone:

and with *zinc-ethyl*, in like manner, the homologous compound methyl-ethyl ketone, $\text{CO}(\text{CH}^3)(\text{C}^2\text{H}^5)$, isomeric with butyrene (Freund, *Ann. Ch. Pharm.* cxviii. 1). Heated in a sealed tube with *phosphorus pentachloride*, it yields trichloroacetic chloride, $\text{C}^2\text{Cl}^3\text{O}.\text{Cl}$, a small quantity of an oily compound, $\text{C}^2\text{H}^3\text{Cl}$, which distils over successively (the latter depositing crystals in the receiver), and a crystalline compound, C^2HCl^3 , which remains in the retort and melts at 180° – 181° (Hübner, *Ann. Ch. Pharm.* cxx. 330). By *silver cyanide*, acetic chloride is converted into acetic cyanide, $\text{C}^2\text{H}^3\text{O}.\text{CN}$ (Hübner). Acetic chloride acts violently on lime which has been slaked and then ignited, the lime sometimes becoming red-hot. On lead oxide, on the contrary, it acts but slightly, even at 100° – 150° . When 2 mols. acetic chloride are gently heated in a sealed tube with 1 mol. caustic baryta, and the product distilled, acetic oxide passes over (H. Gal, *Jahresb.* 1863, p. 321). Heated to 120° with *phosphorous acid*, it yields, as principal product, acetopyrophosphorous acid, $\text{H}^3\text{P}(\text{C}^2\text{H}^3\text{O})\text{O}^3$ (Menschutkin, *iv.* 534).

Monobromoacetic Chloride, $\text{C}^2\text{H}^3\text{BrO}.\text{Cl}$, is produced by the action of phosphorus trichloride on monobromoacetic acid:

It is a colourless, slightly fuming liquid, having a pungent odour, and a sp. gr. of 1.908 at 9° . By the slow access of aqueous vapour, it is converted into monochloroacetic acid (B. P. 180°) and monobromoacetic acid (B. P. 208°) (Geuther, *Ann. Ch. Pharm.* cxxii. 171).

Monochloroacetic Chloride, $\text{C}^2\text{H}^3\text{ClO}.\text{Cl}$.—Produced: 1. By the action of dry chlorine gas on acetic chloride, rapidly in sunshine, in the course of 24 hours in diffused daylight; separated by fractional distillation (Wurtz, *Ann. Ch. Pharm.* cii. 93).—2. By the action of phosphorus trichloride on monochloroacetic acid (De Wilde, *Gal.*)—3. By that of phosphorus pentachloride on sulphactylenic chloride (v. 476).

It is a colourless liquid, having a pungent odour, sp. gr. 1.495 at 0° , and boiling at about 106° (Wurtz). Converted by *water* into chloroacetic acid; by *alcohol* into ethyl chloracetate; by dry *ammonia* gas into chloroacetamide, $\text{C}^2\text{H}^3\text{ClO}.\text{NH}^2$.

Dichloroacetic Chloride, $\text{C}^2\text{HCl}^3\text{O}.\text{Cl}$, has not been obtained, but its ethylic derivative, $\text{C}^2(\text{C}^2\text{H}^5)\text{Cl}^3\text{O}.\text{Cl}$, is formed, together with ethyl dichloroacetate and other products, by the action of sodium ethylate on carbon dichloride, C^2Cl^4 . If the portion of the product of this reaction which boils at 153° be shaken up with excess of potash-ley, the ethyl dichloroacetate dissolves, with formation of chloride, oxalate and dichloroacetate of potassium, while the dichloroethylacetic chloride remains undissolved. It is a liquid having a peculiar acid ethereal odour, boiling at 152° – 153° ; remains unaltered in dry air, or in contact with potash, ammonia, or water, but is easily decomposed by moist air, with formation of oxalic and hydrochloric acids. When heated with *water* it gradually dissolves, yielding alcohol, hydrochloric and glyoxylic acids, with traces of oxalic acid:

(Geuther, *Jahresb.* 1864, p. 317).

Trichloroacetic Chloride, $\text{C}^2\text{Cl}^3\text{O}.\text{Cl}$, is formed, together with tri- and pentachlorinated ethane, $\text{C}^2\text{H}^3\text{Cl}^3$ and C^2HCl^5 , by the action of phosphorus pentachloride on acetic chloride. It is a liquid boiling at 118° (Hübner, *Jahresb.* 1861, p. 437).

ACETIC CYANIDE or **ACETYL CYANIDE**, $\text{C}^2\text{H}^3\text{O}.\text{CN}$ = $\text{C}^2\text{H}^3\text{O}.\text{CN}$.—Produced by the action of acetic chloride on silver cyanide. On heating the two compounds together to 100° in a sealed tube for an hour or two, and subsequently distilling the product, a colourless liquid distils over between 80° and 90° , and afterwards a compound which boils at a much higher temperature. The first-mentioned liquid yields by repeated rectification, acetic cyanide, which boils constantly at 93° , and has a vapour-density of 2.4, agreeing with the formula $\text{C}^2\text{H}^3\text{O}.\text{CN}$ for a two-volume

condensation (calc. 2.3). This compound is lighter than water, which gradually dissolves it, with formation of hydrocyanic and acetic acids; it smells of these acids, and by prolonged contact with the air is converted into crystals soluble in water. When kept in a vessel closed with a cork, or heated with solid potassium hydrate or with sodium, it changes into an oil insoluble in water, and solidifying when washed with water to crystals, which have the composition of acetic cyanide, but a vapour-density of 4.9 to 5.0, agreeing with the formula of diacetic dicyanide, $(C^2H^3O)^2$. $(CN)^2$ (calc. 4.77). This compound melts at 69° and boils at 208° – 209° . When gently heated it remains liquid for a long time, and gradually solidifies again in very large plates. It dissolves in alcohol, ether, ordinary sulphuric acid, strong acetic acid, and strong ammonia, gives off ammonia when boiled with potash, and, like the liquid cyanide, is converted into hydrocyanic and acetic acids by boiling with water, sulphuric acid, or potash. Heated in a sealed tube to 100° with solution of silver nitrate, it yields silver cyanide crystallising in shining needles (H. Hübner, *Ann. Ch. Pharm.* cxx. 230; cxxiii. 271).

Bromacetic Cyanide, $C^2H^2BrO.CN$, is obtained, together with its isomer, cyan-acetic bromide, by heating silver cyanide with bromacetic bromide and chloroform (p. 21).

ACETIC OXIDE or ANHYDRIDE. $(C^2H^3O)^2O$.—The following additional modes of preparing this compound may be noticed: α . By the action of caustic baryta on acetic chloride, C^2H^3OCl , in sealed tubes, first at ordinary temperatures, afterwards at a gentle heat. On distilling the product, the acetic oxide passes over at 137° (H. Gal, *Compt. rend.* lvi. 360).— β . By the action of carbon bisulphide on lead or silver acetate:

A mixture of finely pulverised lead acetate, dried at 100° , and carbon bisulphide, is heated for some time to 165° in a strong sealed glass tube, of which it fills about a third, the tube being opened from time to time to permit the escape of carbonic acid gas. The liquid contents of the tube separated from the lead sulphide yield by distillation, first, the excess of carbon bisulphide, then a small quantity of acetic acid and a trace of acetone, and, lastly, acetic oxide, boiling at 137° . With silver acetate the reaction takes place more quickly.

Reactions.—According to A. Bauer (*Wien. Akad. Ber.* xliii. [2] 709; *Jahresb.* 1860, p. 438), acetic oxide heated to 100° in a sealed tube with zinc-chloride yields a product which separates by fractional distillation into acetic acid at 137° , and a residue which when freed by water from zinc-chloride, consists of a black-brown substance, C^2H^2O or $C^2H^4O^3$. The reaction is:

Glacial acetic acid heated to 150° – 160° with zinc-chloride suffers no alteration.

According to Schützenberger (*Jahresb.* 1863, p. 463), the mixture of acetic oxide and barium peroxide in anhydrous ether, used by Brodie for the preparation of acetyl peroxide (i. 55), gives off, when the barium peroxide is in excess and heat is applied, a large quantity of gas, consisting of 2 volumes carbon dioxide and 1 volume methyl (or ethyl-hydride), and leaves a residue of barium acetate:

Action of Chlorine, Bromine, and Iodine (H. Gal, *Ann. Ch. Phys.* [3] lxvi. 187).—When dry chlorine gas is passed into acetic oxide heated to 100° , acetyl chloride, boiling at 55° , passes over, and monochloroacetic acid, boiling at 187° , remains:

A mixture of 2 at. bromine and 1 mol. acetic oxide becomes heated in a few minutes and yields similar products. Iodine does not act upon acetic oxide at 200° , but at higher temperatures the mass blackens and gives off hydriodic acid.

Dry hydrochloric acid gas acts strongly on acetic oxide at 100° , forming acetyl chloride and acetic acid:

Acetic oxide heated to 60° in a stream of carbonic acid gas with 2 mol. of acetic acid chloride, SO^2HCl , yields an acid, C^2H^3SO , which when converted into a salt by neutralisation with lead carbonate, separated therefrom by hydrogen sulphide, and evaporated, remains as a thick syrup, solidifying in a vacuum to a hard crystalline

very deliquescent mass, insoluble in alcohol and ether. This acid is bibasic; its *potassium salt*, $\text{C}^2\text{H}^3\text{K}^2\text{SO}^7$, is very soluble in water and precipitated by alcohol as a granular powder. The *sodium salt*, $\text{C}^2\text{H}^3\text{Na}^2\text{SO}^7$, crystallises from water in crusts, from alcohol in concentric needles. The *silver salt*, $\text{C}^2\text{H}^3\text{Ag}^2\text{SO}^7$, is insoluble in alcohol and ether, moderately soluble in cold water, and separates from a concentrated solution of the acid mixed with silver nitrate and with alcohol, in large thin plates. The *barium salt*, $\text{C}^2\text{H}^3\text{BaSO}^7$, crystallises in nodular groups of hexagonal plates, and in crusts, insoluble in alcohol and ether, slightly soluble in cold, more freely in boiling water. The *lead salt* crystallises in white prisms.

When 2 mols. acetic oxide are heated with 1 mol. urea to the boiling point of the acetic oxide, the liquid, on cooling and addition of water, yields acetyl-urea, $\text{CH}^3(\text{C}^2\text{H}^3\text{O})\text{N}^2\text{O}$ (Scheitz, Marsh & Geuther, *Bull. Soc. Chim.* [2] x. 460).

Acetic oxide exerts no action on *oxamide* even when the two are heated together to 140° – 160° in a sealed tube (Scheitz, Marsh & Geuther).

Acetic oxide acted with nascent *zinc-ethyl* (a mixture of 2 mol. ethyl iodide and 1 mol. acetic oxide, added by drops to pulverised zinc-sodium in a cooled vessel) yields methyl-ethyl-ketone:

The action is complete in twenty or thirty hours, and on adding potash to the product, drying the separated oil over fused potassium carbonate, rectifying, combining the portion which passes over between 100° with sodium bisulphite, and distilling the resulting crystalline compound with potassium carbonate, methyl-ethyl-ketone is obtained, boiling between 77° and 80° . With *methyl iodide* in like manner, common acetone (dimethyl ketone) is obtained (Saytzeff, *Zeitschr. f. Chem.* [2] vi. 104).

Action of Acetic oxide on Cellulose, Starch, &c.—According to Schützenberger (*Bull. Soc. Chim.* [2] v. 290), the etheroidal compounds formed by cellulose, starch, sugar, &c., with acetic acid are formed more easily and abundantly by the use of acetic oxide, than by prolonged heating with glacial acetic acid, as recommended by Berthelot. The action of the acetic oxide usually begins at its boiling point, and when once set up, goes on spontaneously, yielding the new compound together with acetic acid. *Cellulose* is dissolved to a syrup at 160° . The resulting aceto-cellulose is white, solid, amorphous, insoluble in water and in alcohol, soluble in glacial acetic acid, and easily decomposed by alkalis, with reproduction of cellulose. *Starch* yields two compounds, one of which is insoluble in water, but soluble in alcohol and acetic acid; the other brittle, soluble in water and in alcohol; both are resolved by potash into acetic acid and dextrin. *Cane-sugar, glucose, milk-sugar, mannite, and dulcitol* yield solid or glutinous bodies, having a bitter taste. *Glucosides* are acted upon by acetic oxide in a similar manner.

Compounds of Acetic oxide with Aldehydes (Gauthier, *Jahresb.* 1860, p. 306, 1864, pp. 329, 334).—Acetic aldehyde unites with 1 and 2 molecules of acetic oxide, forming the compounds $\text{C}^2\text{H}^3\text{O}.\text{C}^2\text{H}^3\text{O}^2$ and $\text{C}^2\text{H}^3\text{O}.2\text{C}^2\text{H}^3\text{O}^2$. The first, described at p. 108, vol. i., is prepared by heating its components together in equivalent quantities to 180° . The second is formed by heating elaldehyde (i. 109) with acetic oxide to 160° . It is a liquid having a sp. gr. of 1.07 at 10° .

With *acrolein*, $\text{C}^3\text{H}^3\text{O}$, acetic oxide forms two compounds analogous in composition to those just described. The compound $\text{C}^3\text{H}^3\text{O}.\text{C}^2\text{H}^3\text{O}^2$ is obtained by heating of 1 molecule of acrolein and 1 molecule of acetic oxide in the water-bath for six hours, then washing the product with water and with sodium carbonate, and rectifying. It is also formed by heating one molecule of acrolein-chloride with 2 molecules of silver acetate to about 160° ; but the transformation is never complete. The compound obtained by the first process is a liquid immiscible with water, and having a strong unpleasant fishy colour and very sharp taste; sp. gr. = 1.076 at 22° ; boiling point, 180° . It slowly reduces silver in ammoniacal solution, and is resolved by potassium hydrate into acrolein and potassium acetate. The compound $\text{C}^3\text{H}^3\text{O}.2\text{C}^2\text{H}^3\text{O}^2$ is formed by heating metaacrolein with acetic oxide to 150° ; it is an oily liquid boiling at 184° .

With benzaldehyde.—When bitter almond oil is heated for some time to 150° with acetic oxide, and the product is afterwards washed with water and potassium hydrate, a liquid separates, which does not solidify if left to itself, even after a very long time, but on adding to it a particle of benzylic diacetate, it solidifies immediately into a crystalline mass melting at 44° – 45° . This substance has the composition $\text{C}^9\text{H}^9\text{O}.\text{C}^2\text{H}^3\text{O} + \text{C}^2\text{H}^3\text{O}^2$, and appears to be identical with the benzylic diacetate $\text{C}^9\text{H}^9(\text{C}^2\text{H}^3\text{O})^2$, which Limpricht and Neubauer obtained by the action of benzylic chloride on silver acetate (*Hübner, Zeitschr. f. Chem.* [2] iii. 277).

Aceto-arsenious Oxide, $C^4H^3O^2 \cdot As^3O^3$ or $\begin{smallmatrix} C^4H^3O \\ AsO \end{smallmatrix} O$, is produced by dissolving *arsenious oxide* in an equivalent quantity of *acetic oxide* at the boiling heat; the resulting syrupy liquid solidifies on cooling to a vitreous mass, which quickly absorbs moisture from the air, is resolved by water into acetic and arsenious acids, and decomposes at 220° , giving off a large quantity of carbon dioxide and traces of arsenious oxide, while acetic acid passes over and metallic arsenic remains in the retort.

Boric oxide dissolves slowly in acetic oxide, and the resulting vitreous mass, which is decomposed by water like the preceding compound, gives off acetic acid when heated, and leaves a residue soluble in water, which contains all the boric oxide employed.

When a mixture of acetic oxide and 'anhydrous tartaric acid' (insoluble tartaric anhydride, $C^4H^2O^5$, v. 691), is heated to 100° , the latter gradually dissolves, and a thick yellowish syrup is obtained, which begins to decompose at about 130° , giving off carbon dioxide and carbon monoxide; the same syrupy product is formed, together with lead-chloride, by the action of *acetyl chloride* on lead tartrate.

Vapour of *sulphuric oxide* (SO^2) is absorbed without blackening, by properly cooled acetic oxide, forming a yellowish gummy mass soluble in water. The solution neutralised with baryta-water and filtered from barium sulphate yields crystals of barium sulphacetate.

Aceto-hypobromous Oxide or Anhydride. *Acetate of Bromine*, $C^2H^3BrO^2 = \begin{smallmatrix} C^2H^3O \\ Br \end{smallmatrix} O = CH^3 \cdot CO^2Br$.—This compound, isomeric with bromacetic acid, $CH^3Br \cdot CO^2H$, appears to be formed by the action of bromine on the following compound; the product detonates after a few hours.

Aceto-hypochlorous Oxide or Anhydride. *Acetate of Chlorine*, $C^2H^3ClO^2 = \begin{smallmatrix} C^2H^3O \\ Cl \end{smallmatrix} O = CH^3 \cdot CO^2Cl$ (Schützenberger, *Compt. rend.* lii. 359).—Isomeric with monochloracetic acid, $CH^3Cl \cdot CO^2H$. Formed by passing gaseous hypochlorous oxide into cooled acetic oxide, which absorbs it completely:

$$(C^2H^3O)^2O + Cl^2O = 2(C^2H^3O)ClO.$$

On heating the resulting yellow liquid to 30° , to expel the excess of hypochlorous oxide, the hypochloracetic oxide remains as a very pale yellow liquid, having a strong irritating odour. It is not very stable, detonates violently at 100° , and can only be preserved in the dark and at a low temperature. It is decomposed by water, forming acetic and hypochlorous acids; also by most elementary bodies. Bromine and iodine eliminate the chlorine, and appear to take its place, but the resulting compounds cannot be isolated, the products often detonating spontaneously.

Aceto-cyanic Oxide. *Acetate of Cyanogen*, $C^2H^3NO^2 = CH^3 \cdot CO^2CN$, isomeric with cyanacetic and $CHCN \cdot CO^2H$, is formed by the action of acetic chloride on silver cyanide, but it has not been isolated (ii. 297).

Aceto-hypo-iodous Oxides or Anhydrides. *Acetates of Iodine* (Schützenberger, *loc. cit.*; further, *Compt. rend.* liv. 1026; *Jahresb.* 1862, p. 240).— α . Iodine monoacetate, $C^2H^3IO^2$, is formed by the action of iodine monochloride on sodium acetate, but it cannot be separated from the other products of the reaction.— β . When iodine is gradually added to well-cooled chlorine acetate, it dissolves and expels the chlorine, and after a short time colourless crystals are formed, which under the influence of heat, water, or alcohol, react like the product α ; but the mixture often detonates violently even on adding the first portions of iodine.

γ . Iodine triacetate, $I^3(C^2H^3O^2)^3$, is prepared by passing dry hypochlorous oxide into about 80 grams of acetic oxide containing in suspension 15 grams of pure and dry iodine, the liquid being well cooled. After a short time, yellowish needle-shaped crystals are formed, which afterwards disappear; and when the liquid has become perfectly colourless, it deposits colourless granular crystals of iodine triacetate, which must be drained on a porous tile, and then freed from the last traces of iodine by exposure to a current of dry air at 50° .

This compound, into which the iodine enters as a trivalent, forms large granular crystals, which on exposure to the air quickly acquire a yellowish tinge, changing to brown: they are deliquescent and instantly decomposed by water or alcohol; quickly also when heated to 100° . Heated with acetic oxide, it yields iodine, carbon dioxide, and methylic acetate:

ACETOFORMOBENZOIC ETHER. See FORMOBENZOIC ACID.

ACETOGLYCERAL. See GLYCERALS.

ACETONE. C^3H^6O .—This compound is found in crude aniline, prepared from nitrobenzene, by the action of acetic acid and iron filings (C. G. Williams, *Chem. News*, ii. 231); and in diabetic urine (Petters, Kaulich a. Betz, *Jahresb.* 1861, p. 806). Anthon (*ibid.* 1860, p. 707) has observed its formation by spontaneous decomposition in a solution of grape-sugar.

The constitution of acetone as methyl-acetyl, $CH^3.C^2H^3O$, or dimethyl ketone, CH^3COCH^3 , is clearly shown by its formation from zinc-methyl and acetyl chloride (Freund, *Ann. Ch. Pharm.* cxviii. 1):

It is also produced by the action of sodium methylate on chloracetone or monochlor-ethylidene (Friedel, *Compt. rend.* lx. 930):

Thirdly, by the action of aqueous hypochlorous acid and mercuric oxide on monobrominated or monochlorinated propylene, this reaction giving rise to monochloracetone, which is then converted into acetone by treatment with zinc and hydrochloric acid (Linnemann, *Bull. Soc. Chim.* [2] vi. 216):

Fourthly, from the isomeric compound propylene oxide, by first treating that body with sodium amalgam, whereby it is converted into isopropyl alcohol, and then dehydrogenating the latter by treatment with sulphuric acid and potassium chromate (Linnemann, *Ann. Ch. Pharm.* cxl. 178):

and

Reactions.—1. Acetone treated with sodium-amalgam and water takes up 2 at. hydrogen (which amounts to replacing the diatomic radical oxygen by the two monatomic radicals H and OH), and is converted into isopropyl alcohol (v. 889):

2. By the action of *electrolytic oxygen*, as when a mixture of acetone and dilute sulphuric acid is subjected to the action of a feeble electric current (of three Bunsen's elements), acetone is converted into a mixture of acetic and formic acids, with evolution of carbon dioxide (Friedel, *Jahresb.* 1859, p. 338).—3. When 20 vols. acetone are cautiously mixed with 30 vols. *fuming nitric acid*, a considerable quantity of oxalic acid is produced. When 30 vols. acetone are gradually mixed with 10 vols. *fuming nitric acid*, and water is added before the reaction is completed, an oily body is precipitated, which, when treated with *ammonium sulphide*, is converted into a dark red product (*acetone-red*) soluble in water and in acids (Mulder, *J. pr. Chem.* xci. 472).

4. The action of *ammonia* and *carbon bisulphide* on acetone gives rise to sulpho-carbonate and sulphocarbamate of acetone (p. 29).

5. When acetone saturated with *hydrochloric acid gas* is left to itself for 8 to 14 days, and then mixed with water, a heavy brownish oil separates, consisting mainly of compounds of hydrochloric acid with mesityl oxide, $C^6H^{10}O (= 2C^3H^6O - H^2O)$, and phorone, $C^6H^{10}O (= 3C^3H^6O - 2H^2O)$ (Baeyer, *Ann. Ch. Pharm.* cxl. 297; *Jahresb.* 1866, p. 308). The mesityl-compound, $C^6H^{10}O.2HCl$ or $C^6H^{12}OCl^2$, heated with potassium cyanide, and then with potash, yields the potassium salt of a crystalline monobasic acid, $C^6H^{11}NO^3$:

and

The phorone compound similarly treated is converted into a neutral nitrogenous body slightly soluble in boiling alcohol, from which it crystallises in shining plates, like naphthalene, sublimable at about 300° (Maxwell Simpson, *Proc. Roy. Soc.* xvi. 364).

6. With *hydriodic acid*, acetone yields iodopropylene, C^3H^5I , or an isomeric

compound; with *phosphorous iodide*, a solid together with two liquid iodides; with *hydrobromic acid* it yields merely isomeric modifications of acetone (Harnitz-Harnitzky, *Zeitschr. Ch. Pharm.* 1863, p. 416). According to Berthelot (*Bull. Soc. Chim.* [2] vii. 60), acetone treated with hydriodic acid yields propane, C^3H^8 , together with water and iodine:

7. When acetone is treated with *iodine* and *phosphorus*, and the product is dissolved in water and saturated with barium carbonate, a salt is obtained, having, according to E. Mulder (*Jahresb.* 1864, p. 329), the composition $Ba(C^3H^5PO^3)^2$. When decomposed by sodium carbonate, it yields the corresponding sodium salt, $NaC^3H^5PO^3$.

8. With *chloride of iodine*, acetone yields di-iodacetone, $C^3H^4I^2O$ (p. 28).

9. When *bromine* is gradually added to acetone, both liquids being cooled, the acetone takes up 2 at. bromine, forming the compound $C^3H^5O.Br^2$, which is a viscid liquid, heavier than water, and so unstable that it decomposes even at ordinary temperatures, giving off 1 or 2 molecules of hydrobromic acid, and yielding propionyl bromide, $C^3H^5O.Br$, and its isomer, epibromhydrin, together with acrolein, C^3H^4O , and its hydrobromide, $C^3H^5O.H.Br$. By repeatedly distilling the acetone bromide over caustic potash, there is obtained a mixture of acetone and epibromhydrin; and by distillation over lead oxide, a mixture of acetone and acrolein. With water and excess of silver oxide, acetone bromide yields (together with silver bromide) acrylic acid, or the products of its decomposition, formic and acetic acids. By slowly adding silver oxide to acetone bromide covered with water, silver bromide and propionic acid are formed, together with a small quantity of a body which dissolves in ether, crystallises therefrom in needles, and exhibits the characters of acrolein-hydrobromide (Linnemann, *Ann. Ch. Pharm.* cxxxv. 307). According to E. Mulder, on the other hand (*J. pr. Chem.* xci. 472), the direct action of bromine on acetone gives rise to substitution-products.

Acetone forms crystalline but unstable compounds with the acid sulphites of monamines. Etheral solutions of acetone and *aniline bisulphite* deposit concentric groups of shining needles of the compound $C^3H^5N.H^2SO_3.C^3H^5O$, which, however, remain undecomposed only so long as they are immersed in ether saturated with sulphurous acid. Acetone forms a similar compound with the acid sulphite of *amylamine* (Schiff, *Zeitschr. f. Chem.* [2] iv. 12).

Bromacetones. *Monobromacetone*, C^3H^5BrO , identical with that which Riche obtained by the action of a feeble electric current on a mixture of acetone and hydrobromic acid (i. 31), is produced according to E. Mulder (*loc. cit.*) by treating acetone with less than an equivalent quantity [2 at. ?] of bromine.

On gradually adding 10 pts. bromine to 1 pt. of well-cooled acetone, a solid mass is obtained, which when washed with water, dissolved in alcohol, and reprecipitated by water, deposits first a mixture of tetra- and penta-brominated acetones, and afterwards prismatic and tabular crystals of *hydrated tetrabromacetone*, $C^3H^5Br_4O.2H^2O$. This compound is insoluble in water, soluble in alcohol, melts at 42° or 43° , gives off its water below 100° , and decomposes at a higher temperature.

Pentabromacetone, $C^3H^5Br_5O$, is obtained in colourless needles by adding 12 pts. bromine to 1 pt. acetone, dissolving the product in alcohol and adding water; the crystals melt at 75° (Mulder).

Chloracetones. These bodies are partly described in vol. i. *Monochloracetone*, C^3H^4ClO , produced by the electrolysis of a mixture of acetone and hydrochloric acid, is isomeric with epichlorhydrin. It is a mobile colourless liquid having a sp. gr. of 1.162 at 16° , and boiling at 119° . [Riche found the sp. gr. 1.14 at 14° , and the boiling point 117° .] It dissolves easily in alcohol and in ether, and in about 10 times its own bulk of water. It does not unite with alkaline bisulphites, is reconverted into acetone by zinc and hydrochloric acid, and when heated with moist silver oxide yields acetate and glycolate of silver, together with other products (Linnemann, *Ann. Ch. Pharm.* cxxiv. 170).

Dichloracetone, $C^3H^3Cl_2O$, is produced by the action of phosphorus on acetone; also by the action of chlorine on acetone containing a little iodine (Wroblewski, *Zeitschr. f. Chem.* [2] iv. 585). It boils at 120° . It is decomposed by alcoholic solution of *potassium iodide*, with separation of potassium chloride and free iodine; the resulting liquid smells of acrolein, and contains a tarry volatile body which, in contact with aqueous ammonia, yields iodoform and acetamide. Dichloracetone boiled for two days with *phosphorus pentachloride*, is converted into dichloracetone chloride, $C^3H^3Cl_3$, isomeric with dichloropropylene chloride, $C^3H^3Cl_2.Cl^2$, and isomeric or identical with allylene tetrachloride:

ACETONES—ACETONIC ACID.

This compound, purified by washing, drying, and distillation, is a colourless, oily liquid, having a not unpleasant odour, a sp. gr. of 1.47 at 13°, and boiling at 153°, or about 56° lower than dichloropropylene chloride. Sodium removes the whole of the chlorine, and eliminates allylene, C^3H^4 (Borsche a. Fittig, *Ann. Ch. Pharm.* cxxiii. 111).

With alcoholic potash or ammonia, dichloracetone chloride, or allylene tetrachloride, is decomposed in the same manner as dichloropropylene dichloride, yielding isotrichloropropylene, $C^3H^2Cl^3$, an aromatic liquid boiling at 115°. Chlorine acts upon this latter compound, at ordinary temperatures and in diffused daylight, and on dichloracetone chloride when aided by water and sunshine, forming a solid sublimable body, $C^3H^2Cl^3$, which crystallises from alcohol in flocks of prismatic crystals (Borsche a. Fittig, *loc. cit.*).

Together with the dichloracetone dichloride, there is formed by the action of phosphorus pentachloride on dichloracetone (from admixed trichloracetone) a small quantity of trichloracetone chloride, $C^3H^2Cl^3$ (or chlorallylene tetrachloride)—isomeric with that just mentioned—which boils at 194°, and is also decomposed by alcoholic potash or ammonia, yielding tetrachloropropylene, $C^3H^2Cl^4$, boiling at 165° (Borsche a. Fittig).

According to E. Mulder (*Zeitschr. f. Chem.* [2] iv. 521), dichloracetone treated with potassium sulphhydrate yields sulphacetone, C^3H^4SO , as a light yellow liquid, the alcoholic solution of which yields, with neutral lead acetate, a red amorphous body, $C^3H^4PbSO^2$, which may be regarded as a compound of PbS , with a body, $C^3H^4O^2$, isomeric with glucose. This body decolorises indigo in alcoholic solution. On heating acetone with excess of chlorine, then adding potash, and afterwards hydrochloric acid, also in excess, the odour of caramel becomes perceptible. With potash dichloracetone forms chiefly acetic and formic, no lactic acid. Monochloracetone treated with potash assumes a fine red colour, due to the formation of an acid called by Mulder acetone-carminic acid. Dichloracetone forms with potassium cyanide a crystalline precipitate, $3C^3H^4Cl^2O.CN.NH^4$, which gives with hydrochloric acid a compound, likewise crystalline, consisting of $C^3H^4Cl^2O^2$, designated by Mulder as isodichloracetone. Pentabromacetone forms with potassium sulphhydrate a yellow amorphous body, C^3HBr^5SO (Mulder).

DI-iodoacetone. $C^3H^4I^2O = CO.(OH)I^2$ (Maxwell Simpson, *Laboratory*, p. 79).—Produced by gently heating acetone with an aqueous solution of iodine monochloride:

As soon as the temperature of the mixture rises to 70°, a violent action takes place, and di-iodoacetone separates as a dark-coloured oil, which must be purified by washing with water and dilute potash, and drying over oil of vitriol. When pure it is a heavy straw-yellow oil, soon turning red from separation of iodine; it has a biting taste and smell, and attacks the skin. When heated with silver cyanide, it does not yield di-cyanacetone, but, as principal product, acrolein.

ACETONES. See KETONES.

ACETONIC ACID. $C^3H^4O^3 = \begin{matrix} CH^3 \\ CH^3 \end{matrix} \{ COH.COOH$.—This acid, discovered by Städeler (*Ann. Ch. Pharm.* cxi. 320), and further examined by Morkownikoff (*ibid.* cxvi. 339; *Bull. Soc. Chim.* [2] xi. 488), is produced—1. By the action of a mixture of hydrocyanic and hydrochloric acids upon acetone:

2. From isobutyric acid, $\begin{matrix} CH^3 \\ CH^3 \end{matrix} \{ CH.CO OH$, by introducing an atom of bromine into that acid, and replacing the bromine by OH, by boiling the brominated acid with baryta. Morkownikoff, to whom this method is due, has shown that the *oxy-isobutyric acid*, thus produced, is identical with Städeler's acetic acid; it is likewise identical with Frankland and Duppe's dimethoxalic acid (iv. 274).

To prepare acetic acid, a mixture of acetone, hydrocyanic, and hydrochloric acids is left to itself for three weeks, then boiled for three days in a flask surmounted by a condenser, and finally evaporated till it no longer smells of acetone. To isolate the acetic acid, the concentrated liquid is exhausted with ether, the ether is distilled off, and the remaining acid liquid is boiled with zinc carbonate, to convert it into zinc acetate; and this salt, decomposed by hydrogen sulphide, yields acetic acid, which

ACETONINE—ACETULMIC ACID.

when left to evaporate in a dry atmosphere crystallises to a pulp or rather long needles, which may be further purified by sublimation. It begins to sublime at 74° , melts at 79° , and solidifies at 75° . *Oxyisobutyric acid* exhibits the same properties (Morkownikoff). Acetonic acid distills with vapour of water; sulphuric acid does not attack it at ordinary temperatures, but decomposes it when heated, with evolution of gas, without, however, turning it brown. It is decomposed by hot caustic potash, apparently with formation of acetone. Its ammonium salt reduces silver nitrate after some time. The barium salt is crystallisable, soluble in water and alcohol, insoluble in ether. The zinc salt, $\text{Zn}(\text{C}^{\text{H}}^{\text{I}}\text{O}^{\text{I}})^{\cdot}2\text{H}^{\text{I}}\text{O}$, is slightly soluble in water, and crystallises in small hexagonal plates resembling the lactate (Städeler). The zinc salt of oxyisobutyric acid exhibits exactly the same properties (Morkownikoff).

ACETONINE. $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}$.—Städeler obtained this biacid base by the action of ammonia on acetone (i. 32). Several of its salts have lately been prepared by E. Mulder (*J. pr. Chem.* ci. 401; *Jahresb.* 1867, p. 396), and by Mulder and Wefers Bettink (*J. pr. Chem.* ciii. 178; *Zeitschr. f. Chem.* [2] iv. 377).

The *sulphocarbamate*, $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot 2\text{CH}^{\text{I}}\text{NS}^{\text{I}}$ or $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot 2\text{CH}^{\text{I}}\text{NS}^{\text{I}}$, is produced by the action of ammonium sulphocarbamate on acetone:

It is soluble in water. The hydrochloride and other salts of acetoneine may be prepared from it by the action of the corresponding acids. On evaporating its solution ammonium sulphocyanate remains behind.

The *sulphocarbonate*, $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot \text{H}^{\text{I}}\text{CS}^{\text{I}}$ or $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot \text{CS}^{\text{I}}$, is formed by the action of ammonium sulphocarbonate on acetone:

This is the yellow body which Hlasiwetz obtained by treating acetone with ammonia and carbon bisulphide* (i. 19). It dissolves in acetone and in alcohol and exhibits in alcoholic solution the reactions of a sulphocarbonate. Heated with water or ammonia, it yields ammonium sulphocyanate, together with products of the decomposition of acetone.

Acetone Hydrochloride, $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot 2\text{HCl}$, or *Acetonium Chloride*, $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot \text{Cl}^{\text{I}}$, is obtained in large crystals by precipitating the aqueous solution of the sulphocarbamate with mercuric chloride, filtering, passing hydrogen sulphide through the filtrate, again filtering, evaporating, treating the residue with alcohol, and leaving the alcoholic solution in the exsiccator over calcium chloride. Its solution forms with platinum chloride a crystallisable *platinochloride* easily soluble in water and in alcohol. The *sulphate* and *phosphate* are less easily crystallisable than the chloride. The *acetate* has but little stability, and is decomposed on evaporating its aqueous solution. The *oxalate*, $\text{C}^{\text{H}}^{\text{I}}\text{N}^{\text{I}}\cdot \text{C}^{\text{H}}^{\text{I}}\text{O}^{\text{I}}$, 2aq., crystallises from water in large prisms.

When the aqueous solution of an acetoneine salt is shaken up with potash and ether, the ether leaves on evaporation, not pure acetoneine, but a yellowish easily decomposable liquid having an alkaline reaction.

ACETONITRATES. See ACETATES (p. 10).

ACETONITRILE. Syn. with METHYL CYANIDE. (See CYANIDES, ALCOHOLIC.)

ACETOPHOSPHORIC ACID. Syn. with ACETYLPHOSPHORIC ACID (iv. 595).

ACETOTRYPTOPHOSPHORIC ACID. Syn. with ACETYLTRYPTOPHOSPHORIC ACID (iv. 596).

ACETOSULPHURIC ACID. $\text{C}^{\text{H}}^{\text{I}}\text{SO}^{\text{I}}$.—Syn. with ETHYLANTHRIC ACID (v. 475).

ACETOTOLUIDE. Syn. with TOLYLACETAMIDE (v. 871).

ACETOXACETIC ACID. Syn. with ACETYLGLYCOLLIC ACID. (See GLYCOLLIC ETHERS ii. 917.)

ACETOXYBENZAMIC ACID. See OXYBENZAMIC ACID (v. 891).

ACETULMIC ACID. $\text{C}^{\text{H}}^{\text{I}}\text{O}^{\text{I}}$ (E. Hardy, *Bull. Soc. Chim.* [3] v. 339).—A mixture of acetone and chloroform treated with sodium yields the sodium-salt of chloroacetulmic acid, $\text{C}^{\text{H}}^{\text{I}}\text{ClO}^{\text{I}}$, an amorphous pulverulent substance which by boiling with soda is converted into acetulmic acid, and dioxycetulmic acid, $2\text{C}^{\text{H}}^{\text{I}}\text{ClO}^{\text{I}} + 2\text{KHO} = 2\text{KCl} + \text{C}^{\text{H}}^{\text{I}}\text{O}^{\text{I}} + \text{C}^{\text{H}}^{\text{I}}\text{O}^{\text{I}}$. These two acids separate as

* Ammonia and carbon bisulphide form by their mutual action, sulphocyanate, sulphocarbonate and sulphocarbamate of ammonium. The first of these has no action upon acetone; the second and third yield the products above mentioned.

a bulky precipitate on neutralising the liquid with sulphuric acid. Acetulmic acid is described as a brown uncrystallisable, non-volatile substance insoluble in ether. Its chlorinated, brominated, and nitrated derivatives, described by Hardy, are likewise amorphous and non-volatile so that their formulæ cannot be regarded as determined with precision.

ACETURIC ACID. $C^4H^4NO^2$ (Kraut and Hartmann, *Ann. Ch. Pharm.* cxxiii. 99).—An acid produced by boiling acetic chloride with excess of the silver compound of glycocine:

It forms small white crystals soluble in water, and not decomposed by boiling therewith. Its salts are soluble and crystallisable.

ACETYL. Wislicenus (*Zeitschr. f. Chem.* [2] iv. 681), by treating acetyl iodide with finely divided silver or copper, has obtained a colourless pungent liquid, which is probably free acetyl or diacetyl, $(C^2H^2O)^2$.

ACETYL ALCOHOL. $C^2H^4O = (C^2H^2)HO$; better called VINYL ALCOHOL (p. 37).

ACETYL BROMIDE, CHLORIDE, &c. See ACETIC BROMIDE, CHLORIDE, &c. (pp. 20, 21).

ACETYL SULPHYDRATE and SULPHIDE. Syn. with THIACETIC ACID and ANHYDRIDE (v. 771, 772).

ACETYL-AMYL. $C^8H^{14}O = C^2H^2O.C^6H^{11}$. See KETONES.

ACETYL-ISOPROPYL. See PROPYL-COMPOUNDS.

ACETYLENE or ETHINE. C^2H^2 .—This hydrocarbon is described in the ADDENDA to vol. i. p. 1111; but our knowledge of its properties has been largely increased by recent investigations. The name *acetylene* was given to it by Berthelot because it is related to the radicle C^2H^2 , formerly called acetyl, in the same manner as ethylene to ethyl. *Ethine* is the name assigned to it in the systematic nomenclature of hydrocarbons proposed by Dr. Hofmann (*Proc. Roy. Soc.* xv. 57), and indicates its relation to ethane or ethyl hydride and ethene or ethylene:

Formation.—The formation of acetylene by direct combination of carbon and hydrogen takes place only under the influence of the electric arc; the most intense heat, even that produced by the sun's rays concentrated by a powerful lens, is unable to effect it; neither does the combination take place under the influence of the induction spark. To obtain acetylene in quantity under the influence of the electric arc, it is necessary to employ a powerful battery; with 40 or 50 Bunsen's elements 10 cub. cent. of acetylene may be obtained in a minute. The acetylene as it is formed is carried forward with the stream of hydrogen, and may be collected in an ammoniacal solution of cuprous chloride, and separated from the red precipitate thereby produced by the action of hydrochloric acid (p. 35). To obtain the acetylene quite pure, the charcoal forming the poles of the battery must be carefully purified from tarry matter, and traces of sulphur, iron, silicon, &c., by ignition in a current of chlorine (Berthelot, *Compt. rend.* lv. 640).

The following modes of production of acetylene have also been observed: a. By the incomplete combustion of hydrocarbons, and indeed of organic compounds in general. It may be shown to exist in the middle of the flame of pure ethylene gas (or of coal gas, previously freed from acetylene by passing through ammoniacal cuprous chloride) by drawing off the gases from that part of the flame through a tobacco-pipe stem connected with an aspirator. It is also formed in the imperfect combustion of a mixture of 1 vol. ethylene gas and 2 vols. chlorine (De Wilde, *Bull. Soc. Chim.* 1856, p. 172). Berthelot has devised an ingenious form of experiment by which the production of acetylene in the imperfect combustion of carbon compounds may be strikingly demonstrated. An ammoniacal solution of cuprous chloride is poured into a test-tube and spread over the inner surface; a small quantity of ether or other inflammable organic liquid is then introduced and set on fire, and the tube, held in an inclined position, is turned round slowly in the hand, so as to bring the burning ether as much as possible in contact with the cuprous solution; the characteristic red precipitate of the so-called cuprous acetylde is then immediately produced. A modification of this experiment has been devised by Mr. McLeod, by which considerable quantities of acetylene may be readily obtained. The arrangement consists in burning a jet of

oxygen in an atmosphere of marsh gas, and passing the products of combustion into ammoniacal cuprous chloride, the gases being continuously supplied, so that the process may go on without interruption. The marsh gas may further be replaced by coal gas, and the oxygen by atmospheric air (*Chem. Soc. J.* [2] iv. 152).

Acetylene is also produced in considerable quantity in the incomplete combustion of coal gas in a Bunsen's lamp, when the flame accidentally burns in the interior of the chimney. By placing over the chimney a funnel communicating with a series of bottles containing an ammoniacal silver solution, and finally with an aspirator, a considerable quantity of argentic acetylide may be collected. The formation of acetylene in this manner may be quickly demonstrated as a lecture experiment by inverting a flask over a Bunsen's lamp burning in the manner above mentioned, and afterwards pouring in a solution of cuprous chloride: the sides of the flask become covered with a thick film of the red copper compound (Riesh, *Zeitschr. f. Chem.* [2] iii. 598).

The incomplete oxidation of organic compounds at low temperatures, as when it is effected in the voltaic circuit, also gives rise to the formation of acetylene, as, for example, in the electrolysis of a solution of potassium aconitate or succinate (Berthelot, *Bull. Soc. Chim.* [2] ix. 103).

β. In the incomplete combustion of mixtures of hydrogen and gaseous or vaporous carbon-compounds not containing hydrogen, such as cyanogen, carbon monoxide, and carbon bisulphide. Such mixtures are not affected by heat, but on passing electric sparks through them acetylene is immediately formed. In the case of cyanogen an electrical apparatus of high tension must be used, as this gas offers great resistance to the passage of the spark. With carbon bisulphide there is a deposition of sulphur, which element also unites with the platinum terminals. In operating with a mixture of hydrogen and carbon monoxide, it is necessary to introduce a piece of caustic potash, slightly moistened on the surface, in order to absorb the carbon dioxide formed at the same time, which interferes with the further production of the acetylene (Berthelot, *Bull. Soc. Chim.* [2] v. 169).

γ. By exposing marsh gas to the action of a strong heat or to the spark of a powerful induction coil: $2\text{CH}_4 = \text{C}_2\text{H}_2 + 3\text{H}_2$ (Berthelot, *Compt. rend.* liv. 515). The action of the spark, which is rapid at first, diminishes as the volume of free hydrogen increases; but by absorbing the acetylene as fast as it is formed, about $\frac{1}{2}$ of the marsh gas may be ultimately transformed into acetylene. Coal gas may be used in this reaction instead of pure marsh gas, and Berthelot recommends the process in this form as the readiest mode of preparing acetylene. A portion of the acetylene is however polymerised during the process, being converted partly into benzene, $\text{C}_6\text{H}_6 = 3\text{C}_2\text{H}_2$, partly into black tarry hydrocarbons, which condense on the sides of the tube. A portion of the marsh gas undergoes a different decomposition, being completely resolved into carbon and hydrogen (Berthelot, *Bull. Soc. Chim.* [2] xi. 442).

According to De Wilde (*Bull. Soc. Chim.* [2] v. 267), the vapours of many other organic compounds, as ethylene, alcohol, ether, acetone, amyl alcohol, and especially benzene, likewise yield acetylene when induction sparks are passed through them.

δ. By passing the vapour of methyl chloride through a tube heated to low redness (Berthelot), or that of ethylene chloride through a tube heated to bright redness, hydrogen and marsh gas being produced at the same time, and carbon deposited (De Wilde, *Bull. Soc. Chim.* [2] v. 267). Amyl hydride from American petroleum passed through a red-hot iron tube yields, according to H. Vohl, (*ibid.* [2] iv. 302), 20 p. a. acetylene. If this statement be correct, American petroleum should be the most productive source of acetylene.

ε. By passing a mixture of carbon monoxide and hydrochloric acid gas over red-hot magnesium silicide (Berthelot).

ζ. Styrol (cinnamene) passed through a red-hot tube is partly resolved into benzene and acetylene: $\text{C}_9\text{H}_8 = \text{C}_6\text{H}_6 + \text{C}_2\text{H}_2$ (Berthelot, *Jahresb.* 1866, p. 544).

η. Calcium carbide (produced from the alloy of zinc and calcium formed in contact with charcoal at a very high temperature) is converted by water into calcium hydrate and acetylene (Wöhler, *Ann. (A. Pharm.)* cxiv. 220).

ι. The sodium salts of fumaric and maleic acid are decomposed by the action of the current in such a manner that acetylene (formed by oxidation) appears at the positive pole, and succinic acid (by reduction) at the negative pole (Kekulé, *Jahresb.* 1864, p. 389).

and $\text{C}_6\text{H}_5\text{NaO} + \text{H}^+ \rightarrow \text{C}_6\text{H}_6 + 2\text{CO} + \text{Na}^+ + \text{H}^+$,

Solubility.—At the temperature of 18°, water, carbon bisulphide, and amyl hydride dissolve about their own volume of acetylene; turpentine oil and carbon tetrachloride, 2 vols.; amyl alcohol and styrol, 3½ vols.; glacial acetic acid and absolute alcohol, nearly 6 vols. (Berthelot, *Ann. Ch. Phys.* [4] ix. 425).

Acetylene combines with the hæmoglobin of blood. (See BLOOD.)

Reactions.—1. Acetylene is decomposed by the induction-spark, with separation of charcoal.

2. **Action of Heat.**—When acetylene is heated to dull redness in a bent glass tube standing over mercury, it is gradually but completely converted, with separation of small quantities of carbon and hydrogen and formation of small quantities of ethylene and ethyl hydride, into a series of hydrocarbons polymeric with itself, namely: α . a very volatile liquid hydrocarbon, probably consisting of diacetylene, C^4H^4 ; β . benzene or triacetylene, C^6H^6 , forming about half the entire product; γ . cinna-mene, styrol, or tetracetylene, C^8H^8 , boiling between 135° and 160°, and constituting about ¼ of the whole; δ . a liquid mixture (distilling between 210° and 250°) of naphthalene and another hydrocarbon, probably pentacetylene or naphthalene hydride, $C^{10}H^{10}$; ϵ . a mixture of strongly fluorescent oils distilling at 250°–340°; ζ . retene or enneacetylene, $C^{18}H^{18}$, distilling at 360°, and crystallising in shining needles. The mode of decomposition is greatly influenced by the presence of foreign substances. If a piece of coke, ignited and cooled under mercury, be introduced into the bent glass tube, the acetylene is resolved, under the same conditions as above, into carbon and hydrogen, with scarcely any secondary products. In presence of iron the decomposition takes place more quickly and readily, the acetylene being then partly resolved into its elements, partly converted into other hydrocarbons, different from those above mentioned. When acetylene is slowly passed through a porcelain tube heated to bright redness, it is almost wholly resolved into carbon and hydrogen, the only secondary products being small quantities of ethylene and tar containing naphthalene.

3. **Action of Hydrogen.**—Hydrogen does not act upon acetylene at ordinary temperatures; but when the two gases are heated together, small quantities of ethylene, ($C^2H^4 = C^2H^2 + H^2$), and of benzene and other polymers of acetylene, are produced. The decomposition of acetylene by heat is retarded by the presence of hydrogen and of other gases, e.g. nitrogen, carbon monoxide, marsh gas, ethyl hydride; and hence it is that acetylene can be formed by the action of the electric arc on charcoal in an atmosphere of hydrogen, in spite of its tendency to split up into its elements at high temperatures.

By the action of nascent hydrogen on alkaline, but not on acid liquids, acetylene is converted into ethylene; this result may be obtained by the action of zinc and aqueous ammonia (which evolves hydrogen) on the so-called cuprous acetylide (p. 85).

When acetylene is mixed with excess of hydrogen in a jar standing over mercury, and a small quantity of platinum black enclosed in a spiral of platinum wire is introduced into the mixture, the gases combine in the proportion of 1 vol. acetylene to 2 vols. hydrogen, producing the saturated hydrocarbon, ethane or ethyl-hydride: $C^2H^2 + 2H^2 = C^2H^6$.

4. **Action of Hydrocarbons.**—When acetylene is heated to dull redness with an equal volume of ethylene, two-thirds of the mixture disappear in the course of half an hour, and a number of products are formed, the chief of which is a very volatile liquid, easily absorbed by bromine and by concentrated sulphuric acid, slightly soluble in ammoniacal cuprous chloride, and isomeric or identical with quartine or crotonylene, C^4H^4 (ii. 965). The two gases here unite in equal volumes with a condensation to one-half: C^2H^2 (2 vols.) + C^2H^4 (2 vols.) = C^4H^4 (2 vols.) (Berthelot, *Compt. rend.* lxii. 947). Acetylene heated with excess of benzene is quickly absorbed, scarcely one-fifth of the original volume being left, and on leaving the benzene to evaporate, a crystallised hydrocarbon is obtained, distinct from all known hydrocarbons. Naphthalene likewise absorbs acetylene, and more quickly than benzene; the gaseous residue in both these reactions consists of hydrogen mixed with small quantities of ethylene and ethyl hydride (Berthelot).

5. **Action of oxidising agents, etc.**—Acetylene, subjected at ordinary temperatures to the action of potassium permanganate, takes up oxygen, yielding oxalic acid $C^2H^2 + O = C^2H^2O$, formic and carbonic acids being also produced by a secondary reaction (Berthelot, *Compt. rend.* lxiv. 85). When passed through an ammoniacal solution of cupric oxide, acetylene is slowly absorbed, the greater part of it being oxidised, and at the same time there is deposited on the sides of the vessel a carbonaceous substance, mixed with a small quantity of cuprovinyl oxide (Berthelot *Ann. Ch. Phys.* [4] ix. 422).

6. **Action of Chlorine and Antimonic Chloride.**—Acetylene, either pure or mixed with other gases, sometimes detonates with chlorine, even in diffused daylight.

whether the chlorine or the acetylene is in excess, the products of the reaction being hydrochloric acid and free carbon. Frequently, however, no explosion takes place, but the two gases unite directly, forming the liquid dichloride $C^2H^2Cl^2$; sometimes, again, the action commences with the formation of this compound, and then the mixture suddenly explodes (Berthelot, *Bull. Soc. Chim.* [2] v. 191). When acetylene is prepared from cuprosorinyl oxide by the action of a large excess of hydrochloric acid, the hydrochloride C^2H^2HCl is constantly produced (Berthelot, *Compt. rend.* lviii. 978).

The chlorides of acetylene are best prepared by passing the gas into antimonious chloride, which absorbs it, with considerable evolution of heat, requiring the action to be regulated by moderate cooling. The nearly saturated liquid, on being left to cool, deposits large crystalline laminae of the compound $C^2H^2SbCl^3$, which may be freed from excess of antimonious chloride by draining and evaporation, and dried in a stream of carbonic anhydride. This compound is very unstable, being instantly decomposed by water, and quickly resolved by heat into antimonious chloride, $SbCl^3$, and acetylene dichloride, $C^2H^2Cl^2$. If, however, it be dissolved in excess of antimonious chloride and then heated, a still more violent action takes place, resulting in the formation of acetylene tetrachloride:

The dichloride is most easily prepared by heating the crude compound $C^2H^2SbCl^3$, containing a slight excess of antimonious chloride. A mixture of dichloride and tetrachloride of acetylene is then obtained, which may be separated by fractional distillation. The dichloride $C^2H^2Cl^2$ is a colourless mobile liquid, having a sweetish taste, and a powerful odour, like that of chloroform, which excites headache. It boils at 55° . It is altered by moist air, and slowly decomposed by water at 180° in sealed tubes, with formation of hydrochloric acid and condensed products. When heated by itself to 360° in a sealed tube for 100 hours, it is completely resolved into black laminar charcoal and hydrochloric acid.

The tetrachloride, $C^2H^2Cl^4$, is prepared, as above mentioned, by distilling the compound $C^2H^2SbCl^3$ with excess of antimonious chloride, the operation being conducted cautiously towards the end, to guard against explosion. It is a colourless liquid, resembling chloroform in taste and smell; boils at 147° ; is slowly attacked by water with formation of hydrochloric acid. In an atmosphere of chlorine it is slowly converted into C^2Cl^4 . When very cautiously treated with alcoholic potash it gives up 1 molecule of hydrochloric acid, and yields chlorinated acetylene dichloride, $C^2HCl^3Cl^2$, a colourless liquid boiling at 88° . The tetrachloride is also decomposed by moisture. Heated to 300° for fifteen hours in a sealed tube, it is also resolved into hydrochloric acid and chlorinated acetylene dichloride. By prolonged heating to 360° for 100 hours, another molecule of hydrochloric acid is separated; but the residue consists, not, as might be expected, of carbon monochloride, C^2Cl^2 , but of its polymeride, Julien's chloride of carbon or perchlorobenzene, C^6Cl^6 , the formation of which from the C^2Cl^2 produced in the first instance, is precisely analogous to that of benzene from acetylene (Berthelot & Jungfleisch, *Compt. rend.* lxi. 542; *Zeitschr. f. Chem.* [2] v. 680).

7. *Action of Bromine and Hydrobromic Acid.*—a. Pure acetylene slowly passed into a layer of bromine kept cold under water takes up 2 at. bromine, forming the dibromide $C^2H^2Br^2$, isomeric with dibromethylene. This compound, when purified, is a neutral, colourless, oily liquid, smelling like ethylene dibromide. It cannot be distilled, for when heated it undergoes a polymeric transformation, forming a product which cannot be volatilised without decomposition; nevertheless, the first drops which pass over at about 180° correspond nearly to the formula $C^2H^2Br^2$. Berthelot has recently found that the combination of acetylene with bromine requires the presence of light; on a foggy day he observed that acetylene was not sensibly absorbed by bromine; sometimes, even in bright diffused daylight, a mixture of acetylene and bromine vapour may remain for some minutes without combining, and then the reaction takes place suddenly. These facts are of importance with reference to the analysis of gaseous mixtures containing acetylene (*Bull. Soc. Chim.* [2] xi. 372).—B. When acetylene prepared from ether and not quite pure is passed in a rapid stream through liquid bromine, and the temperature allowed to rise, the tetrabromide $C^2H^2Br^4$ is produced. The latter compound was likewise obtained by Reiboul (i. 1112). The two bromides which Perrot obtained in 1858 (*Compt. rend.* xlvii. 350) by combining with bromine the gases resulting from the decomposition of alcohol vapour by the electric spark, probably also consisted of the dibromide and tetrabromide of acetylene.—γ. With concentrated hydrobromic acid at 100° , acetylene forms a very volatile

Sup.

hydrobromide, probably $C^2H^2.HBr$, which, like acetylene itself, is absorbed by ammoniacal cuprous chloride (Berthelot, *Bull. Soc. Chim.* [2] ii. 202).

Bromacetylene, C^2HBr , and its dibromide, C^2HBr^2 or $C^2HBr.Br^2$, already described in vol. i. p. 1112, are produced by the action of alcoholic potash on bromo-ethylene dibromide, $C^2H^2Br.Br^2$. Bromacetylene is also formed, together with muconic acid, by boiling *muconic acid* (a product of the action of bromine on pyromucic acid, iv. 763) with excess of baryta-water :

(Schmelz a. Beilstein, *Ann. Ch. Pharm. Suppl.* iii. 275).

8. *Action of Iodine and Hydriodic Acid.*—Acetylene does not combine with iodine at ordinary temperatures, even in sunlight. But when the two bodies are heated together to 100° in a closed flask for 15 to 20 hours, the di-iodide $C^2H^2I^2$ is obtained as a crystalline substance melting at 70° (Berthelot, *Bull. Soc. Chim.* [2] ii. 202).

When a concentrated solution of hydriodic acid is placed in contact with acetylene at ordinary temperatures, a mixture of acetylene mono-hydriodide, $C^2H^2.HI$, and dihydriodide, $C^2H^2.(HI)^2$, is produced, from which the former may be obtained pure by distillation with alcoholic potash. It is a colourless fragrant liquid, boiling at 62° , and isomeric with mono-iodoethylene, C^2HI , which boils at 56° (Semenoff, *Compt. rend.* lxi. 646).

The dihydriodide, $C^2H^2.(HI)^2$, isomeric with ethylene iodide, $C^2H^4.I^2$, is obtained, according to Berthelot, by simply leaving concentrated hydriodic acid in contact with acetylene; according to Semenoff, only by heating the strong acid to 100° in contact with acetylene, and even then not quite free from mono-iodide. It is a liquid distilling without decomposition at 180° (Berthelot), and yielding acetylene when decomposed by alcoholic potash.

According to more recent experiments by Berthelot (*Bull. Soc. Chim.* [2] vii. 53; *Jahresb.* 1867, p. 344), the dihydriodide produced in the first instance is converted by further action of the hydriodic acid into ethane, C^2H^6 :

The compounds of acetylene with chlorine, bromine, and iodine above described show that acetylene is a tetratomic or quadrivalent radicle, but that, like all such radicles (tin, titanium, silicon, &c.), it is likewise capable of acting as a bivalent radicle, or rather of forming compounds containing 2 at. Cl, Br, &c., in which its combining capacity is only half saturated.

A tetra-iodide having the composition $C^4H^2I^4$, is produced by passing acetylene into an ethereal solution of iodine, or, better, by agitating argento-vinyl oxide, $(C^2HAg^2)^2O$, suspended in water, with ethereal solution of iodine till the latter is no longer decolourised. On distilling off the ether, the tetra-iodide is obtained as a yellow crystalline mass, having an extremely repulsive odour, volatilising even at ordinary temperatures, and melting at 74° , with decomposition and brown coloration. It dissolves easily in alcohol, ether, and carbon bisulphide, and when heated with alcoholic potash, gives off a large quantity of acetylene, and yields a small quantity of a very volatile oil, probably consisting of iodoacetylene, C^2HI (Max Berond, *Ann. Ch. Pharm.* cxxxi. 122).

The iodide $C^4H^2I^4$ may be regarded as a compound of acetylene C^2H^2 with carbon di-iodide C^2I^2 —these radicles being both bivalent, and saturating one another by their combination—or as a compound of 2 at. iodine with the bivalent radicle di-iodoacetylene, that is as $(C^2HI^2)^2I^2$. Both these views are represented by the constitutional formula

The iodide is decomposed in ethereal solution by excess of *bromine*, yielding the compound $C^4Br^2I^2$ or $(C^2Br^2I^2)^2I^2$:

This bromiodide forms white crystals smelling like bromoform and melting at 100° . At a high temperature it decomposes with separation of iodine, and behaves to solvents in the same manner as the iodide $C^4H^2I^4$.

When a stream of *nitrous acid* vapour is slowly passed through a solution of the tetra-iodide in alcoholic ether, the latter being continually renewed, iodine separates,

and the liquid, which has again become clear, yields on evaporation a residue which crystallises from alcohol or chloroform in white silky needles, corresponding in composition to the formula $[\text{C}^2\text{H}(\text{NO}^2)]^2\text{I}^2$. They are easily decomposed, even in a vacuum, giving off red vapours and leaving the compound C^2H^2 (Berend, *Ann. Ch. Pharm.* cxxxv. 257).

9. *Action of Nitrogen.*—When a series of strong induction sparks is passed through a mixture of acetylene and nitrogen, the two gases unite and form hydrocyanic acid:

Carbon and hydrogen are at the same time set free by a secondary action, but this may be prevented by diluting the gaseous mixture with 10 times its volume of hydrogen. The formation of hydrocyanic acid goes on rapidly at first, but soon slackens, and after the passage of the sparks has been continued for an hour and a half, only about one-fifth of the volume of the mixed gases is found to be converted into hydrocyanic acid. In fact, a reverse action takes place at the same time, part of the hydrocyanic produced being again resolved into acetylene and nitrogen, and after a certain time this reverse action goes on as quickly as the production of the acid. But by introducing a small quantity of strong potash-solution, so as to absorb the hydrocyanic acid as fast as it is formed, the whole of the acetylene and nitrogen, if mixed in equal volumes, will ultimately be converted into hydrocyanic acid (Berthelot, *Compt. rend.* lxvii. 1141).

10. *Action of Metals.*—With the alkali-metals acetylene forms substitution-products. Sodium gently heated in the gas, melts and partly absorbs it, leaving a volume of hydrogen (with small quantities of ethylene and ethyl hydride) equal to about half the volume of the gas, and is converted into sodium-acetylene, C^2HNa . The reaction takes place according to the equations

At a dull red heat disodium-acetylene, C^2Na_2 , is formed, with separation of a volume of hydrogen about equal to that of the original gas: $\text{C}^2\text{H}^2 + \text{Na}^2 = \text{C}^2\text{Na}_2 + \text{H}^2$. Both these compounds are decomposed by water, with formation of acetylene.

Potassium likewise decomposes acetylene, and much more violently than sodium; when melted in the gas it takes fire and is converted into dipotassium-acetylene, C^2K_2 ; the same compound is also formed in small quantity when potassium is heated to dull redness in ethylene gas: $\text{C}^2\text{H}^4 + \text{K}^2 = \text{C}^2\text{K}_2 + 2\text{H}^2$. Traces of it are found in commercial potassium.

Most other metals, except magnesium and iron, appear to be without action upon acetylene: iron decomposes it completely at a dull red heat, but does not unite with it (Berthelot, *Bull. Soc. Chim.* [2] v. 187).

11. *Action of Salts.*—a. The red precipitate produced by acetylene in an ammoniacal solution of cuprous chloride, and originally regarded as cuprosacetylene, C^2HCu , has been shown by Berthelot to contain oxygen. After washing with strong ammonia to remove chlorine, and then with water, it consists of cuprosovinyl oxide, $(\text{C}^2\text{HCu})^2\text{O}$, or vinyl oxide, $(\text{C}^2\text{H}^2)^2\text{O}$, having two-thirds of its hydrogen replaced by cuprosium:

Vinyl oxide.

Cuproso-vinyl oxide.

Its formation is represented by the equation

When heated with hydrochloric acid, it yields cuprous chloride and acetylene:

On heating it with zinc and aqueous ammonia, the nascent hydrogen thereby evolved unites with the elements of the acetylene, producing ethylene:

and

It is a very unstable compound; easily oxidised; detonates when struck or when heated to between 95° and 120° , producing water, copper, carbon, carbon dioxide, and traces of carbon monoxide. An ammoniacal solution of cuprous chloride is capable of detecting $\frac{1}{250}$ of a milligramme of acetylene mixed with hydrogen. In presence of air the delicacy of the reaction is limited to $\frac{1}{100}$ of a milligramme. It is important that the solution used be quite free from cupric salts, as these would oxidise the acetylene and interfere with the formation of the red compound (p. 32).

When a slow current of acetylene is passed into a concentrated solution of potassium cuprous chloride, a yellow crystalline precipitate is formed, which, when washed with a strong solution of potassium chloride, and afterwards with water, leaves cuproso-vinyl chloride, C^2H^2Cl , a compound of darker colour than the oxide; it forms double salts with the chlorides of the alkali-metals, and is converted by ammonia into the oxide. Cuprosovinyl oxychloride is formed by passing acetylene into a solution of cuprous chloride in hydrochloric acid slightly supersaturated with ammonia: it constitutes the chief portion of the crude red precipitate commonly called cuprous acetylene. The bromide and oxybromide of cuprosovinyl and the corresponding iodine and cyanogen compounds are formed by similar processes. A basic cuprosovinyl sulphite is formed by passing acetylene into an ammoniacal solution of cuprous sulphite; and black-brown cuprosovinyl sulphide is obtained, mixed with copper sulphide, by the action of sulphuretted hydrogen on the oxide (Berthelot, *Bull. Soc. Chim.* [2] v. 191; *Jahresb.* 1866, p. 510).

β . Argentovinyl oxide, $(C^2HAg^2)O$, is formed, exactly like the corresponding copper compound, by passing acetylene into an ammoniacal solution of silver nitrate. When it is suspended in water and treated with bromine, silver bromide is formed, and on distilling the liquid, two products are obtained, viz. an oil, C^2HBr^2 , and beautiful white crystals, $C^2HBr^2.HBr$, melting at about 42° , having an agreeable odour, soluble in alcohol, ether, benzene, chloroform, and carbon bisulphide, and yielding acetylene when treated with reducing agents (Berend, *Ann. Ch. Pharm.* cxxxv. 257).

The two brominated compounds just mentioned are isomeric with those which Reiboul obtained by the action of alcoholic potash on dibromethylene dibromide (i. 1112), but it is remarkable that they are inversely liquid or crystallised; thus:

Berend: C^2HBr^2 liquid. $C^2HBr^2.HBr$ crystallised.
Reiboul: C^2HBr^2 crystallised. $C^2H^2Br^2$ liquid.

Argentovinyl chloride, C^2HAg^2Cl , is formed on passing acetylene into an ammoniacal solution of silver chloride, as a white curdy precipitate, which is decomposed by boiling hydrochloric acid, with evolution of acetylene; and by nitric acid, with oxydation of acetylene, separation of silver chloride, and solution of a quantity of silver equivalent to that of the silver chloride separated. With a boiling solution of sal-ammoniac it is decomposed in the manner shown by the equation:

The sulphate, phosphate and benzoate of argentovinyl are obtained in a similar manner (Berthelot, *loc. cit.*).

Argentie bromacetylido is formed by the action of bromiacetylene on ammoniacal silver nitrate. To prepare it, the vapours evolved by treating dibromethylene dibromide with boiling alcoholic potash (i. 1112) are passed into cold alcohol, which then retins in solution dibromethylene, bromacetylene, and small quantities of acetylene; and on diluting this solution with water and ammonia, and then dropping into it an ammoniacal solution of silver nitrate, an explosive precipitate is formed at first, and afterwards a crystalline precipitate. As soon as the latter appears, the solution is to be filtered, and the precipitation completed. The crystalline precipitate consists of argentie bromacetylido having the composition $(C^2BrAg)^2.AgBr.H^2O$. It crystallises in silver-white needles, and detonates with violence by friction, or by contact with strong acids. When it is shaken up with an ethereal solution of iodine, the ether takes up a bromo-iodated compound, probably identical with the bromiodide of carbon, $C^2Br^2I^2$, previously described (p. 34) (Borend, *loc. cit.*).

γ . In a solution of sodio-aurous hyposulphite mixed with ammonia, acetylene produces at first a copious flocculent precipitate, regarded by Berthelot as auroso-vinyl oxide, which, when dried, detonates violently by percussion, and explodes with flame; but the greater part of the aurous double salt remains undecomposed.

δ . Mercurovinyl oxide is produced when acetylene is left for some time in contact with a solution of potassio-mercuric iodide mixed with a little ammonia, and the resulting scaly crystalline precipitate is washed with a strong solution of potassium

iodide to remove ammoniacal mercury-compounds; it then remains in the form of a white highly explosive powder (Berthelot).

When coal gas is passed through a solution of mercuric iodide in potassium iodide and potash, a yellow precipitate is formed, which, after drying, detonates slightly when heated, yielding a sublimate of mercury and mercuric iodide and a carbonaceous residue. Heated with dilute acids, it evolves a combustible gas exhibiting the characters of acetylene. By passing the gases from a Bunsen's burner through the solution of mercuric iodide, a light yellow, somewhat more explosive precipitate was formed, consisting of $C^2H^2I_2HgO$ (Bassett, *Chem. News*, 1869, p. 28).

e. The blue solution of *chromous sulphate* in sal-ammoniac and ammonia absorbs acetylene in large quantity, and is decolorised thereby; but after a while the liquid again becomes coloured, with separation of chromic oxide and evolution of ethylene. Berthelot explains this result by supposing that chromosvinyl oxide is at first produced, and then reacts with water, so as to form chromic oxide and ethylene:

Acid solutions of chromous oxide do not absorb acetylene more abundantly than water, and the corresponding salts of the other metals of the iron group do not act upon acetylene, even in ammoniacal solution and in presence of sal-ammoniac; nevertheless, Berthelot regards the existence of analogous compounds as probable.

11. *Action of Sulphuric Acid.*—Acetylene agitated briskly, and for a long time, with strong sulphuric acid, unites with it, forming vinyl-sulphuric acid, $C^2H^2SO^4 = (C^2H^2)HSO^4$ or $(C^2H^2) \left\{ \begin{smallmatrix} (SO^2)^2 \\ H \end{smallmatrix} \right\} O^2$, originally, but less appropriately, called acetyl-sulphuric acid (i. 1112).

The acid liquid, distilled with water, yields vinyl alcohol (acetyl alcohol), $(C^2H^2)HO$, just as ethyl sulphuric acid yields ethyl alcohol:

This alcohol is monatomic and isomeric with aldehyde and with ethylene oxide. The difference of constitution of these three compounds may be represented by the following formulæ:

ACETYL-METHYL. Syn. with ACETONE.

ACIDS, ORGANIC. The general relations and constitution of organic acids are best understood by regarding them as derived from hydrocarbons containing even numbers of hydrogen atoms, through the medium of alcohols. Consider for example the saturated hydrocarbon ethane or ethyl hydride, C^2H^6 . In this molecule each of the hydrogen atoms is directly associated with an atom of carbon, as shown by the formula:

Now suppose one of these hydrogen atoms to be displaced by an atom of oxygen. This atom, being diatomic, will unite itself by one of its units of equivalence or affinity to the carbon; and by its other unit of affinity will retain the hydrogen which it has displaced, so that this hydrogen will still remain in the molecule united to the carbon, no longer directly, but through the medium of the oxygen, the final result being the same as if the hydrogen were replaced by an atom of oxyhydriyl or hydroxyl, OH. The new molecule thus formed is ethyl-alcohol:

The hydrogen atom thus united to the carbon through the medium of oxygen is replaceable by alcohol-radicles, acid-radicles and alkali-metals, the products of such replacement being ethers: thus from ethyl-alcohol may be formed

Now it is found that the number of times in which this replacement can take place, in other words, the number of ethers that an alcohol can form by substitution of any given acid- or alcohol-radicle for its hydrogen, is equal to the number of atoms of hydroxyl contained in its molecule. Thus, ethyl-alcohol, which contains but one atom of hydroxyl, can form but one set of ethers, viz. neutral ethers like those above formulated; but an alcohol containing two or more atoms of hydroxyl can form unsaturated as well as saturated ethers, thus:

The number of hydrogen atoms thus replaceable by alcoholic or acid radicles, or by alkali-metals, determines what is called the atomicity of the alcohol. An alcohol containing n atoms of hydroxyl is said to be n -atomic.

In an alcohol, however, the hydrogen is never replaced by metals by way of double decomposition with metallic hydrates or oxides, in the same manner as in an acid; in other words, alcohols do not form true metallic salts. The only metals that can replace the hydrogen in them are the alkali-metals, which decompose them as they decompose water, by direct displacement.

To convert the alcohol into an acid, a molecule of hydrogen in immediate connection with at least one atom of hydroxyl, OH, must be replaced by an atom of oxygen; in other words, one at least of the groups CH^2OH in the alcohol must be converted into COOH or CO^2H , called carboxyl or oxatyl; the hydrogen of the hydroxyl then becomes replaceable by metals, so as to form salts by double decomposition, in the same

way as in mineral acids; in other words, it becomes basic; thus ethyl alcohol, $\text{CH}^3\text{CH}^2\text{OH}$,

is in this manner converted into acetic acid, CH^3COOH or $\text{CH}^3\text{CO}^2\text{H}$.

Now it is clear that a monatomic alcohol can yield but one acid, and that this acid must be monobasic, like acetic acid. But a diatomic alcohol may be converted by oxidation either into a monobasic acid, by substitution of O for H^2 , or into a bibasic acid by substitution of O^2 for H^4 ; thus:

The hydrogen of the hydroxyl in the groups CH^2OH , in which the substitution of O for H^2 has not taken place, still retains its alcoholic character, that is to say, its replaceability by acid or alcoholic radicles to form ethers. Hence it follows that the atomicity of an organic acid is the same as that of the alcohol from which it is derived, but its basicity may be either equal to or less than the atomicity. In other words, an n -atomic alcohol may yield a series of acids all of n -atomicity, but of basicity equal to or less than n .

The law that the basicity of an organic acid is equal to the number of atoms of carboxyl, CO^2H , that it contains—in other words, that an organic acid containing n atoms of carboxyl is n -basic—is a result of observation, and we are not at present able

to give a satisfactory account of it on theoretical principles; but it is probable that the entrance of the electro-negative oxygen into the group COOH renders it more disposed than before to take up an electro-positive element such as a metal. For a complete understanding of the matter we must perhaps wait for an exact determination of the quantities of heat evolved in the several changes. At all events, the law above mentioned, that an organic acid containing n -atoms of carboxyl is n -basic, holds good in all cases. It is true there is one apparent exception to it, viz. carbonic acid, which is bibasic, and yet contains but one atom of carboxyl, being represented by the formula

but from the last formula it is clear that the middle atom of oxygen may be considered as attached to either of the groups OH just as well as to the other, and therefore that the exception to the rule is only apparent.

On these principles organic acids may be classified as follows (see table, p. 53, vol. i.).

I. MONATOMIC ACIDS.

Fatty or Adipic Series. $\text{C}^n\text{H}^{2n}\text{O}^2 = \text{C}^{n-1}\text{H}^{2n-2} \cdot \text{CO} \cdot \text{H}$.—The modes of formation and transformation of these acids are for the most part described in vol. i. pp. 50, 51. We have here to add the mode of formation discovered by Harnitz-Harnitzky (*Ann. Ch. Pharm.* cxxxv. 121), which consists in forming the corresponding chlorides by the action of carbonyl chloride (phosgene) on hydrocarbons of the marsh-gas series (paraffins), e.g.,

and converting these chlorides into acids by the action of water.

The following methods afford the means of building up the fatty acids and the corresponding alcohols, starting from methyl alcohol:—

Sodium methide treated with carbon dioxide yields sodium acetate (Wanklyn):

sodium acetate subjected to dry distillation with sodium formate yields acetic aldehyde:

and acetic aldehyde heated with water and sodium-amalgam takes up hydrogen and is converted into ethyl-alcohol: $\text{C}^2\text{H}^2\text{O} + \text{H}^2 = \text{C}^2\text{H}^4\text{O}$. From ethyl-alcohol, sodium ethyl, $\text{C}^2\text{H}^3\text{Na}$, may be obtained (iv. 223); this may be converted into sodium propionate, from which by distillation with sodium formate, propionic aldehyde, $\text{C}^3\text{H}^4\text{COH}$, should be obtained, and thence propylic alcohol, &c. &c. The passing from an alcohol $\text{C}^n\text{H}^{2n+2}\text{O}$ to the next higher fatty acid, $\text{C}^{n+1}\text{H}^{2n+2}\text{O}^2$, may also be effected by the action of alkalis or acids on the cyanides of the alcohol radicles (i. 50), the other stages of the process being the same as above described. It must be observed, however, that the formation of an aldehyde by distilling the salt of the corresponding fatty acid with a formate cannot be expected to be realised very high up in the series. Lieben a. Rossi have, however, made propionic, butyric, and valeric aldehydes by this process.

The fatty acids are distinguished by a remarkable degree of stability. Even some of the highest members of the series, viz. palmitic, stearic, and cerotic acid, may be distilled without alteration, and all of them, except formic acid, offer considerable resistance to the action of oxidising agents. According to Chapman a. Thorp (*Chem. Soc. J.* [2] iv. 477), acetic, propionic, valeric, and caproic acids are not attacked at 100° by a mixture of potassium dichromate and sulphuric acid containing 3, 5, or 8 p. c. of the dichromate, and in such proportions as to produce chromic sulphate and acid potassium sulphate, even when the action is continued for 24 hours in sealed tubes. At 130° , however, they undergo a certain amount of oxidation, which is accelerated by the presence of a large excess of strong sulphuric acid, or of free

chromic acid, or of manganese dioxide, but does not take place at all when phosphoric acid is used instead of sulphuric acid. Dilute solutions of *permanganic acid* act like the chromic acid mixture, producing no oxidation of acetic or propionic acid, even at the boiling heat, and acting but slowly on formic acid in presence of sulphuric acid at ordinary temperatures; concentrated solutions, however, decompose these acids with facility.

According to O. Voel (*Ann. Ch. Pharm.* cxlviii. 160), the fatty acids are converted by oxidation with manganese dioxide and dilute sulphuric acid into one or more compound ethers, which contain alcohol-radicles lower in the carbon series than the acid itself, and yield the original acid by saponification; thus butyric acid yields a number of butyric ethers containing alcohol-radicles with less than 4 at. carbon, the principal product being propyl butyrate, $C^4H^7O^2.C^3H^7$. Valeric acid treated in like manner yields methyl valerate.

For the methods of converting the fatty acids into alcohols, see ALCOHOLS.

Isomerism among the Fatty Acids.—The first three acids of the series $C^nH^{2n}O^2$, do not admit of isomeric modifications. In fact, on looking at the constitutional formula of propionic acid, $C^3H^5O^2$, viz.,

it is clear that so long as the type of an organic acid is preserved, that is, of an alcohol-radicle combined with carboxyl, no other arrangement of the carbon-atoms is possible; still less can this be the case with acetic or formic acid. But in the higher acids of the series isomeric modifications may exist. Thus the formula of butyric acid, $C^4H^7O^2$ or $C^3H^7.CO^2H$, may take either of the two forms

the first containing normal propyl, the second isopropyl (v. 887).

These two acids are produced by the oxidation of normal butylic alcohol or propyl carbinol, and isobutylic alcohol or isopropyl carbinol (the butylic alcohol of fermentation), respectively; also by the action of alcoholic potash on normal propyl cyanide and isopropyl cyanide respectively. Normal butyric acid is further produced by the fermentation of sugar in contact with putrid cheese (i. 691). The two acids exhibit considerable differences of physical and chemical character. In general the derivatives of normal butyric acid have higher specific gravities and boiling points than the corresponding derivatives of isobutyric acid. The latter is also more easily oxidised than normal butyric acid. (See BUTYRIC ACIDS.)

Of valeric acid, $C^5H^9O^2$, four isomeric forms are possible, viz.,

The first and second of these modifications are produced by oxidation of the corresponding amyl alcohols; the third is not known, the fourth has quite recently been obtained by Butlerow (*Zeitschr. f. Chem.* [2] vi. 243) from tertiary butyl alcohol, $C(CH^3)^3.OH$. The optically active and inactive varieties of amyl alcohol yield by oxidation two varieties of valeric acid, exhibiting corresponding differences of optical character, and differing also slightly in boiling point; but these acids, like the alcohols from which they are derived, are probably only physically isomeric, not metameric. (See AMYL ALCOHOLS.)

The higher terms of the fatty acid series are of course susceptible of a still greater number of metameric modifications; but the only one in which such modifications have hitherto been observed is caprylic acid, $C^8H^{15}O^2$ (q. v.).

Acrylic Series. $C^nH^{2n-2}O^2$.—This series comprises two isomeric groups of acids; the one consisting of acids occurring in the vegetable or animal organism, or obtained from natural products by special processes, mostly by saponification of natural fats,

e.g. oleic acid from olein; the other of acids formed by a general synthetical process. The acids of the first group are called normal acrylic acids; those of the second, iso-acrylic acids.

a. Normal Acrylic Acids.—The following are the known acids of this group:—

Acrylic acid	. . .	$C^3H^4O^2$	Physetoleic acid	}	. . .	$C^{18}H^{30}O^2$
Crotonic acid	. . .	$C^4H^6O^2$	Hypogaeic acid			
Angelie acid	. . .	$C^5H^8O^2$	Gaidic acid	}	. . .	$C^{18}H^{31}O^2$
Pyroterebic acid	. . .	$C^6H^{10}O^2$	Oleic acid			
? Damaluric acid	. . .	$C^7H^{12}O^2$	Elaidic acid	}	. . .	$C^{19}H^{32}O^2$
? Damolic acid	. . .	$C^{13}H^{24}O^2$	Doeglic acid			
Moringic acid	}	$C^{15}H^{26}O^2$	Brassic acid	}	. . .	$C^{22}H^{42}O^2$
Cimicic acid			Erucic acid			

Most of these acids are oily liquids. When fused with *potassium hydrate* they yield the potassium-salt of acetic acid and of another acid of the fatty series with elimination of hydrogen, thus:

Generally:

They are also converted into fatty acids by the action of nascent hydrogen; e.g.,

B. Iso-acrylic Acids.—These acids, discovered by Frankland and Duppa (*Chem. Soc. J.* [2] iii. 133), are produced by abstraction of the elements of water from certain

acid ethers derived from oxalic acid, $\begin{array}{c} \text{COOH} \\ | \\ \text{C} \\ | \\ \text{COOH} \end{array}$ or $\begin{array}{c} \text{C} \begin{array}{l} \text{OH} \\ | \\ \text{O} \\ | \\ \text{O} \\ | \\ \text{OH} \end{array} \end{array}$, by substitution of two atoms

of an alcohol-radicle of the series C^nH^{2n+1} for one atom of oxygen (iv. 272), viz.,

Now, when the ethylic ethers of these acids are treated with phosphorous chloride they give up the elements of a molecule of water, (H^2O), at the expense of one of the atoms of hydroxyl, OH, and of an atom of hydrogen abstracted from one of the monad alcohol-radicles, which is thereby converted into a dyad radicle (an olefine, C^nH^{2n}) capable of saturating the unit of equivalence of the carbon-atom left free by abstraction of the hydroxyl. The product is the ethylic ether of an isoacrylic acid; thus:

The ethylic ether thus formed is converted into methacrylic acid by saponification with potash in the usual way. In this manner the following isoacrylic acids have been obtained:—

The actual formation of the ethers of these acids by the action of phosphorous chloride on the oxalic ethers above mentioned takes place as shown by the equation

The transformation may also be effected by phosphoric anhydride, in which case the reaction is like the following:

The isoacrylic acids fused with potassium hydrate are converted, like the normal acids, into two acids of the acetic series. The dyad radicals of the isoacrylic acids is replaced by two atoms of hydrogen derived from two molecules of potassium hydrate, (2KOH), and enters into combination with two atoms of oxygen; and at the same time the two atoms of potassium displace the basic hydrogen-atoms of the two fatty acids thus produced, converting them into potassium salts and expelling the hydrogen as gas; thus:

The normal acrylic acids are decomposed by potash in a similar manner yielding two acids of the series $C^nH^{2n}O^2$; but one of these is always acetic acid; hence it is inferred that they have a constitution represented by the formula $CH(C^nH^{2n})''CO^2H$, and that their decomposition by alkalis takes place in the manner represented by the equation

The formulæ of the individual acids are as follows:—

It is easily seen from these formulæ that crotonic acid, when decomposed by an alkali, must yield two molecules of acetic acid, and that the other acids above represented must yield acetic acid, together with formic, propionic, butyric, and palmitic acids respectively.

3. **Acids of the Series $\text{C}^n\text{H}^{2n-4}\text{O}^2$.**—Of this series only three acids are known, viz. sorbic and parasorbic acids, $\text{C}^6\text{H}^8\text{O}^2$ (v. 352), and camphic acid, $\text{C}^{10}\text{H}^{16}\text{O}^2$ (i. 725).

4. Of the series $\text{C}^n\text{H}^{2n-6}\text{O}^2$ only one acid has yet been obtained, viz. *hydrobenzoic* or benzoic acid, $\text{C}^7\text{H}^{10}\text{O}^2 = \text{C}^7\text{H}^9\text{O}(\text{OH})$, formed, together with other products, by the action of water and sodium-amalgam on benzoic acid: $\text{C}^7\text{H}^8\text{O}^2 + 2\text{H}^2 = \text{C}^7\text{H}^{10}\text{O}^2$ (Hermann, *Ann. Ch. Pharm.* cxxxii. 76).

5. **Aromatic Series. $\text{C}^n\text{H}^{2n-8}\text{O}^2$.**—These acids are related to the aromatic hydrocarbons $\text{C}^n\text{H}^{2n-6}$ in the same manner as the fatty acids to the paraffins. Benzoic acid, $\text{C}^7\text{H}^{10}\text{O}^2$, the lowest member of the series, may be derived from benzene, C^6H^6 , by the substitution of carboxyl, (CO^2H) , for an atom of hydrogen, its rational formula being $\text{C}^6\text{H}^5.\text{CO}^2\text{H}$. All the higher acids of the series exhibit isomeric modifications. Thus from toluene, C^7H^8 , which has the composition of methylic benzene or phenyl-methyl, $\text{C}^6\text{H}^5.\text{CH}^3$ (v. 852), are derived normal toluic acid, $\text{C}^7\text{H}^7(\text{CH}^3).\text{CO}^2\text{H}$, the true homologue of benzoic acid, and alpha-toluic acid, $\text{C}^7\text{H}^7.\text{CH}^2\text{CO}^2\text{H}$, derived from toluene by substitution of carboxyl for an atom of hydrogen in the methyl atom. The known acids of the group are:

The 9-carbon acid admits of another modification, viz. $\text{C}^9\text{H}^8(\text{C}^2\text{H}^5).\text{CO}^2\text{H}$, derived from ethyl-benzene, $\text{C}^8\text{H}^{10}(\text{C}^2\text{H}^5)$, isomeric with xylene, but it has not yet been obtained. The higher acids of the series are susceptible of a still larger number of modifications.

The aromatic acids may be formed synthetically from carbon dioxide by a process analogous to that already described in the case of the fatty acids (i. 61, 3°); e.g. benzoic acid by passing the gas into monobromotoluene containing sodium (Kekulé):

See **TOLUIC ACID** (v. 861). For other modes of formation of these acids, see **AROMATIC SERIES**.

6. **Acids of the Series $\text{C}^n\text{H}^{2n-10}\text{O}^2$.**—The acids of this series are related to the aromatic acids in the same manner as those of the acrylic series to the fatty acids. Only two of them are however at present known, viz. cinnamic acid and atropic acid, both containing $\text{C}^9\text{H}^8\text{O}^2$.

Cinnamic acid, described in vol. i. p. 983, as a product of the oxidation of cinnamic aldehyde, and by heating benzoic aldehyde with acetic chloride, is likewise formed synthetically, by the action of chorethylidene (produced by the action of carbonyl chloride on acetic aldehyde) on potassium benzoate:

Atropic acid is a crystalline acid obtained, together with tropine (v. 895), by the action of alkalis on atropine:

DIATOMIC ACIDS.

These acids are derived from diatomic alcohols by substitution either of O for H², in which case they contain 3 at. of oxygen, and are monobasic, or by substitution of O² for H¹, in which case they contain 4 at. of oxygen, and are bibasic.

The relation between the saturated hydrocarbons, the glycols, and the diatomic acids is shown in the following table :

		Diatomic Acids.	
Hydrocarbons.	Glycols.	Monobasic.	Bibasic.
C^nH^{2n+2}	$C^nH^{2n+2}O^2$	$C^nH^{2n}O^3$	$C^nH^{2n-2}O^4$
C^nH^{2n}	$C^nH^{2n}O^2$	$C^nH^{2n-2}O^3$	$C^nH^{2n-4}O^4$
C^nH^{2n-2}	$C^nH^{2n-2}O^2$	$C^nH^{2n-4}O^3$	$C^nH^{2n-6}O^4$
C^nH^{2n-4}	$C^nH^{2n-4}O^2$	$C^nH^{2n-6}O^3$	$C^nH^{2n-8}O^4$
	&c.	&c.	

Diatomic and Monobasic Acids.

1. **Lactic Series.** $C^nH^{2n}O^3$.—The acids of this series may be divided into two groups, distinguished as normal lactic acids and isolactic acids. The known members of the series are:

Glycollic or Oxalacetic acid, $C^2H^4O^3$.

Lactic or Oxypropionic acid, $C^3H^6O^3$.

Oxybutyric acid, $C^4H^8O^3$, and its isomeride, Dimethoxalic acid.

Oxyvaleric acid, $C^5H^{10}O^3$, and its isomeride, Ethomethoxalic acid.

Leucic or Oxyenproic acid, $C^6H^{12}O^3$, and its isomeride, Diethoxalic acid.

Acids homologous with dimethoxalic acid, and containing 7, 9, and 12 at. of carbon, have also been obtained.

The normal lactic acids correspond to the diatomic alcohols homologous with ethenic alcohol (glycol); thus:

If in the second formula we make n successively equal to 1, 2, 3, &c., we get the series:

Carbonic acid is, however, a bibasic acid, for reasons already explained. The general modes of formation of the normal lactic acids are given in vol. I. p. 52.

The Isolactic acids are represented by the general formula, $(CC^nH^{2n+1})^2O^3H$

They are obtained in the form of ethers by the action of the zinc-compound of an alcohol-radicle, C^nH^{2n+1} , on a neutral ether of oxalic acid containing a radicle of the same series, such as diethylic oxalate. The reaction consists in the replacement of an atom of oxygen in the oxalic ether by two equivalents of alcohol-radicle, and the simultaneous replacement of an equivalent of ethyl, methyl, &c., in the oxalic ether by any equivalent * of zinc, whereby an ether of zinc-diethyloxalic acid, &c., is produced, which by certain obvious transformations may be converted into the required acid; thus:

* To simplify the equations, the equivalent of zinc ($Zn' = 32.5$) is used instead of the atom.

The ethylic diethoxalate is easily decomposed by baryta-water, yielding ethyl alcohol and barium diethoxalate:

And this salt decomposed by sulphuric acid yields diethoxalic acid, $\left\{ \begin{array}{l} \text{C}(\text{C}^2\text{H}^5)^2\text{OH} \\ \text{COOH} \end{array} \right.$.

isomeric with leucic acid.

In the first stage of the process it is found best to use a mixture of ethyl iodide with metallic zinc, which produces zinc-ethide, instead of the latter compound previously prepared. The other isolactic ethers are prepared in a similar manner.

The isolactic acids are described under OXALIC ETHERS (iv. 275).

The acids of either group are reduced by hydriodic acid to the corresponding acids of the acetic series; e.g.,

The ethereal salts of the isolactic acids are converted by phosphorus trichloride or pentoxide into ethers of the iso-acrylic acids (p. 41); the ethereal salts of the normal lactic acids do not exhibit this reaction.

The normal lactic acids, when heated, give up a molecule of water, and are converted into oxygen-ethers or anhydrides; e.g., $\text{C}^3\text{H}^7\text{O}^3$ (lactic acid) $= \text{H}^2\text{O} = \text{C}^3\text{H}^5\text{O}^2$ (lactide). Two molecules of a normal lactic acid may also be deprived of a molecule of water, thereby producing a condensed acid, analogous to the polyethylenic alcohols; e.g., $2\text{C}^3\text{H}^7\text{O}^3$ (lactic acid) $= \text{H}^2\text{O} = \text{C}^6\text{H}^{10}\text{O}^3$ (dilactic acid).

Both the normal and the isolactic acids undergo a characteristic and perfectly definite oxidation by weak solutions of chromic acid, yielding carbon dioxide, water, and an aldehyde or a ketone; thus:

2. Pyruvic Series. $\text{C}^3\text{H}^{2n-2}\text{O}^3$.—This is a small group of acids including pyruvic acid, $\text{C}^3\text{H}^4\text{O}^3$; convolvulinoleic acid, $\text{C}^{13}\text{H}^{22}\text{O}^3$?; jalapinoic acid, $\text{C}^{13}\text{H}^{20}\text{O}^3$?; ricinoleic acid, $\text{C}^{18}\text{H}^{34}\text{O}^3$. These acids are described in the Dictionary in their alphabetical places. There are no general modes of formation or decomposition to be noticed respecting them.

3. Series $\text{C}^n\text{H}^{2n-4}\text{O}^3$.—The only known acid of this series is guaiac acid, $\text{C}^8\text{H}^{12}\text{O}^3$, a crystallisable substance obtained from guaiacum (ii. 948).

4. Series $\text{C}^n\text{H}^{2n-6}\text{O}^3$.—This series includes the following acids, related to the monatomic aromatic acids in the same manner as the lactic acids to the fatty acids:—

Oxybenzoic, Paraoxybenzoic, and Salicylic acids	$\text{C}^7\text{H}^6\text{O}^3$
Formbenzoic, Cresotic, Carboresylic, and Anisic acids	$\text{C}^8\text{H}^6\text{O}^3$
Phloretic and Isophloretic, Hydrocoumaric or Melilotic, and Hydro-paracoumaric acids	$\text{C}^9\text{H}^{10}\text{O}^3$
Thymotic and Thymylcarbonic acids	$\text{C}^{11}\text{H}^{14}\text{O}^3$

Oxybenzoic, para-oxybenzoic and salicylic acids have the constitution represented by the formula $\text{C}^n\text{H}^m(\text{OH}).\text{CO}^2\text{H}$, the differences of chemical character which they exhibit depending most probably upon the different relative positions of the groups OH and CO^2H which they contain. (See AROMATIC SERIES.) They are all resolved by heat, but with various degrees of facility, into carbon dioxide and phenol, salicylic acid undergoing this decomposition easily, and paraoxybenzoic acid still more easily, whereas oxybenzoic acid sublimates undecomposed when slowly heated, and splits up in the manner just mentioned only when quickly heated (iv. 295). Oxybenzoic acid is produced by the action of nitrous acid on amidobenzoic acid:

paraoxybenzoic acid, by heating anisic (methyl-paraoxybenzoic acid) with hydriodic acid :

and salicylic acid, by passing carbon dioxide into phenol containing small quantities of sodium :

Carbocresylic and Cresotic acids, $C^6H^5O^2$, are produced simultaneously by the action of carbon dioxide and sodium on cresol, just as salicylic acid is produced from phenol. Both these acids may be regarded as hydroxyl-derivatives of normal toluic acid :

With regard to facility of resolution into carbon dioxide and cresol, carbocresylic acid appears to be related to cresotic acid, in the same manner as salicylic to oxybenzoic acid (ii. 106).

Formobenzoic or Mandelic acid (iii. 800) is related to α -toluic acid in the same manner as the two preceding acids to normal toluic acid :

It is produced by the action of hydrochloric acid on crude bitter almond oil (containing hydrocyanic acid).

Anisic acid is shown to have the composition of methyl-paraoxybenzoic acid by the fact that it may be produced by treating the potassium salt of paraoxybenzoic acid with methyl-iodide :

Methyl-salicylic and phenyl-glycollic acid, $C^6H^4(C^6H^5)O^2$, are likewise isomeric with the acids of this group.

Ethyl-paraoxybenzoic acid, $C^6H^4(C^2H^5)O^2$, may be prepared in like manner by the action of ethyl-iodide on paraoxybenzoic acid. This acid is identical with hydroparacoumaric acid, and isomeric with hydrocoumaric, phloretic, and isophloretic acids.

Another acid, isomeric with the preceding, is produced by the action of alkalis on the cyanhydrin of anisic alcohol :

Thymyl-carbonic and Thymotic acids, $C^{11}H^{10}O^2$, homologous with carbocresylic and cresotic acids respectively, are produced by the action of carbon dioxide and sodium on thymel (v. 794).

5. Series $C^6H^4-^{10}O^2$.—To this series belongs coumaric acid, $C^9H^8O^2$, produced by the action of boiling potash on coumarin. Homologues of this acid, called *butyric coumaric acid*, $C^{11}H^{12}O^2$, and *valeric coumaric acid*, $C^{12}H^{14}O^2$, have lately been obtained by a synthetical process (Perkin, *Chem. Soc. J.* [2] vi. 475). (See COUMARIC ACID and COUMARIN.)

6. There are no known acids belonging to the series $C^6H^4-^{12}O^2$ and $C^6H^4-^{14}O^2$.

7. Of the series $C^6H^4-^{14}O^2$ the only known member is benzoic acid, $C^7H^6O^2$, produced by the action of alcoholic potash on benzoïn (i. 546). It may be regarded as a derivative of diphenyl; thus :

Maleic and fumaric acids may be regarded as derived from the saturated compound succinic acid, by the loss of 2 atoms of hydrogen; but in the case of maleic acid it may be supposed that the two hydrogen atoms thus removed belonged to the same atom of carbon; in that of fumaric acid, to different atoms of carbon; thus:

The dots in these formulæ represent the gaps left by the removal of the hydrogen atoms, or, in other words, the unsaturated atomicities or equivalencies of the carbon-atoms.

Now it is clear that the addition of H^2 to either of these unsaturated molecules must yield the same product, viz. succinic acid, but that the addition of 2 atoms of bromine to the first or to the second will yield different products, viz.:

Fumaric acid is, however, a much more stable compound than maleic acid, and less inclined to take up hydrogen or bromine than maleic acid: hence it is probable that the two middle atoms of carbon in the former are united more intimately than in the latter, and that it is really a saturated compound represented by the formula:

A body so constituted will not take up a molecule of bromine till the connection between the carbon-atoms has been somewhat loosened by the action of that element; whereas maleic acid, which is an unsaturated compound, can take up the bromine immediately, to form dibromosuccinic acid.

The isomeric acids, $\text{C}^4\text{H}^6\text{O}^4$, may in like manner be represented by the following formulæ:

The first three of these acids, when treated with bromine, take up two atoms of that element, and form dibromopyrotartaric acid, $\text{C}^4\text{H}^4\text{Br}^2\text{O}^4$; but mesaconic acid takes up bromine and hydrogen much less readily than itaconic or citraconic acid, being in fact related to these acids in the same way as fumaric to maleic acid.

The three modifications of dibromopyrotartaric acid are represented by the formulæ :

Itadibromopyrotartaric acid treated with alkalis gives rise to aconic acid, $\text{C}^*\text{H}^*\text{O}^4$, the two atoms of bromine uniting with two atoms of hydrogen, and two molecules of hydrobromic acid being eliminated, while the three carbon-atoms forming the centre of the molecule unite together in a more intimate manner ; thus :

The two other modifications of dibromopyrotartaric acid when similarly treated both yield monobromocrotonic acid, $\text{C}^*\text{H}^*\text{BrO}^2$. These reactions are explained by the following formulæ, in which the elements removed in the form of hydrobromic acid are indicated by brackets :

Another reaction, easily explained by these formulæ, is the conversion of itaconic and citraconic acids into mesaconic acid by the action of hydrobromic acid. The gaps in the molecule are first filled up, and then hydrobromic acid is eliminated ; but to produce this acid the bromine takes up an atom of hydrogen different from that with which it entered. This reaction is represented by the following formulæ, in which the elements of the hydrobromic acid which go out are indicated by a brace, those of the hydrobromic acid which enters, by asterisks ; these latter correspond to the gaps in the generating acids :

This transformation of itaconic and citraconic acids into mesaconic acid shows further that mesaconic acid must be represented by the third and not by the fourth of the formulæ above given (p. 48). An acid having the constitution represented by this last formulæ might indeed be formed from citraconic, but not from itaconic acid.

See.

E

Itamono-chloropyrotartaric acid, $C^8H^5ClO^4$, boiled with water gives up hydrochloric acid, and yields an acid called *paraconic acid*, having the same composition as *itaconic acid*, &c., but *monobasic* (Swarts, *Bull. Acad. Belg.* [2] xxiv. 25). (See **Pyro-carbolic Acids**, under **Citric Acid**.)

Camphoric acid, $C^{10}H^{16}O^4$, is likewise a bibasic acid included in the general formula $C^xH^{2x-4}O^4$. It appears to be a saturated compound, inasmuch as its ethylic ester shows no tendency to take up chlorine or other monatomic elements.

3. **Series** $C^xH^{2x-6}O^4$.—**Aconic acid**, $C^8H^6O^4$, produced by treating itadibromopyrotartaric acid with excess of caustic alkali, is comprised in this formula, but it appears to be monobasic.

4. **Series** $C^xH^{2x-8}O^4$.—The only bibasic acid represented by this formula is **quinoylic or quinonic acid**, $C^6H^4O^4$, which moreover is known only in its dichlorinated derivative, $C^6H^2Cl^2O^4$ (v. 34).

5. **Series** $C^xH^{2x-10}O^4$.—This series includes the isomeric acids, **phthalic**, **iso-phthalic**, and **terephthalic**, $C^8H^6O^4$ or $C^8H^4(CO^2H)^2$, the isomerism of which appears to depend upon the relative positions of the two atoms of carboxyl, CO^2H . (See **AROMATIC SERIES**.)

TRIATOMIC ACIDS.

These acids are derived from triatomic alcohols, by substitution of 1, 2 or 3 at. oxygen for 1, 2 or 3 molecules of hydrogen, and are accordingly either monobasic acids containing 4 at. oxygen, bibasic acids containing 5 at. oxygen, or tribasic acids containing 6 at. oxygen.

Triatomic and Monobasic Acids.—There are only three acids that can with certainty be referred to this group, viz.,

Glyoxylic acid.	$C^2H^2O^4$.
Glyceric acid	:	:	:	:	:	$C^3H^4O^4$.
Oxysalicylic acid	:	:	:	:	:	$C^7H^6O^4$.

Glyoxylic acid may be regarded as a derivative of the unknown ethenyl alcohol, $(C^2H^3)^{(H)}(HO)^2$, thus:

Its composition is indicated by its formation from oxalic acid by the action of nascent hydrogen: $C^2H^2O^4 + H^2 = C^2H^4O^4$, and from bromoglycollic acid by boiling the silver-salt of that acid with water:

For the further discussion of its formula see **GLYOXYLIC ACID**.

Glyceric acid, $C^3H^4O^4$ (ii. 875), is derived in like manner from **propenyl alcohol** or **glycerin** $(C^3H^3)^{(H)}(OH)^2$.

Oxysalicylic acid, $C^7H^6O^4$, which may be regarded as **salicylic acid** having 1 at. H replaced by HO, is produced by the action of boiling potash on mono-iodosalicylic acid:

It is isomeric with **carbo-hydroquinonic**, **hypogallic** and **protocatechuic acids**, all of which are likewise monobasic.

There are a few other monobasic acids containing 4 at. oxygen, which probably also belong to this group, viz. **eugetic acid**, $C^{11}H^{12}O^4$, produced by the action of carbon dioxide and sodium on eugenol or eugenic acid (oxidised essence of cloves), just as **salicylic acid** is produced from phenol; **orsellinic acid**, $C^8H^8O^4$, **everminic acid**, $C^8H^8O^4$, and **parellic acid**, $C^8H^8O^4$, produced by the action of alkalis on the

colouring principles of certain lichens (ii. 611; iv. 235, 355); and piperic acid, $C^{12}H^{10}O^4$, produced by boiling piperine with potash.

Triatomic and Bibasic Acids.—The only known acids of this group are *tartronic acid*, $C^4H^4O^4$; *malic acid*, $C^4H^4O^4$; *itamic acid*, $C^4H^4O^4$; and perhaps also *croconic acid*, $C^3H^2O^3$. The alcohols corresponding to these acids are not known, neither have any general methods of forming the acids been discovered. The relations of tartronic and malic acids to their respective unknown alcohols, $C^3H^3O^3$ and $C^3H^3O^3$, are shown by the following formulæ:

Unknown alcohol.

Tartronic acid.

Unknown alcohol.

Malic acid.

Itamic acid, lately discovered by Swarts, is formed by the action of water or alkalis on itachloropyrotartaric acid, $C^4H^2ClO^4 + H^2O = C^4H^4O^4 + HCl$.

Triatomic and Tribasic Acids.—But few of these acids have been obtained; indeed, the only ones known with certainty to belong to the group are *aconitic acid*, $C^4H^4O^6 = (C^2H^2)^2(CO^2H)^2$, and *tricarballic acid*, $C^4H^2O^6 = (C^2H^2)^2(CO^2H)^2$, which is produced by the action of alkalis on propenyl tricyanide or tricyanhydrin (v. 879).

TETRATOMIC ACIDS.

These acids may be derived from tetratomic alcohols by substitution of 1, 2, 3 and 4 atoms of oxygen for a corresponding number of hydrogen molecules; thus:

Erythrite.

Erythric acid
(monobasic).Tartaric acid
(bibasic).

Only one tetratomic acid has, however, been actually formed by oxidation of the corresponding alcohol, viz. erythric acid, $C^4H^4O^3$, from erythrite, $C^4H^{10}O^4$. The known tetratomic acids are:

Erythric acid	$C^4H^4O^3$	} monobasic.
Gallie acid	$C^4H^4O^3$	
Tartaric acid	$C^4H^4O^4$	} bibasic.
Homotartaric acid	$C^4H^4O^4$	
Citric acid	$C^4H^6O^7$	tribasic.

Homotartaric acid is produced by the action of moist silver oxide on dibromopyrotartaric acid:

Rhodizonic acid, $C^4H^4O^4$, obtained by heating with alcohol the black mass resulting from the action of carbon monoxide on heated potassium, is also a bibasic acid containing 6 at. oxygen.

Citric acid is a tribasic acid, $C^4H^6O^7 = (C^2H^2O)^2(COOH)^2$, which may be derived from the unknown tetratomic alcohol, $C^4H^{10}O^4$.

Tetratomic alcohol.

Citric acid.

Meconic acid, $C^8H^4O^8$, obtained from opium, is also a tribasic acid, but its degree of atomicity has not yet been determined.

PENTATOMIC ACIDS.

There is but one known acid that can be referred to this group, viz. **quinic or kinic acid**, $C^8H^{12}O^8$ (v. 9), which is monobasic, and may perhaps be represented by the formula $(C^8H^9)^{\cdot}\left\{\begin{smallmatrix} (OH) \\ CO^2H \end{smallmatrix}\right.$.

HEXATOMIC ACIDS.

Four acids of this class are known, viz. **mannitic acid**, $C^6H^{12}O^7$, the isomeric acids, **saccharic and mucic**, $C^6H^{10}O^8$, all of which appear to be bibasic, and **mellitic acid**, $C^{12}H^2O^{12}$ which is sexbasic. The first three of these acids are derived from the hexatomic alcohol, mannite, $C^6H^{14}O^6$, in the manner indicated by the following formulæ:

The bibasicity of mannitic acid seems to show that the influence of the oxygen on the group $COOH$, in facilitating the exchange of the typic hydrogen for a metal may extend to the group $CHOH$, which is next to it.

Mannite is actually converted into mannitic acid by oxidation under the influence of platinum-black, and into saccharic acid by the action of nitric acid.

Mellitic acid, formerly regarded as a bibasic acid and represented by the formula $C^6H^2O^8$ (iii. 870), appears from the recent researches of Baeyer (*Ann. Ch. Pharm.* xli. 271) to be a hexatomic and sexbasic acid, $C^6(CO^2H)^6$, derived from benzene, C^6H^6 , by substitution of 6 equivalents of carboxyl, CO^2H , for 6 at. hydrogen. It therefore belongs to the aromatic series. When heated with lime it is completely resolved into carbonic acid and benzene, $C^6(CO^2H)^6 + 6CaO = C^6H^6 + 6CO^2Ca$. When treated with sodium amalgam it takes up 6 at. H, and is converted into the sexbasic acid $C^6H^6(CO^2H)^6$; and this when treated with sulphuric acid is converted into the tetrabasic acid $C^6H^2(CO^2H)^4$.

The preceding groups include all the organic acids containing only carbon, hydrogen and oxygen whose chemical relations have been exactly investigated; but it need scarcely be added that there is still a considerable number, especially those existing in living organisms, whose places in the series cannot at present be determined.

Most organic acids when subjected to the action of *chlorine* or *bromine* give up one or more atoms of hydrogen in exchange for chlorine or bromine. Iodated acids are formed in like manner, sometimes by the action of *iodine*, sometimes by that of *chloride of iodine*. Nitrated acids, in which one or more equivalents of nitryl, NO^2 , are substituted for hydrogen, are formed by subjecting organic acids to the action of strong *nitric acid*. All these substitutions take place within the radicle of the acid, and do not affect its basicity. Another important class of acids is constituted by the amic or amidated acids, formed by dehydration of acid ammonium salts, by the action of hydrogen sulphide or other reducing agents on nitrated acids, and by the action of ammonia on acid ethers, e.g. oxamic acid from acid ethylic oxalate.

Sulpho-acids. There is also a peculiar class of acids containing sulphur, formed by the action of fuming sulphuric acid or sulphuric anhydride on hydrocarbons, alcohols, acids and amides. They contain the elements of a hydrocarbon, an alcohol, or an acid, combined with one or two molecules of sulphuric anhydride, and may be regarded as derived from hydrocarbons, alcohols, and acids by substitution of the univalent radicle SO^2H for hydrogen. Those derived from acids also contain the radicle carboxyl, CO^2H . Thus sulphacetic acid formed by the action of sulphuric

anhydride on glacial acetic acid has the composition $C^2H^4O^2.SO^2$, and its constitution may be represented by the following formulæ:

In like manner, disulphometholic or methionic acid, $\text{CH}^2.2\text{SO}^2$, produced by the prolonged action of fuming sulphuric acid on sulphacetic acid, may be regarded as $\text{CH}^2(\text{SO}^2\text{H})^2$, that is as marsh gas having 2 at. hydrogen replaced by the radicle SO^2H .

Both sulphacetic and disulphometholic acids may be obtained by the action of fuming sulphuric acid on *acetamide* or *acetonitrile*:

In like manner are obtained: from *propionitrile*, $\text{C}^3\text{H}^3\text{N}$:

And from *benzonitrile*, $\text{C}^6\text{H}^5\text{N}$:

Sulphobenzoic acid, $\text{C}^6\text{H}^4(\text{SO}^2\text{H})$, is produced by the action of strong sulphuric acid on benzene.

Sulphonaphthalic acid, $\text{C}^{10}\text{H}^7(\text{SO}^2\text{H})$, and *Disulphonaphthalic acid*, $\text{C}^{10}\text{H}^6(\text{SO}^2\text{H})^2$, are obtained by melting naphthalene with strong sulphuric acid or sulphuric anhydride (v. 567).

A sulpho-acid called *methin-trisulphonic acid* (or *methenyl-trisulphonic acid*) containing three equivalents of the radicle SO^2H , and represented by the formula $(\text{CH})^+(\text{SO}^2\text{H})^3$, is produced, as a calcium-salt, by heating calcium methylsulphate with fuming sulphuric acid (Theilkuhl, *Ann. Ch. Pharm.* cxvii. 134).

Isethionic acid, $\text{C}^2\text{H}^3\text{SO}^3$, ethionic acid, $\text{C}^2\text{H}^4\text{S}^2\text{O}^6$, and ethionic oxide or anhydride, $\text{C}^2\text{H}^4\text{S}^2\text{O}^5$, produced by the action of sulphuric anhydride or fuming sulphuric acid on alcohol and ether, likewise belong to this class of bodies, and may be represented by the following formulæ, which show that isethionic acid is monobasic, ethionic acid bibasic, and ethionic oxide neutral:

or:

The basicity of a sulpho-acid is equal to the number of atoms of SO^2H and CO^2H together contained in its molecule.

The sulpho-acids formed from hydrocarbons or alcohols are described in the Dictionary as sulphurous ethers (v. 555); but they are perhaps more appropriately represented by the formulæ just given, in all of which the sulphur is represented as in

immediate connection with the carbon. In the true sulphurous ethers the sulphur is connected with the carbon only through the medium of oxygen, as in methyl sulphurous acid, $(CH^3)HSO^2$, and neutral methyl sulphite, $(CH^3)^2SO^2$:

Nevertheless, these sulpho-acids resemble the sulphurous ethers in so far that, when treated with alkalis, they are converted into metallic sulphites; and conversely they may be produced by the action of the corresponding chlorides, iodides, &c., on metallic sulphites. For just as ethyl iodide acting on neutral potassium sulphite produces potassium iodide and sulphethylate, according to the equation:

and ethylene bromide with sodium sulphite produces sodium ethylene-sulphite:

so likewise monochloroacetic acid with potassium sulphate forms sulphacetate:

glycollic monochlorhydrin gives rise to potassium isothionate, $C^2H^4(OH).SO^2K$; glyceric dichlorhydrin produces the potassium salt of disulphoglyceric acid, $C^3H^4(OH).(SO^2H)^2$; and trichlorhydrin produces trisulphoglyceric acid, $C^3H^3(SO^2H)^3$.

Sometimes, however, the reaction is less simple; thus chloroform at 180° is but slowly attacked by potassium sulphite, carbon dioxide being evolved, together with a gas (methyl chloride?) which burns with a green flame; and the solution contains sulphomethylic acid and its chlorinated derivatives, together with disulphomethylenic and perhaps also trisulphomethylenic acid. In general, however, in the formation of these sulpho-acids by the reaction under consideration, the bromine, chlorine, or iodine united with the carbon is replaced by the univalent radicle SO^2H .

ACOLYCTINE. A base contained, according to Fr. Hübschmann (*Jahresb.* 1866, p. 483), in the root of wolf's bane, *Aconitum lycoctonum*, which does not appear to contain aconitine. It is obtained, together with another base called lycoctonine, by treating the alcoholic extract of the root, first with lime, then with sulphuric acid, evaporating, removing the resin, decolorising with animal charcoal, evaporating to dryness with sodium carbonate, and exhausting the triturated mass with chloroform or absolute alcohol. On digesting the syrupy residue left on evaporating this extract with ether, the lycoctonine dissolves, while the acolyctine, which is present in larger quantity, remains behind. Acolyctine is a whitish powder easily soluble in water, alcohol and chloroform, but insoluble in ether. It has a bitter taste and alkaline reaction, and neutralises acids.

ACONELLINE. This name is given by T. and H. Smith (*Pharm. J. Trans.* [2] v. 317) to a base different from aconitine, which they have extracted from the root of *Aconitum Napellus*.—The mode of preparation is the same as that given below for aconitine, excepting that the sulphuric acid solution is treated, not with ammonia, but with sodium carbonate, added in such quantity as to leave the acid in slight excess. Aconitine then remains dissolved, and the aconelline crystallises after a day or two on the sides of the vessel.

Aconelline differs from aconitine in not being poisonous. It is isomeric with narcotine, exhibiting the same degree of solubility in water, alcohol, &c., the same reactions, and forming a platinum salt in which the percentage of platinum is the same as in platino-chloride of narcotine.

ACONIC ACID. $C^3H^3O^4 = C^3\left\{\begin{array}{l} (CHCO^2H) \\ (CHCO^2H) \end{array}\right.$ (Kekulé, *Ann. Ch. Pharm. Suppl.* i. 338).—An acid produced by the action of alkalis on itadibromopyrotartaric acid (p. 49). When a solution of this acid neutralised with soda is heated to the boiling point, and then gradually mixed with more soda in the proportion of 3 molecules $NaHO$ to 1 molecule of the acid, and the liquid is evaporated, sodium aconate, $C^3H^3NaO^4.3H^2O$, crystallises out. This salt is easily soluble in water, and crystallises in thin transparent rhombic tables, which effloresce slowly on exposure to the air. The

barium salt, $\text{Ba}^+(\text{C}^2\text{H}^3\text{O}^4)^2$ (at 150°), is formed in a similar manner, and is precipitated in flocks from the concentrated solution by alcohol. The acid is crystallisable and easily soluble in water.

ACONITIC ACID. $\text{C}^4\text{H}^4\text{O}^6 = \text{C}^4\text{H}^3\text{O}^5(\text{OH})^1$.—This acid is formed in very small quantity, together with a volatile acid, when an aqueous solution of citric acid is boiled for 100 hours (Dessaignes, *Bull. Soc. Chim.* [2] v. 355). According to Otto (*Jahresb.* 1863, p. 384), it forms a basic lead-salt containing $\text{Pb}^2(\text{C}^4\text{H}^3\text{O}^5)^2 \cdot 2\text{PbO} \cdot 2\text{H}^2\text{O}$ (at 100°).

By the action of sodium amalgam, aconitic acid is converted into tricarballic acid, $\text{C}^3\text{H}^3\text{O}^4$ (v. 879).

ACONITINE. $\text{C}^8\text{H}^{12}\text{NO}^7$.—The best mode of preparing this base in the pure state appears to be that of Hottot (*J. Pharm.* [3] xlv. 304; *Jahresb.* 1863, p. 451). The pulverised root of monkshood is macerated for a week in alcohol of 85 per. cent.; the filtered tincture distilled over the water bath; the aqueous solution of the residue mixed with milk of lime and shaken from time to time; and the filtered solution precipitated with a slight excess of sulphuric acid. The clear liquid filtered from the calcium sulphate is then evaporated to a syrup; the residue is mixed with three or four times its weight of water; and the resulting solution is left at rest, in order to remove a green oil which rises to the surface and solidifies at 20° ; the last traces of this oil are removed by pouring it through a wet filter. The filtered liquid is next mixed with ammonia, boiled to expel the excess of that alkali, and render the precipitate more compact; and the precipitate, which is a mixture of aconitine with a resinous matter sparingly soluble in ether, is collected on a filter, washed, dried, and treated with pure ether.

The ethereal solution filtered, and left to evaporate, leaves aconitine still impure. To obtain the alkaloid quite pure, it must be redissolved in dilute sulphuric acid, precipitated by ammonia, and boiled; and the precipitate must be washed, dried, and again treated with ether. By repeating this treatment two or three times, taking care in the last repetition to add the ammonia only drop by drop, so that the first portions of the precipitate, which are still coloured, may be separated, the aconitine is ultimately obtained, white, amorphous, and quite pure: 10 kilogr. of the root thus treated yield from 4 to 6 grms. of pure aconitine (Hottot). According to Procter (*Chem. News*, ix. 87), the root of American monkshood contains 4.2 parts per thousand of aconitine; the European root, only 2 parts per thousand.

Aconitine when cautiously heated yields an amorphous sublimate which in contact with ammonia produces characteristic microscopic crystalline formations, like those of a tin-tree (cruciate needles) (Helwig, *J. Pharm.* [3] xlvii. 459). According to Buignet (*ibid.* xl. 25), it turns the plane of polarisation to the left.

ACORIN. A glucosate extracted from the common reed (*Acorus calamus*). It is soluble in alcohol and ether; precipitated from its ethereal solution by benzene. The alcoholic solution is slightly alkaline. It dissolves in hydrochloric acid, but does not neutralise it (A. Faust, *Bull. Soc. Chim.* [2] x. 392).

ACROLEIN. $\text{C}^3\text{H}^3\text{O} = \text{C}^3\text{H}^2\text{COH}$.—This compound, the aldehyde of the acrylic series, is formed, together with other products, by the decomposition of acetone dibromide (? dibromisopropyl alcohol) at ordinary temperatures or when heated:

Acrolein is converted by nascent hydrogen (evolved by zinc and hydrochloric acid) into allyl alcohol, isopropyl alcohol, and acropinacone (p. 66) (Linnemann, *Ann. Ch. Pharm. Suppl.* iii. 257):

A solution of potash (aqueous or alcoholic) saturated with acrolein deposits on addition of an excess of sulphuric acid, brown flocks of hexacrylic acid, and the liquid filtered therefrom yields by distillation a dilute solution of acrylic acid (Clams).

By oxidation with silver-oxide, acrolein is converted into acrylic acid, $\text{C}^3\text{H}^3\text{O}^2$; with potassium bichromate and sulphuric acid, into carbonic and formic acids. With nitric acid of sp. gr. 1.2, or with fuming nitric acid, it yields glycollic, together with oxalic acid. By the direct action of oxygen, it is only partly converted into diacetyl (ii. 336), together with a small quantity of acrylic acid. Heated with aqueous or alcoholic potash

it forms hexacroleic acid, $C^6H^8O^8$ (iii. 151), together with a small quantity of acrylic acid (Claus, *Jahresb.* 1862, p. 245; *Bull. Soc. Chim.* [2] x. 45). This last compound appears also to be formed by treating a mixture of acrolein and ether with sodium ethylate (Alsberg, *ibid.* 1864, p. 487).

Bromine dropped into well-cooled acrolein forms a thick yellow liquid which cannot be distilled alone, but after treatment with alcohol yields by distillation a product passing over between 150° and 170° , and corresponding approximately with the formula $C^2H^4Br^2O$. With chlorine in like manner an oil is obtained which yields by distillation a liquid passing over between 150° and 155° , and having nearly the composition $C^2H^4Cl^2O$. Cyanogen does not unite with acrolein, but accelerates its resinification (Aronstein, *Ann. Ch. Pharm. Suppl.* iii. 180; *Jahresb.* 1864, p. 332).

With phosphorus pentachloride, acrolein yields, besides allylene chloride, $C^3H^4Cl^2$, boiling at 84.5° (i. 56), about an equal quantity of an isomeric compound boiling at 102° , and identical with dihydrochloroglycide or epidichlorhydrin (ii. 896). The portion of the product boiling between 152° and 156° also contains trichlorhydrin, $C^3H^3Cl^3$ (Geuther, *Zeitschr. f. Chem.* 1865, p. 24; *Jahresb.* 1864, p. 333).

Acrolein heated with 2 mol. acetic chloride unites with it, forming the compound $C^2H^4O^2.C^2H^3OCl$, a colourless liquid which boils between 140° and 145° , with partial resolution into its component molecules, and decomposes in like manner in contact with water or with alkalis (Aronstein).

Acrolein heated with ethyl alcohol and its homologues, and a little acetic acid, yields glyceric ethers: thus, triethylin, $C^2H^3(C^2H^5)^3O^3$, is produced by heating 1 vol. acrolein with 1 vol. alcohol and 0.5 vol. acid acid; trimethylin, $C^2H^3(CH^3)^3O^3$, by heating 1 vol. acrolein with 3 vol. methyl alcohol and 0.5 vol. acetic acid; and triamylin, $C^2H^3(C^4H^9)^3O^3$, in a similar manner. When hydrochloric acid gas is passed into a mixture of acrolein with 2 vols. absolute alcohol, diethyl-chlorhydrin, $C^2H^3(C^2H^5)^2ClO^2$, is obtained as a heavy oil of sweetish ethereal odour, and sp. gr. 1.03 at 10.5° (Alsberg, *Jahresb.* 1864, p. 494).

Acrolein acts violently on aniline, forming a yellow inodorous amorphous base called diallylidine-diphenamine, $C^{12}H^{12}N^2 = (C^2H^3)^2(C^6H^5)^2N^2$ (Schiff, *Jahresb.* 1864, p. 414).

Metaacrolein has a sp. gr. of 1.03 at 8° , and is therefore not lighter than water, as was formerly supposed (i. 57). With phosphorus pentachloride it yields the same products as acrolein. Heated with acetic anhydride to 150° , it is converted into oily acrolein diacetate, boiling at 180° . It does not unite with ammonia.

ACROLEIN-ACETAL. Syn. with DIETHYL-GLYCIDIC ETHER.

ACROLEIN-AMMONIA. $C^2H^2N^2O^3$ (or $C^2H^{22}N^2O^4$ if regarded as analogous to ammonium hydrate).—Claus prepares this compound by directing the vapours of acrolein (produced by the action of acid potassium sulphate on glycerin) into aqueous ammonia, then expelling the excess of ammonia by ebullition, and precipitating with alcohol or ether. It acts as a base, forming salts with acids. The hydrochloride has, according to Claus, the composition $C^2H^2N^2O^2Cl^2$, derived from the hydrate by substitution of Cl^2 for $(HO)^2$.

Acrolein-ammonia is decomposed by dry distillation, yielding, among other products, a liquid base, which forms crystallisable salts. The platino-chloride of this base contains $C^2H^4N^2Cl^4.PtCl^4$: consequently the free base in the state of hydrate would be $C^2H^4N^2O^2$, and would be derived from acrolein-ammonia (also regarded as a hydrate) by elimination of 2 mol. water: $C^2H^2N^2O^4 = 2H^2O \rightleftharpoons C^2H^4N^2O^2$ (Claus, *Ann. Ch. Pharm.* cxxx. 185; *Jahresb.* 1864, p. 416).

According to Schiff (*Ann. Ch. Pharm.* [2] viii. 443), acrolein-ammonia decomposes with excess of acrolein, according to the equation:

Acrolein-ammonia. Acrolein.

This base resembles those produced from acetic aldehyde (*q.v.*).

ACROLEIN-OXETHYLCHLORIDE. Syn. with HYDROCHLORIDE OF ETHYL-GLYCIDIC ETHER.

ACROPINACONE. $C^6H^{10}O^3$ (Linnemann, *Ann. Ch. Pharm. Suppl.* iii. 257).—Produced, together with allylic and isopropyl alcohols, by the action of nascent hydrogen, evolved by zinc and hydrochloric acid, on acrolein. Being insoluble in water, it collects on the surface of the zinc, and thereby impedes the action of the acid: hence it is best to mix the acrolein with half its volume of ether and four times its weight of hydrochloric acid of sp. gr. 1.16, cool it, and pour it immediately on the zinc, which has likewise been cooled. When the action is finished, the

acropinacone is dissolved out by repeated agitation with ether, and separated by repeatedly distilling the ethereal solution, and collecting the portion which passes over between 160° and 180°. When recently distilled it is colourless, but gradually turns brown on exposure to the air. It has a peculiar camphorous odour, a sp. gr. of 0.99 at 17°, is insoluble in water, but dissolves easily in alcohol and ether. It is related to acrolein in the same manner as pinacone to acetone, or benzopinacone to benzophenone (iv. 617).

ACROTHIALDINE. $C^3H^{11}NS^2 = N \begin{pmatrix} C^3H^8SH \\ C^3H^8 \end{pmatrix}$.—A base produced by the action

of ammonium sulphhydrate on acrolein (Schiff, *Bull. Soc. Chim.* [2] viii. 444). (See THIALDINE.)

ACRYLIC ACID. $C^3H^4O^2 = CH(CH^2)^2.CO^2H$.—This acid, produced by the direct oxidation of acrolein and of allyl alcohol, is also formed, according to Butlerow (*Ann. Ch. Pharm.* cxiv. 204), together with other products, by the action of iodoform on sodium ethylate. An alcoholic solution of baryta, kept for several years in badly closed bottles, was found by Berthelot (*Jahresh.* 1863, p. 395) to contain an acid isomeric or identical with acrylic acid, together with aldehyde-resin and oxalic acid.

According to Claus (*Ann. Ch. Pharm. Suppl.* ii. 117), the best mode of preparing this acid is to treat acrolein, mixed with 3 vols. water, with recently precipitated silver oxide, as in Redtenbacher's process (i. 57); heat the liquid to the boiling point, after the odour of acrolein has disappeared; add sodium carbonate to slight alkaline reaction; evaporate to dryness; and decompose the residue with sulphuric acid. On distilling the filtrate, acrylic acid passes over as a colourless strongly acid liquid.

Acrylic acid treated with powerful oxidising agents, such as chromic acid, is converted into acetic and formic acids; heated with caustic potash, it yields formate and acetate, with evolution of hydrogen (p. 41).

Acrylic acid in aqueous solution takes up 1 mol. bromine, and forms dibromopropionic acid, $C^3H^4Br^2O^2$, which may be crystallised by slow evaporation (Wichelhaus, *Jahresh.* 1867, p. 403).

The acrylates, excepting the silver salt, are easily soluble in water. They are best prepared by neutralising the acid with sodium carbonate; the solution, even when prepared with perfectly colourless acid, turns yellow, and must be decolorised by animal charcoal. The acrylates, when heated to 100°, all give off part of their acid, and leave basic salts; the potassium, barium, and zinc salts undergo this decomposition, even at ordinary temperatures. The *potassium salt*, $KC^3H^3O^2$, and the *sodium salt*, $NaC^3H^3O^2$, form indistinctly crystalline masses. The *silver salt*, $AgC^3H^3O^2$, forms a curdy precipitate, or lancet-shaped needles; it is moderately soluble in boiling water, and easily reducible. The *barium salt* is gummy, and forms needle-shaped crystals, only after its colourless solution has been left to stand for a long time. The *calcium salt*, $Ca^2(C^3H^3O^2)^2$, remains on evaporation in groups of small, thick needles, which gradually become opaque, and easily lose their acid. The *lead salt*, $Pb^2(C^3H^3O^2)^2$, crystallises from a hot aqueous solution, or better by evaporation under the air-pump, in stellate groups of shining needles, often half an inch long. The *zinc salt*, $Zn^2(C^3H^3O^2)^2$, remains on evaporation in small scales, which do not redissolve completely in water. *Ethyllic acrylate* is not produced by heating the lead-salt with ethylic iodide, the salt being in fact resolved into acrylic acid and a basic salt before the ethylic iodide can act upon it (Claus).

ACRYLIC SERIES OF ACIDS. See p. 40.

ADAMITE. A hydrated zinc arsenate, occurring in a compact limestone at Chanarcillo, in Chile, in honey-yellow grains having a bright vitreous lustre, or in very small violet-coloured right rhombic prisms, having an octohedral character, and exhibiting the combination $\infty P . \infty P_2 . \infty P_2 . \infty P_{\infty} . P_{\infty} . P$, the macropodome predominating, and P being observed only on a few cleavage-faces; most of the faces exhibit wavy striations. Cleavage distinct, parallel to P_{∞} . Angle $\infty P : \infty P = 91^{\circ} 52'$; $\infty P_2 : \infty P_2 = 128^{\circ} 6'$; $P_{\infty} : P_{\infty}$ over the principal axis = $107^{\circ} 20'$. The crystals are optically positive, the plane of the optic axes being parallel to ∞P , and the median line perpendicular to ∞P_{∞} . The crystals scratch calcspar, but are scratched by fluorspar. Sp. gr. = 4.338. Analysis gave 39.86 p. c. As_2O_3 , 54.32 ZnO, 1.48 FeO, with trace of MnO, and 4.55 water (= 100.20), whence the formula $4ZnO.As_2O_3.H_2O$, or $As_2Zn^2H^2O^4$ or $(AsO)^2Zn^2H^2O^4$ (C. Friedel, *Bull. Soc. Chim.* [2] v. 433).

ADIPIIC ACID. $C^6H^{10}O^4$.—This acid, the fifth of the oxalic series $C^3H^2O^4$ (p. 47), is produced, according to Crum-Brown (*Bull. Soc. Chim.* 1863, p. 373), by heating mucic acid with hydriodic acid and phosphorus to 140° in a sealed tube for twenty hours:

L. Marquardt (*Zeitschr. f. Chem.* [2] v. 635) obtains it by the action of sodium amalgam on muconic acid, $C^6H^8O^4$ (v. 1093). Wisliconus (*ibid.* iv. 680), by heating Beilstein's β iodopropionic acid to 150° , with excess of finely divided silver or copper, obtains an isomeride of adipic acid, and represents its formation by the following equation:

α -Iodopropionic acid treated in like manner yields ordinary or α -adipic acid:

(Wisliconus, *ibid.* vi. 247).

According to Arppe (*Acta Scientiarum Societatis fennicæ*, viii.; *Jahresb.* 1864, p. 377), adipic acid is produced by the oxidation of sebic or sebacic acid with nitric acid, and is identical with the acid formerly called *oxypropylic acid* (iv. 319). It is also found in small quantity in the more soluble portion of the products of oxidation of the fatty acids, $C_{11}H^{22}O^4$. It crystallises in vitreous brittle laminae or prismatic flattened needles, melts at 148° , sublimes undecomposed as a crystalline powder when cautiously heated, and dissolves easily in warm water, alcohol, and ether. Its salts were found to exhibit the following characters:

Potassium adipate	$C^6H^8K^2O^4$, $C^6H^8KO^4$	confused crystalline mass.
Sodium	" $C^6H^8Na^2O^4$, $2H^2O$	easily soluble crystalline mass.
Silver	" $C^6H^8Ag^2O^4$	crystalline powder.
Barium	" $C^6H^8BaO^4$	granular powder.
Calcium	" $C^6H^8CaO^4$, H^2O	precipitate on boiling.
Cadmium	" $C^6H^8CdO^4$, $2H^2O$	moderately distinct crystals.
Copper	" $C^6H^8CuO^4$	green precipitate.
Lead	" $C^6H^8PbO^4$	brown-red flocculent precipitate.

Ammonium adipate forms large monoclinic augitic crystals, which between 130° and 150° are converted (with further decomposition) into a crystalline powder (adipamide) soluble in water. *Ethylie adipate* distils unaltered at 245° , and is not decomposed by ammonia (Arppe).

ÆSCYNITE. According to recent analyses by Marignac (*Bull. Soc. Chim.* [2] viii. 179), this mineral consists essentially of titano-niobate of thorium and cerium, with smaller quantities of lanthanum, didymium, yttrium, and iron.

Nb^2O^3 and TiO^2	SnO^2	ThO	CeO	$\frac{LaO}{a. DiO}$	YO	FeO	CaO	Loss
51.45	0.18	15.75	18.49	5.60	1.12	3.17	2.75	1.07 = 99.58

The ratio of the acid oxides appears to be 56.96 niobic to 43.04 titanic oxide, or $2Nb^2O^3 : 5TiO^2$, the same as in euxenite. Hence Marignac concludes that these two minerals may be included in the general formula:

He was unable to find any evidence of the existence of Hermann's ilmenium in this mineral. (For Hermann's analyses, see *Jahresb.* 1865, p. 897; 1866, p. 945.)

ÆSCINIC ACID, ÆSCIGENIN, ÆSCIGLYCOLLIC ACID, ÆSCIOGIN, ÆSCULETIN, &c. See *ÆSCULUS*.

ÆSCULIC ACID. Rochleder (*Bull. Soc. Chim.* [2] ix. 387) assigns to this acid the formula $C^{12}H^{12}O^{12}$, and explains its formation from saponin by the equation :

ÆSCULUS. Rochleder (*Wien. Akad. Ber.* lv.; *Bull. Soc. Chim.* [2] ix. 383) has made further experiments on the chemical composition of the seeds of the horse-chestnut (*Æsculus hippocastanum*). He regards the proximate principles of these seeds, with their derivatives, as forming a series parallel to glycol and its derivatives; thus :

Glycol	$C^2H^4O^2$	Æsiglycol	$C^2H^4O^2$
Glycolal	$C^2H^4O^2$	Æsiglycolal	$C^2H^4O^2$
Glycollic acid	$C^2H^4O^2$	Æsiglycollic acid	$C^2H^4O^2$
Glyoxal	$C^2H^2O^2$	Æsiglyoxal	$C^2H^4O^2$
Glyoxalic acid	$C^2H^2O^2$	Æsiglyoxalic acid	$C^2H^4O^2$
Oxalic acid	$C^2H^2O^4$	Æscioxalic acid	$C^2H^4O^4$

Horse-chestnut seeds contain æsigenin, $C^{12}H^{20}O^2$,* homologous with æsiglycol; æsiglyoxal is present in the form of æsculetin, $C^8H^8O^4$, derived from it by substitution of two atoms of formyl, CH for H²; æsiglyoxalic acid combined with phloroglucin constitutes the tannin of the horse-chestnut.

Æsiglycollic acid was obtained by Hlasiwetz by the action of sodium-amalgam on quercetin. Æscioxalic acid is formed by the action of potash on æsculetin, together with æscorcin, $C^8H^8O^4$, which has the composition of diformyl æsiglycolal. Æsigenin is contained in the cotyledons in three different states, viz. as æscinic acid, argyrescin and aphrodescin (iii. 172).

Strong boiling potash-ley or baryta-water decomposes æsculetin into formic, oxalic and æscioxalic acids, the last being isomeric with protocatechuic acid; and if the reaction be performed in an atmosphere of hydrogen replaced at the last by carbonic acid gas to precipitate the excess of baryta, a solution of a barium salt is obtained, which when decomposed by sulphuric acid yields æscioxalic acid in colourless microscopic crystals containing $C^8H^8O^4.H^2O$.

Æsculetin unites with acid sodium sulphite, forming the compound $C^8H^8O^4.NaHSO_3.H^2O$, from which the æsculetin cannot be recovered in its original state; in fact, the sodium compound when decomposed by an alkali yields an isomeric body; paræsculetin, which has the nature of an aldehyde, dissolves sparingly in water, more freely in alcohol, very easily in water, and crystallises confusedly when the solution is evaporated in a vacuum. The crystals contain $2(C^8H^8O^4.5H^2O)$ and require a high temperature to deprive them of their water. Paræsculetin exposed to an atmosphere of ammonia immediately becomes red, then violet, and ultimately yields a sky-blue liquid, which in presence of sulphuric acid gives off the excess of ammonia and becomes red again. This ammoniacal compound forms a copper-coloured lead-salt containing $3(2C^8H^8NO^2.H^2O).10PbO$, which gives off water at 100°. The blue substance is therefore composed of $C^8H^8NO^2$, and appears to be formed according to the equation :

From its analogy to orcein, Rochleder calls it æsorcin.

Æsculetin unites with nascent hydrogen; when treated with sodium amalgam it forms a liquid which turns red on exposure to the air; but the presence of sulphuric acid prevents the coloration. If the fixation of hydrogen be effected in a solution acidulated with sulphuric acid, an amorphous substance is obtained which may be extracted by ether, and whose aqueous solution forms with lead nitrate a yellow precipitate, turning red in the air, as likewise does the solution, which yields a white precipitate with basic lead acetate. This last precipitate contains an acid isomeric with Hlasiwetz's caffeic acid, $C^8H^8O^4$, and having the composition of orcein, ($C^8H^8O^2$), with C^2O^2 added to it: hence called æsorcin. It dissolves in alkalis with green colour, quickly changing to red. When exposed in the moist state to the action of ammonia gas it is rapidly converted into æsorcin.

Æsculetin reduces the dioxides of lead and manganese, mercuric oxide, and alkaline cupric solutions; it is strongly attacked by chromic and nitric acids, forming amorphous bodies, which are difficult to separate. With silver oxide as the oxidising agent, a brown resinous substance is formed, together with a difficultly crystallisable body isomeric with æsculetin.

Horse-chestnut seeds sometimes contain, instead of argyrescin,† $C^8H^{10}O^2$, another

* Rochleder formerly assigned to this body the formula $C^{12}H^{20}O^4$ (iii. 172).

† Rochleder formerly assigned to this substance the formula $C^{12}H^{20}O^{12}$ (see iii. 172).

substance containing $C^{11}H^2$ less. This substance, if treated first with potash, then with hydrochloric acid in alcoholic solution, yields, not æscigenin, but a diatomic alcohol, $C^{11}H^{10}O^2$ (Rochleder, *Wien. Akad. Ber.* lvi.; *Bull. Soc. Chim.* [2] ix. 385).

AGAVE. Well-preserved juice of *Agave americana*, of sp. gr. 1.046 at 15.2° , was found by J. Boussingault (*Ann. Ch. Phys.* [4] xi. 447) to contain in 1,000 parts:

Levulose	26.45	Albumin	10.13
Cane sugar	61.71	Ammonia	0.06
Malic acid	3.53	Inorganic substances	6.21
Gum	5.45	Water	886.46

The fermented liquid (*pulque*), obtained by the action of yeast on the juice, concentrated and then again diluted nearly to its original strength, was found to contain in a litre, 35.4 grms. alcohol, a quantity of organic acids equivalent to 1.60 grm. sulphuric acid (H^2SO^4) and 0.04 grm. ammonia, but it no longer contained sugar. It was turbid and had a faint vinous odour, but not the disagreeable smell peculiar to *Pulque fuerte*, which this liquid acquires only after standing for a long time over the abundantly separated yeast.

AKAZGA. A poison used in Western Africa, and obtained apparently from a loganaceous plant. It was exported in long delicate tortuous twigs, containing, between the bark and the wood, a few crystals which have not been examined. The alcoholic extract of the bark, treated according to the method of Stas for the discovery of alkaloids, yielded an active principle amounting to 2 per cent. of the weight of the bark. This substance is an alkaloid, soluble in 60 pts. of cold absolute alcohol, in 16 pts. of spirit of 85 per cent., in 120 pts. of anhydrous ether, and in 13,000 pts. of cold water; it dissolves also in chloroform, carbon bisulphide and benzene. The alcoholic solution, slowly evaporated, deposits small prisms. The molecular weight of the base, deduced from the analysis of its hydrochloride and platinochloride, is between 290 and 293. This base, when heated, turns yellow, melts, and decomposes, giving off irritating vapours. Its salts are very bitter and yield amorphous precipitates with alkalis, alkaline carbonates, and most of the other reagents which precipitate alkaloids. Chlorine forms a white precipitate soluble in ammonia. A mixture of sulphuric acid and potassium bichromate produces the same reaction as with strychnine (Fraser, *J. pr. Chem.* civ. 51; *Bull. Soc. Chim.* [2] xi. 176).

ALCEA. The Mexican plant *Alcea rosea* (*passe-rose*) yields a substance intermediate in its properties between the fats and resins. This substance, called by the natives *Obrequin*, is produced by the puncture of an insect on the branches. It is nearly insoluble in alcohol, easily soluble in ether, turpentine-oil, and chloroform, and remains on evaporation of its solutions as a colourless, inodorous, terebinthaceous mass, easily saponified by alkalis (Danzats, *J. Pharm.* [4] v. 174).

ALCOGEL. The gelatinous compound of alcohol with silicic acid. (See COLLOIDAL ACIDS, in Appendix, v. 1089.)

ALCOHOL (ordinary). See ETHYL ALCOHOL.

ALCOHOLS. An alcohol may be derived from a hydrocarbon containing an even number of hydrogen atoms by the substitution of one or more equivalents of hydroxyl, HO , for an equal number of hydrogen atoms, the alcohol being monatomic, diatomic, triatomic, &c., according to the number of equivalents of hydroxyl thus introduced. Alcohols may of course be likewise regarded as compounds of hydroxyl with hydrocarbon-radicles (alcohol-radicles), univalent or multivalent, or again as derived from one or more molecules of water, by substitution of such a radicle for an equivalent number of hydrogen atoms. Thus from propane or propyl hydride,

are derived the three following alcohols:

An alcohol is saturated or unsaturated according to the nature of the hydrocarbon from which it is derived. Thus all the three alcohols derived from propane, C^3H^8 , which is a saturated hydrocarbon, are themselves saturated molecules, not capable of forming new compounds by addition; but from the unsaturated hydrocarbon (C^3H^6) is derived the unsaturated compound allyl alcohol, $\text{C}^3\text{H}^5\text{O}$ or $\text{C}^3\text{H}^5(\text{OH})$, which is capable of taking up 2 at. bromine and forming the compound $\text{C}^3\text{H}^5\text{Br}^2\text{O}$. In like manner, all the allyl-compounds formed on the type $\text{C}^3\text{H}^5\text{R}$ (the symbol R denoting a monatomic acid or chlorous radicle) can take up two additional atoms of such radicle or radicles, whereby they are converted into compounds of the propenyl or glyceryl group (C^3H^5) R^2 . (See ALLYL-COMPOUNDS, i. 141, 142.)

The substitution of an alcohol-radicle for the hydrogen of either of the groups OH in an alcohol converts it into an ether, and the number of ethers which an alcohol can form with the same alcohol-radicle is determined by the number of equivalents of hydroxyl contained in its molecule (see p. 38).

The substitution of O for H^2 in one or more of the groups H^2OH converts the alcohol into an acid, and the removal of 2 atoms of hydrogen from one of these groups without replacement by oxygen converts the alcohol into an aldehyde.

Most of the known alcohols are enumerated and classified in the article ALCOHOLS, vol. i. pp. 97-104. There are however some additions to be made, especially relating to isomeric modifications.

MONATOMIC ALCOHOLS.

a. Series $\text{C}^n\text{H}^{2n+2}\text{O}$ or $\text{C}^n\text{H}^{2n+1}(\text{OH})$.—To the list of these alcohols given in the article just referred to must be added nonyl alcohol, $\text{C}^9\text{H}^{20}\text{O}$, formed from the nonyl hydride, C^9H^{20} , occurring in American petroleum, by converting that compound first into chloride, then into acetate, and distilling the latter with potash (iv. 134). The alcohols containing 12, 14 and 16 atoms of carbon are supposed to exist in spermaceti, together with sexdecyl or cetyl alcohol, because that substance when fused with potash-lime yields the corresponding fatty acids $\text{C}^n\text{H}^{2n}\text{O}^2$ (Heintz, *Pogg. Ann.* lxxxiv. 232; lxxxvii. 553).

The isomeric modifications of these alcohols, *primary*, *secondary*, and *tertiary*, have already been noticed in the article SECONDARY AND TERTIARY ALCOHOLS, by Professor Wanklyn, in vol. v. pp. 215-218. It is there stated that *an alcohol is said to be primary, secondary, or tertiary, according as the carbon-atom which is in combination with hydroxyl is likewise directly combined with one, two, or three other carbon-atoms*. The first and second alcohols of the series can exist in one form only, but the three-carbon alcohol admits of two modifications, viz.,

and the four-carbon alcohol of three modifications, viz.,

The five-carbon alcohol and those above it are also susceptible of three similar modifications; but modifications higher than the tertiary are impossible, inasmuch as

the carbon-atom associated with hydroxyl by one of its atomicities or units of equivalence has only three others to dispose of.

There is still, however, another kind of modification of which the alcohols of each of these three groups are susceptible, arising from modifications in the alcohol-radicles themselves. (See HYDROCARBONS.) The primary four-carbon alcohol, for example, may be represented by either of the formulæ:

Each of these fulfils the essential condition of a primary alcohol; but the first contains normal propyl, $\text{CH}^2(\text{C}^2\text{H}^5)$, whereas the second contains isopropyl, $\text{CH}(\text{CH}^2)^2$; and in the higher alcohols it is easy to see that a still larger number of modifications may exist.

A very convenient nomenclature for these isomeric alcohols has been proposed by Kolbe. Methyl alcohol, $\text{CH}^3(\text{OH})$, is called carbinol; and the primary alcohols formed from it by successive substitution of methyl, ethyl, &c., for an atom of hydrogen are named according to the radicles which they contain; thus:

Carbinol C OH H H H	
Methyl carbinol or Ethyl alcohol C OH H H CH ³	
Ethyl carbinol or Propyl alcohol C OH H H (CH ² CH ³)	
Dimethyl carbinol or Isopropyl alcohol C OH H CH ³ CH ³	
Propyl carbinol or Butyl alcohol C OH H H (CH ² CH ² CH ³)	
Isopropyl carbinol or Isobutyl alcohol C OH H H [CH(CH ³) ²]	
Methyl-ethyl carbinol or Secondary Butyl alcohol C OH H CH ³ (CH ² CH ³)	
Trimethyl carbinol or Tertiary Butyl alcohol C OH CH ³ CH ³ CH ³	

It will be observed that the four-carbon alcohol admits of four modifications, two primary, one secondary, and one tertiary. In like manner it will be found that the five-carbon alcohol admits of eight modifications, and the higher alcohols of a still greater number; but only a few of these modifications are actually known.

All the primary alcohols contain the group CH^2OH , and are converted by oxidation into aldehydes and acids containing the same number of carbon-atoms; thus:

The secondary alcohols, on the other hand, contain two equivalents of alcohol-radicle combined with the group CHOH , and are converted by oxidation into ketones; e.g.,

The tertiary alcohols contain three equivalents of alcohol-radicle associated with COH , and are converted by oxidation into two or more acids containing smaller numbers of carbon-atoms.

Primary Alcohols.—The synthetic methods of forming the alcohols of the three classes are given in the article in vol. v. above referred to. The methods of building up the primary alcohols one from the other through the medium of the fatty acids and aldehydes are mentioned on p. 39 of this volume. The method depending on the action of nitrous acid on the corresponding amines (iii. 164) cannot for the present be regarded as perfectly general, inasmuch as it has not yet been found possible to prepare normal propyl alcohol by it (v. 888) (Linnemann, *Ann. Ch. Pharm.* cxliv, 129).

Linnemann finds, moreover, that the method proposed by Hofmann (conversion of the base by excess of nitrous acid into the corresponding nitrous ether) does not yield good results, because the nitrous ether is produced in small quantity only, and is for the most part carried away by the nitrogen gas, which is evolved in great abundance. Better results are obtained by decomposing the nitrites of the amine-bases by application of heat to their slightly acidulated solutions. The best mode of proceeding is to prepare the nitrite of the amine-base by decomposing the hydrochloride with silver nitrite, filtering from silver chloride, and boiling the slightly acidulated filtrate in a distillatory apparatus. The decomposition takes place below the boiling heat, with formation of nitrogen, water, and an alcohol, and if the liquid is kept slightly acid, it is nearly complete. The formation of an alcohol in this process appears to be almost always accompanied by that of a nitrogenous substance. In one experiment, Linnemann obtained from 15.6 grms. ethylamine, 4 grms. of pure ethyl alcohol boiling between 78° and 79° , about 2 grms. of a neutral yellowish substance boiling at 170° – 172° , and having the composition $C^4H^{11}N^2O$, and 1 grm. of a mixture of this substance with alcohol.

Other recently discovered methods of forming the primary alcohols of this series are the following:

α. By the action of nascent hydrogen (sodium amalgam and water applied in succession) on the corresponding acid oxides or anhydrides: e.g.,

In like manner propionic oxide has been converted into propyl alcohol (Linnemann, *Zeitschr. f. Chem.* [2] v. 143).

β. By the action of sodium amalgam on a mixture of a fatty acid with the corresponding chloride: thus acetic acid and acetic chloride yield ethyl alcohol. Propyl and butyl alcohol have been prepared in a similar manner (Saytzeff, *ibid.* v. 551; vi. 105).

γ. According to Vieil, the fatty acids may be converted by oxidation with manganese dioxide and dilute sulphuric acid into compound ethers, from which the corresponding alcohols may be obtained. (See ACIDS, ORGANIC, p. 40.)

The alcohols produced by fermentation, and those obtained from the paraffins or alcoholic hydrides, C^mH^{2m+2} , by converting those hydrides into chlorides, the latter into acetates, and distilling the acetates with potash, must be regarded as primary alcohols, because they exhibit the essential character of those alcohols, viz. that of yielding by oxidation fatty acids and aldehydes containing the same number of carbon-atoms.

The structure of the radicle in a primary alcohol may be determined in some cases by that of the fatty acid produced from it. The first three primary alcohols of the series $CH^3(OH)$, $CH^3CH^2(OH)$, and $CH^3CH^2CH^2(OH)$, admit of no modifications. Of the four-carbon alcohol, as already observed, there are two modifications, viz. propyl-carbinol and isopropyl-carbinol (p. 62). The first of these is produced, according to Schöyén (*Ann. Ch. Pharm.* cxxx. 233), from diethyl, C^2H^{10} (butyl-hydride), by converting this compound into the chloride and acetate as above described, and distilling the acetate with barium hydrate. The butylic alcohol thus obtained was converted by oxidation with potassium bichromate and sulphuric acid, into normal butyric or ethyl-acetic acid, $CH^3CH^2CH^2.CO^2H$ (p. 40): hence the alcohol itself has the composition of propyl-carbinol, $CH^3CH^2CH^2.CH^3OH$. Lieben & Rossi (*Compt. rend.* lxxvii. 1561) have lately obtained this same alcohol by the action of sodium amalgam on butyric aldehyde.

Isopropyl carbinol, $CH(CH^3)^2.CH^3OH$, is the variety of butyl alcohol found by Wurtz in the fusel-oil obtained by fermenting the molasses of beet-sugar (see v. 733, where it is designated as normal butylic or terylic alcohol). When oxidised in the manner above mentioned, it yields isobutyric or dimethyl-acetic acid, $CH(CH^3)^2.COOH$ (p. 40). See, further, BUTYL COMPOUNDS, in this volume.

The primary 5-carbon or amyl alcohol, $C^5H^{12}O = C^4H^9.CH^3OH$, is susceptible of four modifications, accordingly as the radicle C^4H^9 takes the form $CH^3CH^2CH^2CH^3$, or $CH^3CH(CH^3)^2$, or $CH(CH^3)(C^2H^5)$, or $C(CH^3)^3$. The first of these, or normal amyl alcohol, has quite recently been obtained from normal butyl alcohol by a synthetic process to be described further on. The second, as shown by Erlenmeyer, is the ordinary amyl alcohol of fermentation; and this again, as shown some years ago by Pasteur, exhibits two modifications closely resembling one another in most of their properties, but differing in their relations to polarised light; these however are probably only physical modifications of one and the same chemical compound (see AMYL

COMPOUNDS). The primary amyl alcohols containing the third and fourth of the radicles above mentioned are not known.

A primary hexyl alcohol, probably amyl carbinol, $C^5H^{11}.CH^2OH$, is obtained from sextane or hexyl hydride (from American petroleum) through the medium of the chloride in the manner already described. It has the odour of amyl alcohol and boils at 150° , that is to say about 22° higher than amyl alcohol. By oxidation with chromic acid it yields caproic acid. The six-carbon alcohol found by Faget in a peculiar kind of fusel-oil (iii. 152) also yielded caproic acid, or an isomeride, by oxidation, and therefore exhibited the essential character of a primary alcohol; but there is not much known respecting it.

Of primary heptyl alcohols only the normal compound, or hexyl-carbinol, $C^6H^{13}.CH^2OH$, is known with certainty. It is obtained either by the action of sodium amalgam and water on cenanthylic aldehyde or cenanthol, $C^6H^{13}.COH$, or from the septane or heptyl hydride, C^7H^{16} , found in American petroleum. It boils at 164.5° (Schorlemmer). Faget obtained a seven-carbon alcohol from fusel-oil.

A primary octyl alcohol, $C^7H^{15}.CH^2OH$, is obtained from the octyl hydride of American petroleum, and another from the volatile oil of the seeds of *Heracleum sphondylium*. (See OCTYL COMPOUNDS.)

The higher alcohols of the series $C^2H^{2n+2}O$ at present known all yield by oxidation acids containing the same numbers of carbon-atoms; they are therefore primary alcohols.

Secondary Alcohols, $C^2H^{2n+2}O$.—The lowest secondary alcohol of this series is isopropyl alcohol, $(CH^3)^2.CHOH$, which is produced from acetone, $(CH^3)^2.CO$, by the action of nascent hydrogen, and reconverted into that compound by oxidation with chromic acid (v. 889). It is obtained also by several other synthetical processes (see PROPYL ALCOHOLS), among which the following may be noticed in this place, as it is applicable also to the formation of other secondary alcohols. Glycolic iodhydrin or ethylene oxyiodide, $C^2H^4(OH)$, treated with zinc-methyl yields a crystalline mass consisting of $\left\{ \begin{smallmatrix} C^2H^7 \\ (CH^3Zn) \end{smallmatrix} \right\} O$; thus:

and

and this compound, when heated with water under pressure, yields secondary propyl alcohol:

The propyl alcohol thus formed also yields acetone by oxidation (Butlerow a. Ossokin, *Zeitschr. f. Chem.* [2] iii. 680).

The secondary 4-carbon or butyl alcohol, which has the composition of methyl-ethyl carbinol, $(CH^3)(C^2H^5).CHOH$, was discovered by De Laynes, who obtained the corresponding iodide, $(CH^3)(C^2H^5).CHI$, by the action of hydriodic acid upon erythrite (v. 890). It is also produced synthetically by the second process above mentioned for the preparation of secondary propyl alcohol, using zinc-ethyl instead of zinc-methyl (Butlerow a. Ossokin); and by the successive action of zinc-ethyl and hydriodic acid on chlorinated ethyl oxide (Lieben). (See BUTYL COMPOUNDS.) This alcohol boils at 95° – 98° (about 10° lower than the normal primary alcohol), and when heated to 250° is for the most part resolved into water and butylene.

Of secondary 5-carbon or amyl alcohols there may be three modifications, viz.,

The first two of these are known. The first is produced by the action of nascent hydrogen on propyl-methyl ketone or methyl-butyryl, $CO \left\{ \begin{smallmatrix} C^2H^7 \\ CH^3 \end{smallmatrix} \right\}$ (Friedel), and by

decomposing the hydriodide of isoamylene or ethyl-allyl, $C^5H^{10}.HI$, with moist silver oxide (Wurtz); the second in like manner from ordinary amylene:

Both these alcohols are distinguished by the facility with which they are resolved into amylene (or isoamylene) and water, and both yield ketones by oxidation. (See AMYL ALCOHOLS.)

A secondary hexyl alcohol, probably consisting of isobutyl-methyl-carbinol, $C \begin{Bmatrix} CH^2CH(CH^3) \\ CH^3 \\ H \\ OH \end{Bmatrix}$, is produced from mannite, $C^6H^{14}O^6$, in the same manner as second-

dary butyl alcohol from erythrite (iii. 152). It resembles the two last-described compounds in the facility with which it is resolved into water and hexylene, and is converted by oxidation with the chromic acid mixture into a ketone, $C^6H^{12}O =$

$C \begin{Bmatrix} CH^2CH(CH^3) \\ CH^3 \\ O \end{Bmatrix}$, which, when further treated with the oxidising mixture, yields isobutyric and acetic acids: hence the constitution of the alcohol is inferred.

The three secondary alcohols just described are sometimes regarded as belonging to a peculiar class of alcohols designated by Wurtz as pseudo-alcohols, on account of the great facility with which they yield the corresponding olefines, C^5H^{10} . With reference to this character, they may indeed be conveniently formulated as hydrates of olefines (a constitution formerly assigned by Dumas to all alcohols) and regarded as intermediate between the primary alcohols and the glycols; e.g.,

This character however is merely relative, inasmuch as any alcohol may be resolved without much difficulty into water and the corresponding olefine, the facility with which the change takes place appearing to increase with the complexity of the molecule. There does not therefore appear to be any sufficient reason for erecting these alcohols into a distinct class, more especially as Wurtz's pseudo-amyl alcohol and the β -hexyl alcohol obtained from mannite—which, from its mode of formation, is evidently the true homologue of the butyl alcohol obtained from erythrite—exhibit the essential character of secondary alcohols, namely, that of yielding ketones by oxidation.

Secondary octyl alcohol or methyl-hexyl carbinol, $C^8H^{18}O = C \begin{Bmatrix} C^6H^{14} \\ CH^3 \\ H \\ OH \end{Bmatrix}$, is the alcohol produced by heating sodium ricinoleate (castor-oil soap)

with excess of alkaline hydrate (iv. 170). It boils at 181° , and when oxidised with the chromic acid mixture yields methyl-hexyl ketone:

By the prolonged action of the oxidising mixture this ketone is further oxidised to caproic acid and acetic acid:

These reactions show that the castor-oil alcohol is a secondary alcohol (Schorlemmer, *Proc. Roy. Soc.* xvi. 378). Moreover, by converting it into the corresponding iodide, $C^8H^{17}I$, and treating this iodide with zinc-turnings and hydrochloric acid, a hydrocarbon, C^8H^{18} , is obtained which boils at 124° . Now Schorlemmer has shown, by considerations for which we must refer to the articles HYDROCARBONS in this volume, that a hydrocarbon C^8H^{18} boiling at this temperature most probably contains one atom of carbon combined directly with three other carbon-atoms. The alcohol from which it is obtained in the manner just described will have a similar structure, and may therefore be represented by the formula

ALCOHOLS (MONATOMIC),

Tertiary Alcohols. $C^3H^{2n+2}O$.—The known compounds of this group contain four, five, and six atoms of carbon.

Tertiary butyl alcohol or trimethylcarbinol, $C\left\{\begin{smallmatrix} (CH^3)^3 \\ OH \end{smallmatrix}\right.$, is produced by heating zinc-methyl with carbonyl chloride (phosgene) or with acetyl chloride, and submitting the product to the action of water:

According to Butlerow (*Bull. Soc. Chim.* [2] viii. 268), it is contained in the commercial butylic alcohol, prepared at Wyl, Canton St. Gall, and is therefore also a product of fermentation.

The properties of the alcohol have not been much studied. By oxidation with dilute chromic acid it is converted into formic and propionic acids:

A tertiary amyl alcohol or dimethyl-ethyl carbinol, $C(CH^3)^2(C^2H^5).OH$, is produced in like manner by means of zinc-methyl and propionyl chloride.

Of tertiary hexyl alcohols there may be three varieties, viz.,

The third has not yet been obtained. The first is prepared by treating zinc-ethyl with acetyl chloride and decomposing the resulting methyl-diethyl-chlorethane,

$C\left\{\begin{smallmatrix} CH^3 \\ (C^2H^5)^2 \\ Cl \end{smallmatrix}\right.$, with water; the second by proceeding in like manner with zinc-ethyl and butyryl chloride, $CO(C^3H^7)Cl$.

β. Monatomic Alcohols. $C^3H^{2n}O$.—Two alcohols of this series are known, viz.,

The first, discovered by Berthelot in 1860 (*Compt. rend.* 1. 805), is produced by combining ethine or acetylene with sulphuric acid, and distilling the product with water, just as in the preparation of ethyl alcohol from ethylene:

It is an easily decomposable liquid, having a highly pungent odour, somewhat more volatile than water, soluble in 10 to 15 parts of that liquid, and precipitated from the solution by potassium carbonate. Its chemical reactions have not been much examined, but it is probably an unsaturated secondary alcohol, represented by the formula

$\cdot CH^2 \cdot$, the dots denoting unsaturated atomicities. It is isomeric with acetic aldehyde and ethylene oxide. The univalent radicle vinyl, C^2H^3 , which may be supposed to exist in it, is related to the trivalent radicle ethenyl, in the same manner as allyl to propenyl.

Allyl alcohol, C^3H^4O , is a primary alcohol, yielding acrolein, C^3H^4O , and acrylic acid, $C^3H^4O^2$, by oxidation. It is moreover an unsaturated compound, being capable of taking up 2 atoms of bromine and forming the compound $C^3H^4Br^2O$:

hence it may be represented by the formula $\begin{array}{c} \cdot CH^2 \\ | \\ \cdot CH \\ | \\ CH^2OH \end{array}$. All its derivatives are like-

wise unsaturated compounds, capable of taking up 2 atoms of chlorine, bromine, or other monatomic elements, and passing into glyceryl compounds.

γ. Monatomic Alcohols. $C^6H^{12-2}O$.—Only one alcohol of this series is known, viz. camphol, $C^{10}H^{18}O$; of this however there are four modifications, which appear to be, not metameric, that is to say distinguished by different arrangements of the atoms within the molecule, but only physically isomeric, that is differing from one another by the arrangement of the molecules amongst themselves. They differ in fact by physical, not by chemical characters. One variety, called borneol or Borneo camphor, found in cavities in the trunks of old trees of *Dryobalanops camphora*, has a dextro-gyrate power of 34.4° ; a second, produced by the action of alcoholic potash on common camphor, has a dextro-gyrate power of 44.9° ; a third, obtained by distilling amber with potash, has a dextro-gyrate power of 45° ; and a fourth, called levo-camphol, found in the alcohol produced in the fermentation of sugar from madder-root, has a levo-gyrate power of 33.4° , equal and opposite to that of borneol (i. 626, 726).

δ. Monatomic Alcohols. $C^6H^{12-6}O$.—These alcohols are derived from the aromatic hydrocarbons, C^6H^{12-6} , namely, benzene and its homologues, in the same manner as the fatty alcohols, $C^6H^{12+2}O$, from the paraffins. The lowest number of the series, corresponding to benzene, C^6H^6 , has therefore the composition C^6H^6O or C^6H^5OH . This is the body called *phenol* or *phenyl alcohol*; it is the only alcohol of the series containing 6 atoms of carbon. The higher alcohols of the series admit of isomeric modifications: for every hydrocarbon homologous with benzene may be regarded as a compound of phenyl, C^6H^5 , with one or more alcohol-radicles of the series C^2H^{2n+1} , and the formation of an alcohol from such a hydrocarbon by substitution of OH for H may take place either in the phenyl-atom or in one of the alcohol-radicles combined with it: thus from toluene, $C^6H^5.CH^3$, may be obtained the two alcoholic bodies,

and the higher hydrocarbons of the series are capable of yielding a still greater number of metameric alcoholic compounds. The properties of the compounds thus formed differ considerably accordingly as the hydroxyl is introduced into the phenyl, or into one of the associated alcohol-radicles. The compounds formed in the latter case—benzyl alcohol for example—are true alcohols, analogous in all their reactions to the fatty alcohols; but those in which the hydroxyl replaces a hydrogen atom in the phenyl group possess very different properties, the hydrogen of the hydroxyl being much less readily replaced by other radicles than in their isomerides. These bodies are called by the generic name of phenols. (See AROMATIC SERIES in this volume; also Dictionary, v. 852.)

ε. Monatomic Alcohols. $C^9H^{18-8}O$.—Two only of these bodies are known, viz. cinnyl alcohol, styryl alcohol, or styrene, $C^9H^{10}O$, and cholesterolin, $C^{26}H^{44}O$ (i. 925, 992).

DIATOMIC ALCOHOLS.

These alcohols are derived from saturated hydrocarbons, by substitution of two equivalents of hydroxyl for two atoms of hydrogen, and may therefore be regarded as compounds of bivalent alcohol-radicles with hydroxyl. Two series of them are known, the first, called glycols, being derived from the paraffins, C^2H^{2n+2} ; the second, called diatomic phenols, from the aromatic hydrocarbons, C^6H^{12-6} .

1. Glycols. $C^2H^{2n+2}O = (C^2H^{2n}) \cdot \begin{array}{c} OH \\ OH \end{array}$.—The following table exhibits the names and formulae of the glycols at present known, together with their boiling points:

	Boiling point
Ethylene alcohol, $C^2H^4O^2 = C^2H^4(OH)^2$. . .	197°-5°
Propylene alcohol, $C^3H^6O^2 = C^3H^6(OH)^2$. . .	188°-189°
Butylene alcohol, $C^4H^{10}O^2 = C^4H^{10}(OH)^2$. . .	183°-184°
Amylene alcohol, $C^5H^{12}O^2 = C^5H^{12}(OH)^2$. . .	177°
Hexylene alcohol, $C^6H^{14}O^2 = C^6H^{14}(OH)^2$. . .	207°
Octylene alcohol, $C^8H^{18}O^2 = C^8H^{18}(OH)^2$. . .	235°-240°

The glycols are colourless, inodorous, more or less viscid liquids, easily soluble in water and in alcohol; ethylene alcohol is but sparingly soluble in ether, the rest dissolves easily in that liquid.

The boiling points of the first four glycols in the table exhibit the singular anomaly of becoming lower as the molecular weight of the compound increases, whereas the six- and eight-carbon glycols have higher boiling points. This anomaly doubtless arises from difference of constitution in the successive terms of the series. Thus

ethylene glycol has the constitution $\begin{array}{c} CH^2OH \\ | \\ CH^2OH \end{array}$, and propylene glycol might be represented by either of the formulæ:

Now the first of these is the true homologue of ethylene glycol; but the actually known propylene glycol appears to have the constitution represented by the second formula, inasmuch as it is converted by oxidation into ordinary lactic acid, which has

Of the six-carbon glycol, $C^6H^{14}O^2$, two modifications have been obtained by Wurtz (*Ann. Ch. Phys.* [4] iii. 122), viz. normal hexylene glycol, $C^6H^{14}(OH)^2$, $\begin{array}{c} CH^2OH \\ | \\ (CH^2)^4 \\ | \\ CH^2OH \end{array}$

or probably $\begin{array}{c} CH^3 \\ | \\ CHOH \\ | \\ CH^2OH \end{array}$, produced by combining hexylene, C^6H^{12} (from mannite or from

American petroleum), with 2 at. bromine, converting the resulting bromide into an acetate, and distilling this compound with potash; the second, called diallyl-dihydrate or pseudo-hexylene glycol, by distilling diallyl-dihydriodide with potash. (See ALLYL-COMPOUNDS.)

Both these compounds are syrupy liquids, the first boiling at 207°, or 30° higher than amyleneglycol; the second at 215°. When heated with concentrated hydriodic acid, they yield different products, as shown by the following equations:

and

The chemical reactions of the glycols are, for the most part, similar to those of the monatomic alcohols; but inasmuch as the glycols contain 2 atoms of replaceable

hydrogen, or of hydroxyl, the reactions generally take place by two stages, yielding two series of products.

1. Ethylene alcohol treated with *nitric acid* gives up 2 or 4 atoms of hydrogen in exchange for oxygen, and is converted into glycollic or oxalic acid, accordingly as the action takes place at ordinary or at higher temperatures:

Under certain circumstances the corresponding aldehydes are also produced, as glyoxal, $\begin{array}{c} \text{COH} \\ | \\ \text{COH} \end{array}$, from ethylene alcohol, by removal of 4 hydrogen-atoms without substitution.

Propylene glycol, $\text{C}^3\text{H}^5\text{O}^2$, is converted into lactic acid, $\text{C}^3\text{H}^4\text{O}^3$, by oxidation in contact with *platinum black*. When heated with dilute *nitric acid*, it yields glycollic acid, $\text{C}^3\text{H}^4\text{O}^3$, losing carbon as well as hydrogen; and concentrated nitric acid oxidises it still further to oxalic acid. Butylene glycol, $\text{C}^4\text{H}^8\text{O}^2$, is converted by slow oxidation with *nitric acid* into oxybutyric acid, $\text{C}^4\text{H}^6\text{O}^3$, and when the action is accelerated by heat, into oxalic acid. Amylene glycol likewise yields oxybutyric acid by slow oxidation with nitric acid.

Other *oxygen-acids* heated with the glycols in closed vessels act upon them in the same manner as on the monatomic alcohols, forming compound ethers, monoacid or diacid according to the proportions used. In the diacid glycol-ethers, the two acid radicles by which the type hydrogen is replaced may either be the same or different:

The *haloid acids* act in the same manner, excepting that the reaction never goes beyond the first stage; e.g.,

The dichlorinated, dibrominated ethers, &c., of the diatomic alcohol-radicles are obtained from the glycols by the action of the chlorides, bromides, and iodides of phosphorus, e.g.,

The same compounds are also produced by direct combination of chlorine, bromine and iodine with the olefines.

The monochlorinated, monobrominated ethers, &c., of the glycols, when treated with aqueous alkalis, give up hydrochloric, hydrobromic acid, &c., and leave the oxides of the diatomic alcohols; e.g.,

Ethylene oxide is isomeric with acetic aldehyde and with vinyl alcohol (p. 66).

It is distinguished from aldehyde by its behaviour with ammonia, with which it forms several bases (ii. 587), all of which are syrupy liquids, whereas aldehyde forms

with ammonia a crystalline compound not possessing basic properties. A further distinction between these two isomeric bodies is that aldehyde forms crystalline compounds with the acid sulphites of the alkali-metals, a property not possessed by ethylene oxide.

Ethylene oxide is moreover a powerful base, uniting directly with acids to form ethers, and with water to form glycol and the polyethylenic alcohols (ii. 576).

The oxygen-ethers of the higher glycols are not much known, but they appear to be less disposed to combine with water and with acids as their molecules become heavier; thus amylene oxide does not appear to reproduce amylene alcohol by combination with water.

2. Diatomic Phenols. $C^mH^{2n-2}O^2$.—There are seven known compounds included in this general formula, viz.,

Oxyphenol or Pyrocatechin	}	$C^6H^4O^2$
Resorcin				
Hydroquinone				
Orcin	}	$C^7H^2O^2$
Guaiacol (in part)				
Creosol	}	$C^8H^{10}O^2$
Veratrol				
Beta-orcin				

For their characters and modes of formation, see AROMATIC SERIES.

TRIAOMIC ALCOHOLS.

These compounds, of which only a small number have yet been obtained, are derived from saturated hydrocarbons by substitution of 3 equivalents of hydroxyl for 3 at. hydrogen, and may therefore be regarded as compounds of triatomic alcohol-radicles with 3 equivalents of hydroxyl.

Of triatomic alcohols derived from the paraffins, C^mH^{2n+2} , only two are at present known, viz. propenyl alcohol or glycerin, $C^3H^5O^3$, derived from propane or propyl hydride, C^3H^8 , and quintenyl alcohol or amyl-glycerin, $C^5H^{12}O^3$, from quintane or amyl hydride, C^5H^{12} .

Glycerin is oxidised by strong nitric acid, yielding glyceric acid, $C^3H^4O^4 = CH^2OH.CHOH.COOH$, which is related to glycerin in the same manner as glycollic acid to glycol, or acetic acid to alcohol. The formula of glycerin indicates the possibility of effecting a second substitution of the same kind, which would yield the acid $C^3H^2O^5$; but this acid has not been actually obtained. By a mixture of strong nitric and sulphuric acids, glycerin is converted into the highly explosive compound nitroglycerin, $C^3H^5(NO^2)_3O^3$, which is in reality propenyl trinitrate.

Other oxygen-acids, especially organic acids, heated with glycerin in various proportions, convert it into compound ethers or glycerides, in which 1, 2 or 3 atoms of typic hydrogen are replaced by the radicle of the acid. Hydrochloric and hydrobromic acids act in the same manner, excepting that the reaction always stops at the second stage, just as in the action of these acids upon the glycols it stops at the first stage (p. 69); thus with hydrochloric acid glycerin forms monoethylhydrin, $C^3H^7(OH)Cl$, and diethylhydrin, $C^3H^7(OH)_2Cl$, but not triethylhydrin, $C^3H^7Cl^3$. The chlorides and bromides of phosphorus act upon glycerin in the same manner as hydrochloric and hydrobromic acids, but their action goes on to the third stage, forming trichlorhydrin and tribromhydrin. Iodide of phosphorus acts in a totally different manner, forming iodopropylene or allyl iodide, C^3H^5I .

The formation and properties of the glycerin-ethers or glycerides, and of the glycidic ethers formed from the chlorhydrins and bromhydrins by abstraction of the elements of hydrochloric or hydrobromic acid, are fully described in the articles GLYCERIDES and GLYCIDIC ETHERS (ii. 877, 896).

Polyglycerins, analogous to the polyethylenic alcohols, and consisting of two or

more molecules of glycerin united into a single molecule, with elimination of a number of water-molecules less by one than the number of glycerin-molecules which combine together, have also been described (ii. 894). Their constitution may be represented by the following general equation :

The atomicity of the resulting polyglycerin (determined by the number of equivalents of hydroxyl contained in it) is $n + 2$.

Quintenyl alcohol or Amyl glycerin, $\text{C}^5\text{H}^{12}\text{O}^3 = (\text{C}^3\text{H}^5)^3(\text{OH})^3$, is formed from dibromide of bromoquintene or bromamylene, $\text{C}^5\text{H}^7\text{Br}_2$, or quintenyl bromide, $\text{C}^5\text{H}^7\text{Br}$, by the series of processes represented in the following equations :

Quintenyl alcohol is a thick colourless liquid, having a sweet aromatic taste, and soluble in water (Bauer, *Zeitschrift für Chem. u. Pharm.* 1861, p. 673).

Triatomic Phenols. $\text{C}^3\text{H}^5-\text{O}^3$.—There are three compounds represented by the formula $\text{C}^3\text{H}^5\text{O}^3$, and exhibiting a certain relationship to the phenols; these are : 1. Pyrogallol or pyrogallie acid, formed from gallic (dioxysalicylic) acid, in the same manner as oxyphenol from oxysalicylic acid and phenol from salicylic acid; $\text{C}^3\text{H}^5\text{O}^3 = \text{CO}^2 + \text{C}^2\text{H}^3\text{O}^3$; 2. Phloroglucin, produced from phlorizin, a crystalline substance existing in the root-bark of the apple, pear, plum and cherry trees; and 3. Frangulin, a yellow crystallisable substance existing in the bark of *Rhamnus frangula* (ii. 706). The last two form explosive substitution-products with nitric acid; phlorizin and pyrogallol form substitution-products with bromine.

TETRATOMIC ALCOHOLS.

The only tetratomic alcohols at present known are erythrite, erythromannite, or phycite, $\text{C}^4\text{H}^{10}\text{O}^4 = (\text{C}^3\text{H}^5)^4(\text{OH})^4$, a saccharine substance existing in *Protococcus vulgaris* (iv. 504); and propylphycite or trityl-phycite, $\text{C}^6\text{H}^{12}\text{O}^4 = (\text{C}^3\text{H}^5)^3(\text{OH})^4$, produced by combining epichlorhydrin, $\text{C}^2\text{H}^3\text{OCl}$, with hypochlorous acid, HClO , treating the resulting dichlorhydrin of propylphycite, $(\text{C}^3\text{H}^5)^3\text{Cl}_2(\text{OH})^2$, with silver acetate, whereby it is converted into the corresponding diacetin, $(\text{C}^3\text{H}^5)^3(\text{OC}^2\text{H}^3\text{O})^2(\text{OH})^2$, and heating this diacetin with aqueous potash (v. 898).

These two alcohols are of decidedly saccharine character, and form explosive nitro-compounds. They contain 4 atoms of hydrogen, replaceable by acid or alcoholic radicles, so as to form ethers; but two of these hydrogen-atoms are more easily replaceable than the other two, probably those which in the following formulæ are contained in the hydroxyl belonging to the two groups CH^2OH :

Propylphycite.

Erythrite.

Hexacid ethers of these acids are also formed by combination of the tetracid ethers with two molecules of free acid, e.g. erythritic hexbenzoate

PENTATOMIC ALCOHOLS.

Pinite and quercite, two saccharine bodies having the composition $C^6H^{12}O^4$, probably belong to this class of bodies, inasmuch as they form ethers when treated with acids, and the atomicity of an alcohol is equal to the number of oxygen-atoms which it contains. Pinite forms two benzoic ethers, viz. $C^6H^7(OC^6H^5O)^2(OH)^2$ and $C^6H^7(OC^6H^5O)(OH)$.

HEXATOMIC ALCOHOLS.

This class of compounds includes most of the saccharine substances found in plants, and others produced from them by artificial transformation. Two of the natural sugars, mannite and dulcite, having the composition $C^6H^{14}O^6$ or $(C^2H^3)^4(OH)^2$, are saturated hexatomic alcohols derived from the saturated hydrocarbon, C^6H^{14} . Several others, called glucoses, contain $C^6H^{12}O^6$; that is to say, 2 atoms of hydrogen less than mannite and dulcite, and may therefore be regarded—so far as composition is concerned—as the aldehydes of these alcohols; ordinary glucose (grape-sugar) is, in fact, converted into mannite by the action of nascent hydrogen, just as acetic aldehyde, C^2H^4O , is converted into common alcohol, C^2H^6O . Further, there are diglucosic alcohols, $C^{12}H^{22}O^{11}$ ($= 2(C^6H^{12}O^6 - H^2O)$), related to the glucoses in the same manner as diethylene-alcohol to glycol, or diglycerin to glycerin: the most important of these are cane-sugar and milk-sugar; and, lastly, there are certain vegetable products—viz. starch, cellulose, and a few others, represented by the formula $n(C^6H^{10}O^5)$ (mostly $C^{12}H^{20}O^{10}$)—which may be regarded as the oxygen-ethers or anhydrides of the glucoses, or rather of polyglucosic alcohols, from which indeed they differ by the elements of a molecule of water.

Mannite, $C^6H^{14}O^6 = (C^2H^3)^4(OH)^2$, the essential constituent of manna, is formed artificially by treating a solution of glucose with sodium amalgam, $C^6H^{12}O^6 + H^2 = C^6H^{14}O^6$. The same transformation of glucose takes place under the influence of certain ferments.

By oxidation with platinum-black, mannite is converted into mannitic acid, $C^6H^{12}O^7$, and mannitose, $C^6H^{12}O^6$, a sugar isomeric with glucose; and by oxidation with nitric acid, into saccharic acid, $C^6H^{10}O^8$, and finally into oxalic acid. Mannitic and saccharic acids are related to mannite in the same manner as glycollic and oxalic acids to glycol, as shown by the following formulæ:

For the other reactions of mannite, see vol. iii. p. 823.

Dulcite, obtained from *Melampyrum nemorosum*, and from a crystalline substance of unknown origin imported from Madagascar, resembles mannite in most of its chemical relations, but differs from it in solubility, in crystalline form, and in yielding by oxidation with nitric acid, not saccharic acid, but the isomeric compound mucic acid.

Isodulcite, a saccharine substance obtained, according to Hlasiwetz and Pfandler (v. 465), by the action of dilute acid on quercitrin, forms large crystals having the same composition as mannite and dulcite, but giving off 1 molecule of water at 105° – 110° .

With fuming nitric acid, all three of these substances yield nitric ethers of a more or less explosive character. Nitromannite, $C^6H^{11}(NO_2)^4O^6$, explodes violently by percussion, or when suddenly heated; hexanitrodulcite, $C^6H^{11}(NO_2)^5O^6$, gives off nitrous fumes when heated, but does not explode, and is slowly converted at ordinary temperatures into tetra-nitrodulcite, $C^6H^{10}(NO_2)^4O^6$. Nitro-isodulcite, $C^6H^{11}(NO_2)^5O^6$, is slightly explosive.

The glucoses $C^6H^{12}O^6$, as already observed, are related in composition to the saturated hexatomic alcohols in the same manner as aldehydes to alcohols, and may be converted into the saturated alcohols by the action of nascent hydrogen. But they exhibit the characteristic property of alcohols, in forming ethers by combination with acids and elimination of water. They are at once poly-alcohols and aldehydes, just as lactic acid is half alcohol and half acid. The following varieties of glucose are known:

1. *Ordinary glucose*, produced by hydration of starch under the influence of dilute

acids or of diastase, and existing ready-formed, together with other kinds of sugar, in honey and various fruits, especially in grapes, and alone in diabetic urine.

2. *Maltose*, produced by the limited action of diastase on starch, and differing from glucose only in its optical rotatory power.

3. *Levulose*, existing in cane-sugar which has been acted upon by acids, and obtained pure by the action of dilute acids upon the variety of starch called inulin.

4. *Mannitose*, produced by oxidation of mannite.

5. *Galactose*, formed by the action of acids on milk-sugar.

6. *Inosite*, existing in muscular flesh.

7. *Sorbin*, obtained from mountain-ash berries.

8. *Eucalyn*, existing, together with another kind of sugar, in the so-called Australian manna.

The first four of these glucoses exhibit but very slight diversity in their chemical properties, differing chiefly indeed in their action on polarised light, and a few other physical properties. They all yield saccharic acid by oxidation. Galactose differs from them in yielding mucic acid when oxidised. Inosite, sorbin, and eucalyn exhibit still greater differences in their chemical properties, especially in not being fermentable except under very peculiar circumstances, whereas the five other glucoses undergo vinous fermentation when placed under certain conditions in contact with yeast.

All the glucoses, except inosite, are decomposed by boiling with aqueous alkalis; this property distinguishes them from mannite and dulcitol. They are not carbonised by strong sulphuric acid at ordinary temperatures. When boiled with a solution of potassio-cupric tartrate, they throw down the copper in the form of red cuprous oxide.

Glucosates or Glucosides.—When ordinary glucose is heated to 100°–120° for fifty or sixty hours with acetic, butyric, stearic, benzoic, and other organic acids, the two unite, with elimination of water, and compound-ethers called glucosates are formed, analogous to the mannitanates. A number of these artificial glucosates have been prepared by Berthelot, who regards them as derivatives of *glucosan*, $C^6H^{10}O^3$, because when heated with alkalis they yield glucosan, not glucose. Thus, there is a glucosobutyric ether to which Berthelot assigns the formula $C^6H^9(C^4H^7O)^2O^2$, and an acetic ether, which he regards as hexaceto-glucosan, $C^6H^4(C^2H^3O^2)^6O^2$; but they are merely oily liquids which are very difficult to obtain pure, and therefore their analyses are not much to be depended on.

The natural glucosates, many of which constitute the neutral bitter principles of the vegetable kingdom, have a similar constitution. None of them have been prepared artificially; but they are all resolved by boiling with dilute acids into glucose and some other compound (see vol. pp. 865–872).

The polyglucosic alcohols, including cane-sugar and other bodies more or less resembling it, may be regarded as formed by the combination of two or more molecules of glucose, with elimination of a number of water-molecules less by one than the number of glucose molecules which enter into the combination; thus:

generally: $nC^6H^{12}O^6 - (n-1)H^2O = C^{6n}H^{12(n+1)}O^{5n+1}$.

The only known alcohols of this group are diglucosic alcohols, $C^{12}H^{22}O^{11}$; but starch, cellulose, and other neutral plant-constituents may be regarded as the oxygenethers or anhydrides of polyglucosic alcohols of higher orders.

The known diglucosic alcohols are the following:

1. *Cane-sugar or saccharose*, widely diffused in the vegetable kingdom, and existing in particular abundance in the sugar-cane and in beet-root.

2. *Parasaccharose*, produced, according to Jodin (v. 473), by a peculiar spontaneous fermentation of cane-sugar.

3. *Melitose*, from the manna of various species of *Eucalyptus*.

4. *Melzitose*, from the manna of *Larix europæa*.

5. *Trehalose*, from Trehala manna, and from a species of *Echinops* growing in the East; and *Mycose*, perhaps identical with it, from ergot of rye.

6. *Milk-sugar, lactin, or lactose*, from milk.

7. *Gum*, a widely diffused constituent of plants, exhibiting several varieties, which differ considerably in physical properties, solubility, &c.

The anhydrides of the polyglucosic alcohols, derived from these compounds

by elimination of a single molecule of water, are all polymeric one with another, as shown by the following equations:

Glucose.

Digluco-
saccharol.

Trigluco-
saccharol.

The known bodies of this group are starch, dextrin, cellulose, inulin from *dahlia tubers*, and glycogen, obtained from the livers of animals, and entering largely into the composition of most of the tissues of the embryo (ii. 906).

Starch and cellulose appear to consist of $C^{18}H^{32}O^{16}$. That such is the molecular formula of starch appears from the manner in which that substance is converted into dextrin and glucose by the action of dilute acids or of diastase. It was formerly supposed that, in the action of acids or of diastase upon starch, the starch is first converted into dextrin by a mere alteration of physical structure, and that the dextrin then takes up the elements of water, and is converted into glucose, this second stage of the process occupying a much longer time than the first; but from recent experiments by Musculus (*Comptes rendus*, l. 785; liv. 194; *Ann. Ch. Phys.* [3] lx. 208; [4] vi. 177), it appears that both dextrin and glucose are produced at the very commencement of the reaction, and always in the proportion of 1 molecule of glucose to 2 molecules of dextrin, whence it may be inferred that the molecule of starch contains $C^{18}H^{32}O^{16}$, and that it is resolved into glucose and dextrin by taking up a molecule of water:

When the conversion is effected by a dilute acid, the dextrin is, after several hours' boiling, completely converted into glucose, which is therefore the sole ultimate product of the reaction. But when diastase is used as the converting agent, the production of glucose goes on only so long as there is any unaltered starch still present, the dextrin undergoing no further alteration.

That cellulose consists also of $C^{18}H^{32}O^{16}$ appears from the substitution-products (pyroxylin) which it yields under the influence of strong nitric acid and a mixture of nitric and sulphuric acids, these products being represented (according to Hadow's results) by the formula: $C^{18}H^{22}(NO_2)^7O^{16}$ (cotton-xyloidin); $C^{18}H^{22}(NO_2)^8O^{16}$; and $C^{18}H^{21}(NO_2)^9O^{16}$ (trinitrocellulose or gun-cotton). See PYROXYLIN (iv. 777).

ALCOSOL. The gelatinous compound of alcohol with colloidal silicic acid (see COLLOIDAL ACIDS, in Appendix, vol. v. p. 1089).

ALDEHYDE. C^2H^4O .—Produced: α . By heating ethylene bromide with water to 150° – 160° in a sealed tube (Carius, *Ann. Ch. Pharm.* cxxxi. 172):

β . When aqueous ethylamine is poured upon crystallised potassium permanganat (Carstangen, *J. pr. Chem.* lxxxix. 486).— γ . By the action of a powerful electric current on a mixture of 100 pts. absolute alcohol and 1 pt. strong sulphuric acid c 1 pt. potassium hydrate, hydrogen being at the same time evolved at the negative pole: $C^2H^4O = C^2H^4O + H^2$ (Jaillard, *Compt. rend.* lviii. 1203).— δ . Together with formic acid, by heating fermentation lactic acid for several hours to 130° with dilute sulphuric acid, the reaction probably taking place by the following two stages

(Erlenmeyer, *Zeitschr. f. Chem.* [2] iv. 343).

Pure aldehyde heated to 160° for a hundred hours in a sealed tube is resolved, without formation of gas, into water, and a resinous product which is a mixture of hydrocarbons polymeric with acetylene. A small quantity of alcohol is formed at the same time, together with an acid, probably acetic acid: $2C^2H^4O + H^2O = C^2H^4O + C^2H^3O^2$ (Berthelot, *Compt. rend.* lvi. 703).

Vapour of aldehyde passed over heated quicklime yields, together with gases, a liquid distillate, consisting of acetone and other ketones richer in carbon (Schlammilch, *Zeitschr. f. Chem.* [2] v. 336).

Aldehyde treated with *hydriodic acid* at high temperatures yields ethane, C^2H^6 , together with water and free iodine: $C^2H^4O + 4HI = C^2H^6 + H^2O + 2I^2$ (Berthelot, *Bull. Soc. Chim.* [2] vii. 59).

Aldehyde exposed for six months to the action of a solution of ammonia in absolute alcohol forms a brownish liquid, which when distilled gives off ammonia and a volatile base, C^2H^4N . The residue is resinous, and when purified forms a yellow powder which combines with acids, and has the composition of triethylene-diamine, $N^2(C^2H^4)^2$. It is decomposed by water and acids, in the manner represented by the equation:

The new base, $C^2H^{11}NO$, which is amorphous, yellow, and soluble in water, is a tertiary monamine, and is likewise formed when an alcoholic solution of aldehyde-ammonia containing excess of aldehyde is exposed to a temperature of 50°–60°:

When aldehyde is decomposed by ammonia at 100°, two other bases are formed, viz. $C^2H^{10}NO$ and $C^2H^{12}NO$, which are probably constituted similarly to the base $C^2H^{11}NO$ (H. Schiff, *Bull. Soc. Chim.* [2] viii. 443).

Aldehyde heated to 100° with strong solutions of certain *neutral salts*, as formate or acetate of potassium, is converted into vinyl oxide, $C^2H^4O = 2C^2H^3O - H^2O$ (Lieben, *Rép. Chim. pure*, 1861, p. 190).

Aldehyde (2 mol.) treated with *ammonium sulphocarbamate* (1 mol.) is converted into water and carbothialdine:

(E. Mulder, *J. pr. Chem.* ciii. 178).

Aldehyde mixed with water and saturated with cyanogen deposits crystals of oxamide, the mother-liquor retaining a compound of aldehyde and oxamide, which is decomposed by ebullition, the aldehyde distilling over slowly, and crystals of oxamide being deposited (Liebig, *Ann. Ch. Pharm.* cxiii. 360). According to Berthelot, a. Péan de St. Gilles (*Bull. Soc. Chim.* 1863, p. 502), cyanogen gas passed into crude aldehyde forms a white precipitate, $C^2H^{10}N^4O^4$, which contains the elements of cyanogen, water, and aldehyde, $(4CN + 3H^2O + C^2H^4O)$, or of aldehyde and oxamide, with elimination of water, $C^2H^{10}N^4O^4 = C^2H^4O.2C^2H^4N^2O^2 - H^2O$. Aldehyde dissolves *cyanamide*, and the mixture after 24 hours, changes into a body resembling copal resin, soluble in alcohol, and precipitated therefrom in white flocks by ether. This compound contains $N^2C^2H^4O$ (Knop, *Ann. Ch. Pharm.* cxxx. 253). When a mixture of aldehyde, hydrocyanic acid, and hydrochloric acid is left to itself, lactic acid is produced, together with a small quantity of formic acid:

(Wislicenus, *Ann. Ch. Pharm.* cxviii. 1).

A compound of aldehyde with *mercurous bromide*, $C^2H^4O.Hg^2Br^2$, is obtained by heating vinyl bromide (monobromethylene) with mercuric acetate to 100°:

The compound separates as a white amorphous precipitate, which turns brown in the air, with evolution of aldehyde (Saytzeff a. Glinsky, *Zeitschr. f. Chem.* [2] iii. 676).

Hydrocyanide of Aldehyde. $CNH.C^2H^4O$.—Aldehyde and hydrocyanic acid, both anhydrous, if mixed in molecular proportion, unite in the course of 8 or 10 days, forming a liquid the greater part of which distils between 171° and 185°, the portion of constant boiling point distilling between 182° and 184°. On attempting to fractionate this product, it splits up into its components, a considerable portion

distilling between 40° and 60° ; but if the distillate be left to itself, the two bodies reunite and reproduce the compound distilling at 184° .

Hydrocyanide of aldehyde is a colourless oily liquid, having a bitter acrid taste, and smelling somewhat like its components; it becomes syrupy at -21° . Its decomposition by heat is accelerated by *potash*, the products then formed being potassium cyanide and resin of aldehyde. It absorbs ammonia gas at -10° , forming a basic compound which yields a crystalline hydrochloride and platinochloride. Aqueous ammonia appears to act in the same manner.

Hydrochloric acid in strong aqueous solution acts violently on aldehyde-hydrocyanide at ordinary temperatures, but the two liquids may be mixed quietly below 0° , and the liquid if then left to get gradually warm is resolved into sal-ammoniac, which crystallises out, and lactic acid, which remains in the liquid state:

The reactions with potash and with hydrochloric acid show that the compound is not identical, but only isomeric, with glycolic monocyanhydrin (Maxwell Simpson & Geuther, *Bull. Soc. Chim.* [2] viii. 277).

Polymeric Modifications of Aldehyde.—Acetaldehyde, $C^2H^4O^2$, first observed by Wurtz, is produced, together with aldehyde, by the action of zinc chloride on glycol. On treating the resulting liquid with calcium chloride, acetaldehyde separates as a liquid lighter than water, and having a pungent odour. It is soluble in all proportions in water, alcohol, and ether, and reduces an ammoniacal solution of silver nitrate. It boils at 110° , and has a vapour-density of 2.877, which is nearly double that of aldehyde (Bauer, *Rép. Chim. pure*, 1868, p. 294).

The solid modifications, paraldehyde and metaldehyde, are described in vol. i. p. 109; the liquid modification, paraldehyde, in vol. iv. p. 349.

Chloraldehydes. *Monochloraldehyde*, C^2H^3ClO , is produced by passing vinyl chloride into well-cooled hypochlorous acid. It is a neutral, oily, easily decomposable liquid, which on exposure to the air is converted into chloroacetic acid (Saytzeff & Glinsky, *Zeitschr. f. Chem.* [2] iii. 675). On leaving it to stand at a lower temperature, in a well-stopped flask in contact with hypochlorous acid and excess of mercuric oxide, a crystalline crust is formed at the bottom of the vessel, consisting of a compound of chloraldehyde with calomel, $C^2H^3ClO.Hg^2Cl^2$. This compound melts at 96° to a transparent mass, gradually changing to a crystalline powder. In cold aqueous solution it is slowly resolved into calomel and chloraldehyde. Hydrogen sulphide decomposes it immediately, precipitating the mercury, and setting the chloraldehyde free. Mixed in aqueous solution with iodide or cyanide of potassium, it is converted into iodoaldehyde or cyanoaldehyde (Glinsky, *ibid.* iv. 617).

Vinyl bromide passed into cold aqueous hypochlorous acid forms an easily soluble product, not volatile without decomposition, and probably consisting of a mixture of chloraldehyde and bromaldehyde (Saytzeff & Glinsky).

Dichloraldehyde, $C^2H^2Cl^2O$ (E. Paterno, *Giornale di Scienze nat. ed econom. di Palermo*, v. 123, 127).—Produced by distilling dichloroacetal with 4 to 6 vols. sulphuric acid in an oil-bath heated to 130° . On rectifying the distillate, the dichloraldehyde passes over at 88° – 90° . It is a liquid which boils at 89° – 90° , attracts moisture from the air, and is thereby converted into a hydrate crystallising in beautiful laminae. Left to itself, even in sealed tubes, it becomes dense, and changes into a white amorphous mass, which has the aspect of porcelain, but when heated to 120° is reconverted into the original product. Dichlorinated aldehyde dissolves without decomposition in alcohol and ether; when poured into water it first sinks to the bottom, and then dissolves, especially on application of heat; in short, it exhibits the most complete analogy with chloral. It is difficult to oxidise, its vapour not undergoing any sensible alteration when mixed with air or oxygen and passed over red-hot spongy platinum; but when gently heated with several times its own volume of fuming nitric acid, it is energetically attacked and converted into *dichloroacetic acid*, $C^2H^2Cl^2O^2$. Phosphorus pentachloride attacks it strongly, producing the compound $C^2H^2Cl^4O$ or $C^2H^2Cl^3O.C^2H^2Cl^4$, the action doubtless consisting in the replacement of O by Cl^2 (as in the action of PCl^3 on aldehydes in general), whereby $C^2H^2Cl^4$ is produced, which, as soon as it is formed, unites with a portion of the undecomposed dichlorinated aldehyde, producing the compound $C^4H^4Cl^4O$. The constitution of this body may be represented by the following formula:

or perhaps by

The compound $\text{C}^4\text{H}^2\text{Cl}^6\text{O}$ is a colourless oil, having an irritating odour, heavier than water, soluble in alcohol and ether; it distils at 250° , emitting acid vapours. Alcoholic potash attacks it strongly, with evolution of heat and formation of potassium chloride; and on adding water to the resulting liquid, a heavy aromatic oil separates, boiling at 196° , and having the composition $\text{C}^4\text{H}^2\text{Cl}^4\text{O}$, that is to say, containing 2HCl less than the preceding. This last compound unites directly with 4 at. bromine, forming the crystalline compound $\text{C}^4\text{H}^2\text{Cl}^4\text{Br}^4\text{O}$. In this respect the compound $\text{C}^4\text{H}^2\text{Cl}^4\text{O}$ is analogous to Malaguti's *chloroxéthose*, $\text{C}^4\text{H}^2\text{O}$, which he obtained by abstracting 4 at. chlorine from perchlorinated ethylic oxide, $\text{C}^4\text{Cl}^4\text{O}$ (i. 924). According to this analogy, the compound $\text{C}^4\text{H}^2\text{Cl}^4\text{O}$ may be designated as *hexchlorinated ethylic oxide*, and $\text{C}^4\text{H}^2\text{Cl}^4\text{Br}^4\text{O}$ as *tetrachloro-tetrabrominated ethylic oxide*. The two compounds $\text{C}^4\text{Cl}^4\text{O}$ and $\text{C}^4\text{H}^2\text{Cl}^4\text{O}$ may also be regarded respectively as *perchlorinated vinyl oxide*, $\text{C}^2\text{Cl}^2\text{O}$, and *tetrachlorinated vinyl oxide*.

Iodinaldehyde, $\text{C}^2\text{H}^2\text{IO}$, is produced by boiling the aqueous solution of monochloraldehyde with potassium iodide, and may be dissolved out by ether from the solution, after the latter has been left to itself for about twelve hours. On evaporating the ether, iodinaldehyde remains as a liquid, which at first is tolerably mobile, and has a faint odour like that of aldehyde, but after a while becomes thicker and acquires a stronger odour. It is decomposed by distillation, giving off aldehyde and its polymerides, and leaving a residue chiefly consisting of iodine. A similar decomposition takes place when the aqueous solution is heated. When oxidised in ethereal solution, with a few drops of fuming nitric acid, it is converted into iodoacetic acid, $\text{C}^2\text{H}^2\text{IO}^2$ (Glinsky, *Zeitschr. f. Chem.* [2] iv. 618).

Cyanaldehyde, $\text{C}^2\text{H}^2(\text{CN})\text{O}$, separates in heavy oily drops on adding potassium cyanide to an aqueous solution of monochloraldehyde. It is sparingly soluble in water; decomposes easily in the moist state and in aqueous solution; cannot be distilled; does not unite with sodium bisulphite. By oxidation with nitric acid it is converted into cyanacetic acid (Glinsky).

ALDEHYDES. These bodies are derived from alcohols by elimination of one or more molecules of hydrogen, (H^2), without the introduction of an equivalent quantity of oxygen, so that they hold a position intermediate between the alcohols and the acids; e.g.,

The hydrogen eliminated in the conversion of an alcohol into an aldehyde is that which is in immediate connection with the hydroxyl, or which belongs to the group CH^2OH ; consequently a monatomic alcohol can yield but one aldehyde; but a diatomic alcohol may yield two, by removal of H^2 and of 2H^2 ; a triatomic alcohol three, and so on. At present, however, we are acquainted only with aldehydes derived from monatomic and diatomic alcohols, and even among these it is only the series of aldehydes derived from the monatomic alcohols of the series $\text{C}^n\text{H}^{2n+2}\text{O}$ and $\text{C}^n\text{H}^{2n+4}\text{O}$ that exhibit any approach to completeness.

The statement in vol. i. p. 110, that monatomic aldehydes are the ethers of diatomic alcohols, was founded on observations which subsequent investigation has shown to be inexact; the aldehydes are isomeric, not identical, with the ethers of diatomic alcohols.

To the list of monatomic aldehydes, $\text{C}^n\text{H}^{2n+2}\text{O}$, corresponding to the fatty acids, must now be added the first of the series, namely, formic aldehyde, CH^2O , recently discovered by Hofmann (*Proc. Roy. Soc.* xvi. 156). It is produced when a current of air, charged with vapour of methyl alcohol, is directed upon an incandescent spiral of platinum wire; by suitable condensing arrangements, a liquid may be obtained consisting of a solution of the aldehyde in methyl alcohol. This liquid, rendered slightly alkaline by ammonia, and gently warmed with silver nitrate, yields a beautiful specular deposit of silver, with greater ease even than ordinary acetic aldehyde. The same solution, heated with a few drops of caustic potash, deposits drops of a brownish oil, having the odour of the resin of acetic aldehyde.

Formic aldehyde has not yet been obtained in the pure state; but by treating its solution with hydrogen sulphide, and heating the resulting liquid with strong hydro-

chloric acid, it solidifies, on cooling, to a dazzling white mass of felted needles, consisting of the corresponding sulphur-compound, CH_2S .

To the list of aromatic aldehydes, $\text{C}^7\text{H}^{2n-8}\text{O}$, must be added toluic aldehyde, $\text{C}^7\text{H}^6\text{O} = \text{C}^6\text{H}^5\cdot\text{CHO}$, produced by distilling a mixture of the calcium-salts of toluic and formic acids (v. 864); and syccocerylic aldehyde, $\text{C}^{12}\text{H}^{20}\text{O}$, which appears to be formed by oxidation of syccocerylic alcohol (v. 646).

Reactions of Aldehydes.—The following reactions, in addition to those mentioned in vol. i., are common to all the monatomic aldehydes.

1. By fusion with *potassium hydrate*, they are converted into the corresponding acids, with evolution of hydrogen:

2. *Nascent hydrogen*, evolved by the action of water on sodium amalgam, converts them into the corresponding alcohols; e.g., $\text{C}^2\text{H}^4\text{O} + \text{H}^2 = \text{C}^2\text{H}^6\text{O}$. If, however, the aldehyde belongs to a non-saturated series, the action goes further, an additional quantity of hydrogen being taken up, whereby the alcohol first formed is converted into a saturated alcohol belonging to another series; thus:

and

Nascent hydrogen evolved by the action of zinc on sulphuric acid does not appear to unite with aldehydes.

Benzoin aldehyde, under the influence of nascent hydrogen evolved by the action of zinc on hydrochloric acid, doubles its molecule and takes up 2 at. of hydrogen:

3. *Phosphorus pentachloride* converts aldehydes into chloraldehydes, compounds derived from aldehydes by substitution of Cl^2 for O; thus:

The compounds thus produced are isomeric with the chlorides of the olefines, and with the monochlorinated chlorides of the corresponding monatomic alcohols; e.g.,

Ethylidene chloride, $\text{CH}^3\cdot\text{CHCl}^2$, is identical with chlorinated ethyl chloride.

4. *Chlorine* and *bromine* convert aldehydes into chlorides of acid radicles:

5. The *alkali-metals* dissolve in aldehydes, eliminating an equivalent quantity of hydrogen:

or possibly as follows:

6. Aldehydes treated with *hydrocyanic acid*, *hydrochloric acid*, and *water*, are

converted into an ammonium-salt, or an amidated acid, containing an additional atom of carbon, the former reaction taking place chiefly in the aromatic series, the latter in the fatty series :

7. All aldehydes combine with *aniline*, the reaction taking place between 2 molecules of aniline and 1 or 2 molecules of the aldehyde, with elimination of 1 or 2 molecules of water; thus :

The resulting compounds are isomeric with the diamines derived from the glycols. This reaction is perfectly general, and may be used, as well as the reaction with alkaline bisulphites, for the recognition of aldehydes (Schiff, *Ann. Ch. Pharm. Suppl.* ii. 343; *Jahresb.* 1864, p. 413).

8. Aldehydes also form crystalline compounds with the *acid sulphites of monamines*; thus valeraldehyde forms with amylamine bisulphite the compound $\text{C}^5\text{H}^{13}\text{N}.\text{SH}^2\text{O}^2$, $\text{C}^2\text{H}^4\text{O}$; and similar compounds are formed by *cinnanthol* and bitter almond oil. These compounds are soluble in water and in alcohol; they decompose at 100° , water and sulphurous anhydride being given off, and the aldehydes reacting with the bases so as to form diamines like those above mentioned (Schiff, *Zeitschr. f. Chem.* [2] iv. 11).

9. Aldehydes act upon *urea*, either in the solid state or in alcoholic solution, in such a manner as to form condensed ureas containing aldehyde-residues,—compounds which may be represented by the general formula

and by further treating these products with aldehydes, ureas of a still higher degree of condensation are obtained. A solution of urea in absolute alcohol forms with *cinnanthol* colourless needles of *cinnanthyl-diurea*, $(\text{CO})^2\text{N}^2\text{H}^4(\text{C}^7\text{H}^{11})^2$. By the direct action of *cinnanthol* on solid urea, *dicinnanthyl-triurea*, $(\text{CO})^3\text{N}^3\text{H}^6(\text{C}^7\text{H}^{11})^3$, is produced; and these compounds heated to 100° with *cinnanthol* are converted respectively into *tricinnanthyl-tetra-urea*, $(\text{CO})^4\text{N}^4\text{H}^8(\text{C}^7\text{H}^{11})^4$, and *pentacinnanthyl-hexurea*, $(\text{CO})^5\text{N}^5\text{H}^{10}(\text{C}^7\text{H}^{11})^5$. Similar compounds are obtained with benzoic aldehyde. All these compounds are resolved by boiling water into aldehydes and urea, and by heating above their melting points, into decomposition-products of urea, and ammonia derivatives of the aldehydes (II. Schiff, *Compt. rend.* lxx. 801; *Jahresb.* 1867, p. 498).

In addition to these general reactions, there are others which are limited to particular classes of aldehydes.

The aldehydes $\text{C}^2\text{H}^4\text{O}$ are resinified by *alcoholic potash*; unite directly with *ammonia*, forming crystalline compounds; are oxidised by *nitric acid*, without formation of substitution-products; and have a great tendency when left to themselves to change into polymeric compounds. Heated with *slaked lime*, they yield the calcium salt of the corresponding acid, together with the corresponding alcohol; e.g.,

When *hydrochloric acid gas* is passed into a solution of one of these aldehydes in absolute alcohol, a compound is formed containing the elements of the aldehyde and those of ethylic chloride: e.g.,

The chlorinated compounds thus formed are isomeric with the glycolic chlorhydrins; thus the ethylic compound formed as above is isomeric with glycolic or ethylene,

ethyl-chlorhydrin, $\begin{array}{c} \text{CH}^2\text{Cl} \\ | \\ \text{CH}^2(\text{OC}^2\text{H}^5) \end{array}$. When treated with *sodium ethylate*, they exchange their chlorine for oxethyl, OC^2H^5 , forming compounds called *acetals*, containing the elements of the aldehyde and ethylic oxide, and isomeric with the glycolic ethers; thus in the acetic series:

Acrolein or acrylic aldehyde, $\text{C}^3\text{H}^4\text{O}$, the only known aldehyde of the series $\text{C}^n\text{H}^{2n-2}\text{O}$, is similar in most of its reactions to the aldehydes $\text{C}^n\text{H}^{2n}\text{O}$, but when submitted to the action of powerful oxidising agents it yields, not only acrylic acid, $\text{C}^3\text{H}^3\text{O}^2$, but likewise a small quantity of acetic acid, $\text{C}^2\text{H}^4\text{O}^2$.

The aromatic aldehydes, $\text{C}^n\text{H}^{2n-8}\text{O}$, are not resinified by *alcoholic potash*, but acted upon in the same manner as the aldehydes $\text{C}^n\text{H}^{2n}\text{O}$ are acted upon by slaked lime, yielding the corresponding acid and alcohol; e.g.,

Ammonia does not combine directly with them, but converts them into hydramides, with elimination of water. With fuming *nitric acid* they form nitro-substitution-products, benzoic aldehyde, for example, yielding nitrobenzoic aldehyde, $\text{C}^7\text{H}^5(\text{NO}^2)\text{O}$. When left to themselves they do not form polymeric compounds; but benzoic aldehyde, mixed with hydrocyanic acid, is converted under the influence of alcoholic potash into benzoin, $\text{C}^7\text{H}^6\text{O}^2$.

Cinnamic aldehyde, $\text{C}^9\text{H}^8\text{O}$, the only known member of the series of unsaturated aldehydes, $\text{C}^n\text{H}^{2n-10}\text{O}$, yields by oxidation, benzoic acid, $\text{C}^7\text{H}^5\text{O}^2$, as well as cinnamic acid, $\text{C}^9\text{H}^8\text{O}^2$.

Constitution of Monatomic Aldehydes.—It has been pointed out in the article ALDEHYDES in vol. i. that monatomic aldehydes may be formulated either as hydrides of monatomic oxygenated radicles, or as hydrates of monatomic non-oxygenated radicles, or as oxides of diatomic non-oxygenated radicles: thus for acetic aldehyde we have the three rational formulæ:

The first of these formulæ corresponds to the conversion of aldehydes into acids by oxidation, and by fusion with potash (p. 78); the second, to certain reactions which have been observed only with acetic aldehyde, viz. its conversion into chlor-ethylidene, $\text{C}^2\text{H}^3\text{Cl}$, by the action of carbonyl chloride (i. 107), and into vinyl oxide, $(\text{C}^2\text{H}^3)^2\text{O}$, with elimination of water, by the action of certain salts: $2\text{C}^2\text{H}^3\text{OH} - \text{H}^2\text{O} = (\text{C}^2\text{H}^3)^2\text{O}$. The third formula corresponds to the action of phosphorus pentachloride (p. 78), whereby an aldehyde $\text{C}^n\text{H}^{2n}\text{O}$ is converted into the chloride $\text{C}^n\text{H}^{2n}\text{Cl}^2$; to the action of aniline on aldehydes in general; and to that of ammonia on the aromatic aldehydes.

It is clear that these three formulæ are all included in, and may be deduced from, the constitutional formula

which accordingly applies to all the reactions and all the modes of formation of monatomic aldehydes.

Aldehydes derived from Diatomic Alcohols.

A diatomic alcohol may give rise to two aldehydes, one corresponding to the monobasic, the other to the bibasic acid derived from it. Thus propylene alcohol, $\text{C}^3\text{H}^5\text{O}^2$, might yield the two aldehydes $\text{C}^3\text{H}^4\text{O}^2$ and $\text{C}^3\text{H}^3\text{O}^2$, the first corresponding to lactic, the second to malonic acid:

Only a very few of these aldehydes have, however, been obtained.

Of aldehydes derived from the glycols, $C^2H^{2n+2}O^2$, only one is known, namely glyoxal, $C^2H^2O^2 = \begin{matrix} COH \\ | \\ COH \end{matrix}$, the second aldehyde of ethylene alcohol. This compound

has not, however, been actually formed from glycol, but only by oxidation of ethylic alcohol. By a small quantity of nitric acid it is oxidised to glyoxylic acid, $C^2H^2O^4$; by a larger quantity, to oxalic acid, $C^2H^2O^4$. For its other reactions see ii. 920.

Of aldehydes derivable from diatomic alcohols belonging to the other series, and corresponding to monobasic acids, three only are known, viz. salicyl, anisic aldehyde, and furfural; the relations of these bodies to the corresponding alcohols and acids are shown in the following table:

ALCOHOLS.	ALDEHYDES.	ACIDS.
$C^7H^8O^4$ Saligenin.	$C^7H^8O^2$ Salicyl.	$C^7H^8O^4$ Salicylic acid.
$C^8H^{10}O^2$ Anisic alcohol.	$C^8H^{10}O^2$ Anisal.	$C^8H^{10}O^4$ Anisic acid.
$C^8H^{10}O^2$ Pyromucic alcohol.	$C^8H^{10}O^2$ Furfural.	$C^8H^{10}O^4$ Pyromucic acid.

Salicyl, $C^7H^8O^2 = \begin{matrix} OOC^6H^3 \\ | \\ O > C - H \end{matrix} = C \begin{Bmatrix} OC^6H^3 \\ O^- \\ H \end{Bmatrix}$, is produced by the action of oxi-

dising agents on saligenin, or on salicin, which is a glucoside of saligenin; or on populin, which has the composition of benzoyl-salicin. It is converted by oxidising agents into salicylic acid, and by ammonia into hydro-salicylamide (v. 168). It exhibits the characters of an aldehyde in forming crystalline compounds with alkaline bisulphites, and resembles the phenols in forming saline compounds when acted upon by metallic oxides and hydrates, the metal then taking the place of an atom of hydrogen in the phenyl molecule: thus, sodium salicyl = $C^7H^7NaO.CO.H$; cupric salicyl = $(Cu^{II}(OC^6H^3)(COH))^2$, &c. Sodium salicyl, treated with methyl-iodide, yields methyl-salicyl, $C^8H^9(CH^3)O.CO.H$, a compound exhibiting properties analogous to those of salicyl itself. Ethyl-salicyl, $C^9H^{11}(C^2H^5)O.CO.H$, is obtained in a similar manner. By treating sodium salicyl with acetic oxide, aceto-salicyl, $C^9H^{10}O^2$, is obtained; thus:

This compound is isomeric with coumaric acid (ii. 93). By peculiar treatment in the process of preparation it may be deprived of a molecule of water, and then yields a crystalline substance, $C^9H^8O^2$, identical in every respect with coumarin, the odorous principle of the Tonka bean. Further, by treating sodium salicyl with butyric and valeric oxides, butyro-salicyl, $C^{11}H^{14}(C^4H^7O)O.CO.H$, and also valero-salicyl, $C^{12}H^{16}(C^5H^9O)O.CO.H$, are obtained, and these yield by dehydration corresponding homologues of coumarin (Perkin, *Chem. Soc. J.* [2] vi. 53, 181). For details respecting all these compounds see the article SALICYL in this volume.

Anisic aldehyde, anisol, or anisyl hydride, $C^8H^{10}O^2$, is formed, together with anisic acid, by oxidation of anisic alcohol in contact with platinum-black, or, together with oxalic acid, by oxidising anise-oil with warm nitric acid (i. 307). It is converted by oxidation into anisic acid, by ammonia into anisidramide, $C^{10}H^{14}O^2.N^2$, and by alcoholic potash into potassium anisate and anisic alcohol:

Furfural, $C^8H^{10}O^2$, the oily liquid produced by distilling bran with dilute sulphuric acid, is shown to be the aldehyde of pyromucic acid by being converted into that acid by oxidation (ii. 752), and into pyromucic acid and the corresponding alcohol by treatment with alcoholic potash (iv. 765):

There is but one known aldehyde corresponding to a bibasic acid, viz. phthalic aldehyde, $C^8H^6O^2 = C^6H^4 \begin{Bmatrix} CO.H \\ CO.H \end{Bmatrix}$ derived from phthalic acid, $C^8H^4 \begin{Bmatrix} CO.OH \\ CO.OH \end{Bmatrix}$, by substitution of 2 atoms of hydrogen for two equivalents of hydroxyl. It is produced by the action of zinc and hydrochloric acid on phthalic chloride. The aldehyde, extracted from the product by ether and purified by combination with an alkaline bisulphite,

Sup.

G

&c., is a white substance having an aromatic odour. It melts at 65° , dissolves easily in alcohol and in ether, sparingly in cold, abundantly in hot water, and crystallises therefrom in small rhombic plates. The warm aqueous solution solidifies with sodium bisulphite to a crystalline mass composed of silky needles (Kolbe a. Wischin, *Chem. Soc. J.* [2] iv. 339).

ALDEHYDINE. $\text{NC}^{\text{H}}\text{H}^{\text{O}}$.—A base produced by heating a mixture of aldehyde-ammonia, urea, and ammonium acetate to 120° – 130° : $4(\text{C}^{\text{H}}\text{H}^{\text{O}}\cdot\text{NH}^{\text{A}}) = \text{NC}^{\text{H}}\text{H}^{\text{O}} + 3\text{NH}^{\text{A}} + 4\text{H}^{\text{O}}$. It is an oil, boiling at 175° , lighter than water, slightly soluble therein, slightly narcotic, smelling like conine, and containing 4H less than that base; it is *not*, however, converted into conine by treatment with sodium amalgam, and contains 1 mol. H^{O} less than Schiff's tetraldine. Aldehyde forms with hydrochloric acid an easily soluble salt, crystallising in needles. Platinic chloride converts it into a resin. With potassium ferricyanide and mercuric nitrate it forms crystalline precipitates (Ador a. Beyer, *Zeitschr. f. Chem.* [2] iv. 724).

ALIZAREIN. A solution of alizarin in ammonia, which is violet-red when recently prepared, turns blue in about two months at ordinary temperatures, or in 48 hours at 100° , and then yields with hydrochloric acid a violet-coloured precipitate of alizaroin or alizaramide, which appears to have the composition $\text{C}^{20}\text{H}^{12}\text{O}^6\cdot 3\text{NH}^{\text{A}}$, or, according to some analyses, $\text{C}^{20}\text{H}^{12}\text{O}^6\cdot 2\text{NH}^{\text{A}}$ [perhaps $\text{C}^{\text{H}}\text{H}^{\text{O}}\cdot 2\text{NH}^{\text{A}}$]. It is violet-red while moist, nearly black when dry, unalterable in the air, nearly insoluble in cold water, but soluble in alcohol, forming a reddish-violet solution, from which it is deposited by spontaneous evaporation as a crystalline powder (Schützenberger a. Paraf, *Zeitschr. Ch. Pharm.* 1862, p. 40; Stenhouse, *Proc. Roy. Soc.* xii. 638).

ALIZARIN. Wolff a. Strecker assigned to this body the formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, founded on certain relations which it was supposed to bear to naphthalene and phthalic acid (1. 113). Schunck, on the other hand, represented it by the formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, founded upon the analyses of alizarin itself, and of its compounds with bases; and finally Graebe a. Liebermann (*Bull. Soc. Chim.* ix. 297) assigned to it the formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, based upon the conversion of alizarin into anthracene, $\text{C}^{\text{H}}\text{H}^{\text{O}}$, by heating with zinc-dust:

The correctness of this formula has lately been strikingly confirmed by the further discovery of Graebe a. Liebermann (*Bull. Soc. Chim.* [2] xi. 516) that alizarin may also be produced from anthracene by the following series of processes, which neither increase nor diminish the number of carbon-atoms in the molecule:

1. Conversion of anthracene into oxanthracene or anthraquinone, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, by oxidation.
2. Conversion of this latter compound by the action of bromine into dibrom-anthraquinone, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Br}^2\text{O}^{\text{A}}$.
3. Conversion of dibromanthraquinone into alizarin, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$, by heating it with an alkali, the change consisting in the replacement of Br^2 by $(\text{OH})^2$. The details of the process will be given further on.

Further confirmation of the formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$ is afforded by some analyses of alizarin (from madder) made by Strecker in 1864 (*Zeitschr. f. Chem.* [2] iv. 263). Schunck's analyses also agree very nearly with the same formula.

According to Roehleder (*Ann. Ch. Pharm.* lxxii. 205), morindone, the substance obtained by the decomposition of morindin (iii. 1049) by heat, is probably identical with alizarin; and this view is corroborated by Stenhouse (*Chem. Soc. J.* [2] ii. 333), who indeed regards *Morinda citrifolia* as the best source of alizarin, since it yields that substance free from purpurin. W. Stein, on the other hand (*J. pr. Chem.* xvii. 234), denies the identity of morindone with alizarin, inasmuch as, according to his experiments, morindone gives with sulphuric acid an indigo-blue solution which afterwards turns purple-red, whereas alizarin gives at once a purple-red solution; ferric chloride colours the alcoholic solution of morindone blackish-green, that of alizarin red-brown; and lastly morindone when oxidised by nitric acid yields only phthalic acid, whereas alizarin yields both phthalic and oxalic acids. Stein gives provisionally for morindone the formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^{\text{A}}$. Respecting Bolley's views of the composition of alizarin and other colouring matters of madder see *Zeitschr. Ch. Pharm.* 1864, p. 174; 1866, p. 112; *Jahresb.* 1864, p. 544; 1866, p. 643).

Alizarin is reduced by nascent hydrogen. The violet-coloured solution of alizarin in potash turns brownish-yellow in contact with zinc or iron, and if then supersaturated with an acid, yields a brownish-yellow precipitate richer in hydrogen than alizarin. This substance is easily alterable; when heated it yields a red sublimate of regenerated alizarin, leaving an abundant carbonaceous residue, and is quickly reconverted into

alizerin by oxidation in alkaline solution (Bolley, *Jahresb.* 1866, p. 644). According to Schützenberger (*Dictionnaire de Chimie*), alizerin is also easily reduced in alkaline solution by stannous salts or by aldehyde, the solution changing from blue to orange, and yielding yellow flocks when saturated with an acid.

Alizerin treated with excess of hydriodic acid is converted into a mixture of hydrocarbons, chiefly saturated, the most abundant being sextane and octane:

(Berthelot, *Bull. Soc. Chim.* [2] ix. 207).

Alizerin treated with fuming nitric acid yields a yellow, crystalline, but very unstable, product, which when boiled with water, gives off nitrogen dioxide and yields a deposit of nitroxyalizerin, $C^4H^4(NO^2)O^4$. This compound is a red crystalline powder, which dissolves in alcohol and ether, with red colour also in potash, and with light-red colour in boiling alum-solution (Strecker, *Bull. Soc. Chim.* [2] xi. 260).

Preparation of Alizerin.—E. Kopp (*Bull. Soc. Chim.* [2] ii. 231) prepares pure alizerin from his green alizerin (see Madder, iii. 749) as follows. The green alizerin is boiled for about a quarter of an hour with 15 to 20 times its weight of hydrocarbon-oils or paraffins (obtained from any source whatever, purified by distillation over quicklime, boiling not above 160°); and the brownish-yellow oil, which quickly clarifies, is poured off as soon as it has cooled to 100° , and mixed, by repeated and violent agitation, with about $\frac{1}{10}$ of its bulk of weak soda-ley (5 to 8 per cent.). The violet-blue alkaline solution is then separated from the oil, and decomposed by dilute sulphuric acid, and the precipitate is purified by washing. Three or four boilings are sufficient for the complete exhaustion of the crude green alizerin. The black residue yields by oxidation with nitric acid a colouring matter called *xanthazarin* (v. 1049).

According to J. W. Young (*Chem. News*, xii. 296), small quantities of alizerin may be conveniently prepared by cautiously heating the residue of the alcoholic extract of good garancin in a porcelain dish covered with bibulous paper (pierced with holes?). The sublimed alizerin collects in a beaker glass inverted over the dish.

A method of preparing alizerin by the transformation of other colouring matters of madder is given by M. Martin of Avignon (*Bull. Soc. Chim.* [2] viii. 463).

According to Bolley (*Jahresb.* 1866, p. 644), purpurin is partially converted into alizerin by the action of a strong heat, in sealed glass tubes, between 210° and 220° .

Separation of Alizerin and Purpurin.—Purpurin dissolves pretty freely in water at 25° to 55° , whereas alizerin begins to dissolve only at 75° . A separation of these principles may therefore be effected by passing a jet of steam into water containing madder in suspension, at such a rate as to keep the temperature constantly at 55° , never allowing it to rise higher, and repeating this treatment till the wash-waters run off quite colourless. On adding lime-water, or, better, baryta-water, to these waters, purpurin is precipitated in the form of a lake, from which it may be separated by hydrochloric acid, and, if necessary, further purified by solution in wood-spirit. The madder thus freed from purpurin is next to be dried and treated several times with wood-spirit, in vessels heated by steam. The resulting solution, poured into cold water slowly and with constant stirring, deposits a hydrate of alizerin, less soluble than alizerin itself. The precipitate after desiccation is almost chemically pure alizerin. Madder thus treated yields from 2 to 3 per cent. of purpurin and 4 to 4½ per cent. of alizerin (Leitenberger, *Bull. Soc. Chim.* [2] x. 333).

Preparation from Anthracene.—The conversion of anthracene into alizerin is made, as already observed (p. 82), by three stages: (1) Anthracene, $C^{14}H^{10}$, is converted into anthraquinone (Anderson's oxanthracene), $C^{14}H^8O^2$, a compound related to anthracene in the same manner as ordinary quinone, $C^6H^4O^2$, to benzene, thus:

This transformation is effected either by heating 1 pt. anthracene with 3 pts. potassium dichromate and sulphuric acid, or by heating 1 pt. anthracene with 3 pts. potassium dichromate and 1 pt. glacial acetic acid. The anthraquinone thus obtained

* Respecting the molecular structure of anthracene and its derivatives, see AROMATIC SERIES.

is purified by washing with water and solution in alcohol or benzene, from which it crystallises in yellow needles.

2. The anthraquinone is either directly converted into dibromanthraquinone by heating it with bromine to 80°-130°:

or 1 mol. anthracene is treated with 8 at. bromine, whereby tetrabromanthracene is formed:

and this last compound is converted into dibromanthraquinone by means of either of the oxidising mixtures above mentioned. In this series of processes, chlorine may be used instead of bromine, but it does not appear to yield equally good results.

3. The transformation of dibromanthraquinone into alizarin is effected by heating it to 130°-260° with caustic potash or soda:

A blue colour is thereby produced, which gradually becomes deeper, the operation, being completed when the depth of the tint no longer increases. The saline mass, when cold, is treated with water, the solutions are filtered, and an acid is added in excess, whereby a yellow precipitate is formed, consisting of alizarin. This, after washing with water and drying at a gentle heat, is identical in every respect with alizarin obtained from madder, and yields exactly similar colours when used for dyeing and printing (Graebe & Liebermann, *Brevet*, No. 83,557; *Bull. Soc. Chim.* [2] xi. 516; *Moniteur scientifique*, No. 296, Avril 15^{me}, 1869; *Zeitschr. f. Chem.* [2] v. 602).

The formation of alizarin in this manner affords the first example of the synthetical product of a natural colouring matter. The process could not, however, be carried out on the manufacturing scale until some reagent had been discovered, less expensive than bromine, which could be used in its stead for effecting the conversion of the anthraquinone. This great improvement has been made by Perkin, who has shown that anthraquinone when strongly heated with sulphuric acid, is converted into *disulph-anthraquinonic acid*:

and that this acid heated with potassium hydrate to a temperature above 180°, becomes coloured and is converted into potassium sulphite and potassium alizarate:

The alizarin thrown down from this alkaline product by hydrochloric acid is generally of a bright yellow colour, and quite as pure as the analogous precipitate obtained when dibromanthraquinone is used.

The formation of alizarin, however, is not the primary result of the action of potash on the disulpho-acid, an intermediate compound being first formed, namely, *sulph-oxanthraquinonic acid*, thus:

This acid is crystalline and of a yellow or orange colour, easily soluble in water, and yields blue or violet solutions with alkalis. When heated with potash it decomposes, yielding sulphurous acid and alizarin (Perkin, *Chem. Soc. J.* [2] viii. 133).

ALKALIS. According to Debray (*Bull. Soc. Chim.* [2] v. 404), *phosphomolybdic acid* affords a delicate test for certain alkali-metals, as well as for ammonia and organic bases. Potassium, cesium, rubidium, and thallium are precipitated by it from acid solutions; sodium, lithium, and other metals give no precipitates. This test will indicate the presence of 1 pt. of potassium hydrate in 500 pts. of liquid. All the precipitates are yellow, very slightly soluble, and contain only very small quantities of the alkali-metal. The phosphomolybdic acid used for this reaction is prepared by boiling the yellow ammonium phosphomolybdate with nitromuriatic acid.

Böttger (*J. pr. Chem.* ci. 290) recommends the alcoholic extract of the leaves of *Coleus Verschoffeti* as a delicate test for alkalis. To prepare it, the fresh leaves are agitated with absolute alcohol acidulated with a few drops of sulphuric acid, and the

digestion is continued for twenty-four hours. The tincture imparts to paper a fine red colour, which is turned green by alkalis. Paper thus prepared is very sensitive; a strip of it held before a jet of coal gas is soon turned green by the ammonia in the gas.

A solution of sodium nitroprusside yields the well-known purple coloration with soluble metallic sulphides, but not with hydrogen sulphide. Hence a solution of this salt mixed with hydrogen sulphide affords an extremely delicate test of the alkalinity of a solution, such a mixture turning blue in contact, not only with free alkalis, but likewise with alkaline carbonates, bicarbonates, borates, silicates, phosphates, and, in short, with all salts of the alkali-metals which turn litmus-paper blue (Fihol, *Zeitschr. f. Chem.* [2] iv. 568).

Stolba (*ibid.* 94) recommends a solution of cupric silicofluoride as a precipitant for alkalis; it keeps well and does not corrode glass vessels.

ALKALOIDS. Compounds of alkaloids, natural and artificial, with iodine monochloride have been prepared by W. A. Tilden (*Chem. Soc. J.* [2] iv. 145). They are obtained by mixing the aqueous solution of iodine monochloride with the acidulated hydrochloride of the base. A precipitate is formed which soon becomes crystalline, and in some cases may be recrystallised without decomposition from hydrochloric acid. With tetraethylammonium chloride, fern-like crystals are formed containing $(C_2H_5)_4NCl \cdot I$ (v. 731); with triethylammonium chloride, the compound $(C_2H_5)_3HNCI \cdot I$, which crystallises in slender, easily decomposable needles. The caffeine compound $C_8H_{10}N_4O_2 \cdot HCl \cdot I$ forms crystals, apparently having the form of oblique rhombic prisms. The precipitate formed with quinine hydrochloride is yellow, and becomes darker in colour when recrystallised from dilute hydrochloric acid.

Periodides of several alkaloids have been obtained by Jørgensen (*Zeitschr. f. Chem.* [2] v. 673). (See the several ALKALOIDS.)

According to R. Palm (*Jahresb.* 1863, p. 433), many alkaloids combine with sulphur in one or more proportions. Some, as morphine, atropine, papaverine, form only monosulphides; others, as quinine, strychnine, codeine, thebaine, berberine, veratrine, delphinine, and aconitine, form monosulphides and polysulphides; and a few, as trimethylamine and conine, form monosulphides, polysulphides, and sulphhydrates. Some of the weaker bases, as cinchonine, brucine, narcotine, and emetine, do not combine with sulphydric acid. The sulphides corresponding to the metallic monosulphides are produced by mixing a salt of the alkaloid with a soluble metallic sulphide, or by precipitating the alcoholic solution of the base with hydrogen sulphide; the polysulphides, by precipitation with a metallic polysulphide (such as K_2S_3); the sulphhydrates of trimethylamine and conine, by saturating the base with sulphydric acid. The sulphur-compounds of the oxygenated bases are amorphous or crystalline, colourless, yellow, or red-brown precipitates, which, with a few exceptions, are decomposed by drying, or even by keeping.

Detection and Separation of Alkaloids.—According to J. Trapp (*Jahresb.* 1863, p. 702), the yellow pulverulent or flocculent precipitates produced in the acid solutions of many organic bases by phosphomolybdic acid are insoluble in dilute nitric acid, but easily soluble in ammonia and the fixed alkalis. The solutions of the several precipitates in ammonia exhibit the following colour-reactions:

	Precipitate.	Solution in Ammonia.	On boiling.
Aconitine	. . . yellow	blue	colourless.
Atropine			
Bebeerine			
Berberine			
Brucine	. . . orange	yellow-green . . .	brown.
Codeine	. . . yellow	green	orange-red.
Quinine	. . . yellow	insoluble . . .	colourless.
Quinidine			
Caffeine	. . . yellow	colourless	—
Conine	. . . yellowish-white . . .	light-blue	colourless.

With digitaline ($\frac{1}{10}$ of a grain) and phosphomolybdic acid there is formed a yellow liquid, which becomes green on boiling, deep indigo-blue on addition of ammonia, green again on heating, and then colourless.

Metatungstic acid (v. 311) is, according to Scheibler (*Jahresb.* 1860, p. 157), a more delicate reagent for alkaloids than phosphomolybdic acid, all such bases being precipitated by it in white flocks. For this reaction it is not necessary to use pure metatungstic acid, as it is produced equally well by a solution of a metatungstate

mixed with any mineral acid, or even by ordinary sodium tungstate mixed with phosphoric acid—the so-called *phosphotungstic acid*—inasmuch as phosphoric acid removes part of the base from an ordinary tungstate and converts it into a metatungstate. Some alkaloids, as morphine, narcotine, and nicotine, are also precipitated by the so-called *phosphantimonic acid*, prepared by dropping antimonious chloride into aqueous phosphoric acid (F. Schulze, *Ann. Ch. Pharm.* cix. 179).

Potassio-mercuric iodide, first recommended by De Vrij (*Jahresb.* 1867, p. 602) as a very delicate test for strychnine, likewise produces in solutions of nearly all non-volatile alkaloids, yellowish-white precipitates insoluble in acids and in dilute alkalis, slightly soluble in excess of the reagent, easily soluble in alcohol, and generally also in ether. Strychnine is precipitated from solutions containing only 1 pt. of the base in 100,000; with volatile bases the reaction is not delicate. Theobromine and caffeine, bitter principles, carbohydrates, and organic acids are not precipitated by potassio-mercuric iodide; but with albuminous and gelatinous substances, and with extractive matters, in presence of free acid (but not in alkaline solutions) it forms tenacious elastic precipitates (A. Valser, *Zeitschr. anal. Chem.* ii. 79). According to F. J. Mayer (*Ann. Ch. Pharm.* cxxxiii. 236), the precipitation of alkaloids from acid solutions may be effected as completely by potassio-mercuric iodide (in some cases also by mercuric bromide or cyanide) as by phosphomolybdic or phosphotungstic acid. It is best to apply this reagent to the solution obtained by treating either the vegetable substance itself or its aqueous extract with acidulated alcohol. The precipitates vary greatly in composition. They are, with a few exceptions (as with morphine), sparingly soluble in water, pulverulent, or (as with the volatile bases) resinous and gummy. To separate the base, the precipitate is triturated with stannous chloride and a sufficient quantity of potash-ley to render the mass strongly alkaline, and the basic is then extracted with ether or chloroform, or, if insoluble therein, with strong alcohol, after addition of pulverised sodium carbonate.

According to Dragendorff (*Zeitschr. anal. Chem.* v. 405), *potassio-bismuthous iodide* (prepared by treating sublimed bismuth iodide with a hot concentrated solution of potassium iodide, and mixing the decanted liquid with an equal volume of the same solution) may also be used for the precipitation of organic alkaloids. Its solution, slightly acidulated with sulphuric acid and added to the very dilute solutions of most vegetable alkaloids (likewise acidulated with sulphuric acid), forms almost instantly a flocculent precipitate having the colour of precipitated antimonious sulphide. The double chlorides of iridium and rhodium also give precipitates with some bases (strychnine and brucine).

A volumetric process for estimating morphine and other alkaloids by means of potassio-mercuric iodide has been given by F. F. Mayer (see MORPHINE, iii. 1053).

The following alkaloids are precipitated by *potassio-cadmic iodide*, even from very dilute solutions acidulated with sulphuric acid: nicotine, conine, piperine, morphine, codeine, thebaine, narcotine, quinine, quinidine, cinchonine, strychnine, brucine, veratrine, berberine, atropine, hyoscyamine, aconitine, delphinine, emetine, curarine, and cytisine. The precipitates are white and flocculent at first, but mostly become crystalline. Quinine and strychnine are entirely precipitated, even when diluted with 10,000 pts. of water. These precipitates are insoluble in ether, soluble in alcohol, slightly soluble in water, soluble in excess of potassio-cadmic iodide. They give up their alkaloid when agitated with a suitable solvent, after addition of an alkali. They are closely analogous to the compounds of the alkaloids with the iodomercurides and iodobismuthides (Marmé, *Bull. Soc. Chim.* [2] ix. 203).

Respecting the precipitation of alkaloids by *sodium nitroprusside*, see Horsley (*Chem. News*, v. 355).

Many alkaloids and salts of alkaloids, when heated with an alkaline solution of *potassium permanganate*, give off half their nitrogen in the form of ammonia; such is the case with morphine, codeine, papaverine, strychnine, methylstrychnine-iodide, brucine, the sulphates of quinine and cinchonine, nicotine, naphthylamine, toluidine, and acetate of rosaniline. Creatine similarly treated gives off a third of its nitrogen as ammonia; theine, a fourth (Wanklyn and Chapman, *Chem. Soc. J.* [2] viii. 161).

Dragendorff recommends the use of *benzene* as a solvent for separating alkaloids from substances with which they may be mixed, as in toxicological investigations. The crude aqueous extract of the substance under examination is first freed from foreign substances by means of benzene, and after neutralisation more benzene is added to dissolve out the base. The separation of the benzene as a distinct layer is facilitated by heating the liquid to 50° or 60°, or by addition of a little alcohol. This mode of separation is applicable to strychnine, veratrine, atropine, aconitine, quinine, cinchonine, quinidine, codeine, narcotine, thebaine, papaverine, conine, and nicotine

(for the last two, however, and for atropine, on account of their volatility, ether is to be preferred to benzene). Caffeine, theobromine, colchicine, piperine, curarine, narcaine, and berberine cannot be separated in this way, because they are already dissolved out by benzene from the acid solution; neither can the method be applied to morphine or solanine, which are nearly insoluble in benzene.

β. To detect the presence of alkaloids in organic liquids, strychnine in beer for example, R. Wagner (*Zeitschr. anal. Chem.* iv. 387) mixes the liquid, diluted with 2 vol. water ($\frac{1}{2}$ to one litre), with about 5 c. c. of a solution of iodine in potassium iodide (12·7 grms. iodine to the litre), and a few drops of sulphuric acid; dissolves the precipitate, separated from the supernatant liquid, in a dilute solution of sodium hyposulphite, and separates it again by means of the iodine solution. If this new precipitate be now dissolved in aqueous sulphurous acid, the solution will leave on evaporation the pure sulphate of the base.

According to Grandeau (*Bull. Soc. Chim.* [2] ii. 74), alkaloids, such as morphine, brucine, and digitaline, contained in solutions, together with animal substances, (urine, &c.), may be easily separated from the latter by dialysis, and obtained in the pure state by treating the evaporated residue of the dialysate with alcohol. According to A. T. Machattie (*Chem. News*, x. 183), strychnine, as well as arsenious acid, may be separated by dialysis, if, instead of parchment paper, the membranes of the stomach or intestines be employed as the diaphragm.

Helvig has shown (*Zeitschr. anal. Chem.* iii. 43; *Jahresb.* 1864, 726) that many organic bases may be obtained in a state fit for microscopic examination by sublimation. A very small quantity of the finely pulverised base is cautiously heated on a piece of platinum foil, having a hemispherical depression in the middle, and covered at that part with a small glass plate such as are used for mounting microscopic objects; the sublimate then collects on the glass, and may be easily examined with a magnifying power of 80. Morphine thus treated yields a layer of round granules, which in contact with a drop of water, and somewhat more slowly with ammonia, are converted into six-sided prisms: with dilute hydrochloric acid, into tufts of long needles. Dilute chromic acid, on the contrary, does not give rise to any formation of crystals. The sublimate exhibits the reaction of morphine with iodic acid and starch, that is to say, it reduces the iodic acid, and consequently turns the starch blue. Strychnine yields a similar amorphous sublimate, which when moistened with water changes into four-sided prisms laid over one another in stars or crosses, with ammonia into quadrate octohedrons, or characteristic short, truncated, four-sided prisms. Hydrochloric acid forms, sometimes tufts of needles, sometimes broad four-sided prisms; dilute chromic acid forms the yellow stellate crystals and double pyramids of strychnine chromate; and strong sulphuric acid with potassium bichromate produces the well-known colorisation. Brucine yields a similar granular sublimate, which, however, seldom becomes crystalline with water or with hydrochloric acid, more easily with sulphuric or nitric acid, and is converted by ammonia into a deep yellow amorphous mass; with chromic acid, it gradually forms dark yellow stars or rosettes composed of short prisms. *Veratrine* sublimates in crystals, partly having the form of a rather long distorted rectangle, partly of stars composed of needles or four-sided laminae. *Aconitine* forms an amorphous sublimate, which in contact with ammonia produces characteristic crystalline formations like the tin-tree (needles arranged in cruciform groups). *Atropine* sublimates very easily in transparent drops, which in contact with hydrochloric acid change in the course of 24 hours into distinct octohedrons. *Solanine* sublimates as a network of tuft-like or lozenge-shaped groups of slender needles. *Digitaline* does not yield a characteristic sublimate.

On the microscopic characters of organic alkaloids, see also Helvig's *Das Mikroskop in der Toxicologie*, Mainz, 1864; Deane and Brady, *On Microscopic Research in Relation to Pharmacy* (*Chem. Soc. J.* [2] iii. 34); Wormly, *The Micro-chemistry of Poisons*, New York, 1867; Erhard (*N. Jahrb. Pharm.* xxv. 129, 193, 283; xxvi. 9, 129).

Alkaloids of Opium.—Kubly (*Jahresb.* 1866, p. 823) has determined the solubility of the several opium alkaloids in benzene and in amyl alcohol. The results obtained at ordinary temperatures are given in the following table:

100 pts. amyl alcohol dissolve :					100 pts. benzene dissolve :				
Morphine	0·260	Morphine	0		Narcotine	4·614			
Narcotine	0·325	Papaverine	2·73		Thebaine	5·27			
Papaverine	1·30	Codeine	9·66						
Thebaine	1·67								
Codeine	15·68								

If the solution of these bases obtained by extraction with acids be supersaturated with alkali, and repeatedly treated while warm with benzene, *narcotine*, *papaverine*, *thebaine*, and *codeine* will pass into solution; and the aqueous liquid will then give up to hot amyl alcohol the *morphine*, and after evaporation to dryness it will yield to hot ethyl alcohol the *narcotine*. For the approximate separation of the four bases first named Kuby treats the residue left on evaporation of the benzene with a small quantity of cold amyl alcohol, which dissolves chiefly the *codeine*; he then digests the residue with water containing acetic acid, to dissolve out the *papaverine* and *thebaine*, the *narcotine* remaining undissolved. *Papaverine* and *thebaine* may be separated in sulphuric acid solution by potassio-bismuthous iodide, which dissolves only the *thebaine*. The use of ethyl acetate (100 pts. of which dissolve 0.213 pts. *morphine*), instead of amyl alcohol, for extracting the *morphine*, is, according to Kuby, attended with considerable loss of the alkaloid.

Dragendorff (*Jahresb.* 1864, p. 727) has examined the reactions of the opium alkaloids with sulphuric acid, both pure and containing nitric acid. *Codeine* dissolves slowly in pure sulphuric acid, forming a greenish, or after a week an indigo-blue liquid, which becomes dark-brown at 150°, and after cooling with nitric acid nearly blood-red. With sulphuric acid containing nitric acid the same changes of colour take place, but more quickly. *Papaverine* is coloured dark bluish-violet, both by pure sulphuric acid and by that which contains nitric acid, and dissolves to a reddish-violet liquid, which does not alter at 150°. *Narcotine* forms a blood-red liquid, becoming dark-brown to garnet-coloured at 150°, and light red-brown after cooling with nitric acid. *Thebaine* forms a dark-red to orange-coloured solution, gradually turning to olive-green at 150°. *Porphyroxine* dissolves to a black-brown liquid becoming dark garnet-coloured at 150°. *Chelidonium* is coloured green by sulphuric acid containing nitric acid, at 150° olive-green, and after cooling with nitric acid dark-brown. When *morphine* is boiled with a not too dilute solution of phosphorus or hypophosphorous acid, and the liquid is then mixed with a large quantity of strong sulphuric acid, it assumes a reddish-violet colour, becoming yellowish with a little nitric acid; and if it be then warmed in contact with metallic copper, it gradually assumes a greenish and then a splendid blue colour. *Narcotine* boiled with hypophosphorous acid, and then poured into strong sulphuric acid, forms a dark cherry-red solution, becoming yellow with nitric acid, and gradually colourless in contact with copper.

Matthiessen a. Wright (*Proc. Roy. Soc.* xvii. 455, 460) have shown that *morphine* and *codeine* heated in sealed tubes with hydrochloric acid of ordinary strength are converted, by loss of the elements of water, into apomorphine, $C^{10}H^{13}NO^2$ (q.v.).

Alkaloid produced by Alcoholic Fermentation.—According to J. Oser (*J. pr. Chem.* ciii. 192), the fermentation of sugar by purified yeast is attended with the formation of an alkaloid containing $C^{12}H^{20}N^4$. Its hydrochloride dried in a vacuum forms a white very hygroscopic laminated mass, which quickly turns brown on exposure to the air, and has a burning taste with very bitter after-taste. This alkaloid appears to be formed from the azotised constituents of the yeast, and should be found in liquids produced by alcoholic fermentation, such as wine and beer.

ALLANTOÏN. $C^4H^4N^4O^3$.—This substance is converted by hydriodic acid into hydantoïn (iii. 177) and urea (Bayer, *Ann. Ch. Pharm.* cxviii. 178), and by water and sodium amalgam into glycoluril, $C^4H^4N^4O^2$ (v. 960) (Strecker a. Rheineck, *ibid.* cxxxi. 119):

ALLOCLASE. A mineral from Orowicza, in the Bannat, formerly regarded as a radial cobalt-glance. It occurs generally in steel-grey, broadly cauliflower aggregates, more rarely in separate crystals belonging to the rhombic system, and exhibiting the combination ∞P . $P\infty$. Angle $\infty P : \infty P = 106^\circ$; $P\infty : P\infty = 68^\circ$. Cleavage perfect, both prismatic and basal. Hardness above 4. Sp. gr. = 6.6. According to an analysis by Heine, it contains:

S	As	Bi	As	Fe	Zn	Co	Ni
16.22	32.69	30.15	0.68	5.58	2.41	10.17	1.55 = 99.45.

These numbers may be represented by the formula $Co^4As^{12}S^8$, or perhaps $3CoS \cdot 3CoAs^{12}S^8$, one-fourth of the arsenic being replaced by bismuth (Teichermak, *Mon. Abh. An. liti.* [1] 1; *Jahresb.* 1866, p. 913).

ALLOPHANIC ETHERS. *Ethyl allophanate* is produced, together with oxamide and alcohol, by heating urea with ethyl oxalate in a sealed tube to 135°–170° (Grabowski, *Ann. Ch. Pharm.* cxxxiv. 115):

Also, together with hydrochloric acid, by heating equivalent quantities of urea and ethyl chlorocarbonate (i. 916) in a flask provided with an ascending condenser:

(Wilm a. Wischin, *Zeitschr. f. Chem.* [2] iv. 5).

Phenyl Allophanate, $\text{C}^6\text{H}^5.\text{C}^2\text{H}^3\text{N}^2\text{O}^3$, is formed by passing cyanic acid vapour into perfectly anhydrous phenol. When dissolved out of the resulting pasty mass with alcohol, and precipitated by ether, it forms slender, inodorous, and tasteless crystals, *unctuous to the touch, insoluble in cold water.* At 150° it is resolved into phenol and cyanic acid. With alcoholic potash it forms potassium allophanate; with baryta-water, barium allophanate (Tuttle, *Jahresh.* 1857, p. 451).

Oxethyl-acetyl-allophanic Acid, $\text{C}^4\text{H}^{10}\text{N}^2\text{O}^5 = \text{C}^2\text{H}^2(\text{C}^2\text{H}^3\text{O})(\text{C}^2\text{H}^3\text{O})\text{N}^2\text{O}^3$ (also called *oxethyl-glycolyl-allophanic acid*).—An acid formed by heating potassium cyanate with ethyl monochloracetate:

When 100 grams of each of these substances are boiled for 15 hours with about 10 vol. of 90 per cent. alcohol, potassium chloride is separated; and the liquid, decanted while still hot and mixed with the alcohol used for washing the potassium chloride, separates, after distillation to $\frac{1}{10}$ of its volume, and admixture with ether, into a supernatant liquid and a semi-crystalline deposit. The liquid yields by spontaneous evaporation ethyl allophanate, formed by the action of alcohol and water on the potassium cyanate:

The lower layer, when treated with cold water, also yields a small quantity of ethyl allophanate, and the liquid decanted therefrom and mixed with dilute sulphuric acid, deposits after a while crystals of oxethyl-acetyl-allophanic acid. This acid separated from its lead-salt, crystallises in oblique rhombic tables, sparingly soluble in cold water, alcohol, and ether. Its potassium and sodium salts are very soluble and crystallisable; the barium salt, $\text{Ba}(\text{C}^4\text{H}^{10}\text{N}^2\text{O}^5)^2$, crystallises in microscopic rhombic tables; the lead-salt, $\text{Pb}(\text{C}^4\text{H}^{10}\text{N}^2\text{O}^5)^2$, in sparingly soluble needles; the silver salt is very soluble in water and decomposes when its solution is warmed.

Oxethyl-acetyl-allophanic acid is decomposed by heat, giving off cyanic acid. Boiled with strong potash-ley, it is resolved into glycollic acid, carbonic acid, alcohol, and ammonia:

It is not decomposed by nitric or nitrous acid. With strong sulphuric acid it turns brown and gives off a large quantity of carbon dioxide. By boiling with dilute sulphuric acid, it is converted into a new acid (likewise produced in the reaction of ethyl chloracetate on potassium cyanate), which neither crystallises nor forms crystalline salts. This acid is insoluble in ether, and is also converted into glycollic acid by boiling with potash (Saytzeff, *Ann. Ch. Pharm.* cxxxiii. 329).

ALLOXAN and ALLOXANTIN. The following method of preparing alloxan from crude uric acid, such as is extracted from guano, is given by Liebig (*Ann. Ch. Pharm.* cxlvii. 366; *Bull. Soc. Chim.* [2] xi. 152). The crude uric acid is added by small portions to nitric acid of sp. gr. 1.42, mixed with 8 to 10 parts of water and heated to 60° to 70°, whereupon abundant frothing takes place, accompanied by the emission of nitrous vapours. When the nitric acid no longer takes up the uric acid, and acquires the colour of onion-peel, the liquid is to be boiled and filtered. On adding to this liquor, which contains alloxan, a concentrated solution of tin in hydrochloric acid mixed with its own volume of that acid, a pulverulent precipitate is formed consisting of alloxantin, which is to be collected, washed, and dried. To recover this alloxantin into alloxan, it is moistened with a mixture of 2 parts fuming nitric acid (sp. gr. 1.52) and 1 part ordinary nitric acid (sp. gr. 1.42), whereupon small quantities of nitrous acid are evolved. The reaction is complete, and the mass being then completely soluble in water. This mass is to be dried.

tile, dried over the water-bath till all the nitric acid is driven off; and the alloxan is finally crystallised from water. This process yields nearly the theoretical quantity of alloxan.

Alloxan is formed, together with urea, by bringing bromine in contact with uric acid suspended in water:

If the mixture be heated during the reaction, parabanic acid, oxalic acid, and ammonium bromide are also formed. Chlorine and iodine act upon uric acid in the same manner (L. Hardy, *Bull. Soc. Chim.* [2] i. 445).

Anhydrous alloxan heated to 260° is converted into an isomeric modification which is soft and red, and when treated with bases forms salts, called by Hardy isalloxanates, which are isomeric with the alloxanates (i. 138). The ammonium and silver salts are red precipitates; the ammonio-argentic salt, $\text{C}^4\text{H}^2(\text{NH}^4)\text{AgN}^2\text{O}^3$, is a blue precipitate. The potassium, sodium, barium, strontium, calcium, lead, and mercury salts also form coloured precipitates (Hardy, *loc. cit.*).

Alloxan or alloxantin boiled for a long time with very dilute sulphuric acid yields a large quantity of ammonium hydruilate (iii. 220); with strong sulphuric acid, there is formed (together with dialuric acid) a sparingly soluble ammonium salt, which differs from the hydruilate in not producing a green colour with ferric salts. When a solution of alloxantin in 3 or 4 parts of strong sulphuric acid is heated as long as sulphurous oxide is evolved, and the resulting yellow solution is mixed with an equal volume of water, a sparingly soluble powder (amounting to 60 per cent. of the alloxantin) is separated, which is resolved by boiling with water into barbituric and parabanic acids. In one experiment, however, hydruilic acid was obtained instead of barbituric acid (Finck, *Ann. Ch. Pharm.* cxxii. 298).

Bromalloxan or *Dibromo-barbituric acid*, $\text{C}^4\text{H}^2\text{Br}^2\text{N}^2\text{O}^3$, is described among the derivatives of uric acid (v. 961).

ALLYL. C^3H^3 .—See DIALLYL (p. 92).

ALLYL ALCOHOL. $\text{C}^3\text{H}^4\text{O} = \text{C}^3\text{H}^3\text{OH}$.—Produced, together with isopropyl alcohol and acropinacone (p. 56), when acrolein is treated with zinc and hydrochloric acid: $\text{C}^3\text{H}^4\text{O} + \text{H}^2 = \text{C}^3\text{H}^4\text{O}$ (Linnemann, *Ann. Ch. Pharm. Suppl.* iii. 257). According to Tollens and Henninger (*Bull. Soc. Chim.* [2] xi. 394), the best mode of preparing this alcohol is to distil a mixture of glycerin and oxalic acid in certain proportions. Oxalic acid heated with glycerin is resolved, as is well known, into carbon dioxide and formic acid, which latter may be obtained by distilling the mixture with water (ii. 686), or, according to Lorin (*Jahresb.* 1865. p. 296), with a fresh quantity of oxalic acid. But if the mixture be continuously heated without addition either of water or of oxalic acid, the formic acid retained by the glycerin reduces it, and forms allyl alcohol,* which passes into the receiver:

Part of the alcohol is however converted into allyl formate.

Four parts of glycerin are heated with one part of crystallised oxalic acid in a retort provided with a thermometer, the receiver being changed when the temperature rises to 190° , and the distillation continued from that point to 260° . The distillate consists of aqueous allyl alcohol mixed with allyl formate, acrolein, glycerin mechanically carried over, and formic acid. The residue, which consists of glycerin, may be used for a fresh preparation of allyl alcohol by distillation with another portion of oxalic acid. To separate the allyl alcohol, the crude distillate is rectified; and the new distillate is dried over potassium carbonate, freed from allyl formate and acrolein by means of solid potash, again distilled, and freed from the last traces of water by rectification over anhydrous baryta. A quantity of allyl alcohol is thus obtained equal to one-fifth of the weight of the oxalic acid used.

The presence of an alkali in the oxalic acid, uncombined with a stronger acid, greatly interferes with the production of allyl alcohol: hence it is advisable to add from $\frac{1}{2}$ to

* The reaction really takes place by two stages, monoformin, $(\text{C}^3\text{H}^3)^n$, $(\text{OH})^n(\text{COOH})$ being first produced by the mutual action of the formic acid and glycerin, and then decomposed, as shown by the equation:

The monoformin may be isolated by heating the mixture of glycerin and oxalic acid to 100° and agitating it with ether.

4 per. cent. of hydrochloric acid or sal-ammoniac to the oxalic acid. The quantity of allyl alcohol produced is in direct proportion to the carbon dioxide evolved above 200°. Free sulphuric acid or a large quantity of hydrochloric acid should be avoided: the latter gives rise to the formation of mono-allylin, $C^3H^3(OH)(OC^3H^3)$ (Tollens, *loc. cit.*). According to Swartz (*Zeitschr. f. Chem.* [2] iv. 259), allyl alcohol is formed by heating dichlorhydrin, $C^3H^3Cl^2O$, with solution of potassium iodide:

Allyl alcohol boils at 91° (at 103° according to Hofmann a. Cahours), and solidifies at -54°. It is not completely dehydrated by potassium carbonate (Tollens a. Henninger). It is an unsaturated compound, capable of uniting with 2 atoms of bromine, chlorine, &c., and is not converted into propylic or isopropylic alcohol by the action of nascent hydrogen (Tollens, *ibid.* vi. 268). Its aqueous solution takes up 2 atoms of bromine, forming allyl-alcohol bromide, $C^3H^3OBr^2$, isomeric, or perhaps identical, with dibromhydrin. This bromide is a colourless oil, which boils at 219°, and, like dibromhydrin, is resolved by aqueous potash into potassium bromide and glycerin. By nascent hydrogen, evolved either by sodium amalgam or by zinc and dilute sulphuric acid, it is converted into a liquid, which appears to be identical with the original alcohol. On mixing it with zinc-ethyl in ethereal solution, a large quantity of combustible gas is evolved, and a white solid mass is formed, which when treated with water gives off gas, and is resolved into zinc-oxide and the original bromine-compound (Morkownikoff, *Jahresb.* 1864, p. 490). Allyl alcohol also unites with chlorine, forming several products, one of which, boiling at 180°-184°, has the composition of dichlorhydrin, $C^3H^3OCl^2$ (Tollens a. Henninger), and is reconverted into allyl alcohol by nascent hydrogen, like the bromide. Allyl alcohol also unites with iodine; forming a heavy, colourless liquid (Tollens).

ALLYL BROMIDES. The monobromide C^3H^3I , prepared by the action of phosphorus pentabromide on allyl alcohol, is a colourless liquid having an irritating odour; sp. gr. 1.4507 at 0°, 1.438 at 15°; boiling at 70° under a pressure of 753 mm. The isomeric compound bromopropylene boils at 62° according to Reynolds, at 54° according to Vogt. Allyl bromide is decomposed by potassium and silver salts; heated with potassium sulphide, it forms allyl sulphide, boiling at 140°. With alkaline sulphocyanates it yields allyl sulphocyanate, having the properties of volatile mustard-oil (Tollens, *Bull. Soc. Chim.* [2] xi. 397).

Allyl dibromide, $C^3H^3I^2$, and the corresponding iodide (i. 141, 142), are, properly speaking, diallyl compounds, C^3H^3Br and C^3H^3I (see DIALLYL).

The tribromide, $C^3H^3Br^3$, is converted by prolonged boiling with alcoholic potash into propargyl-ethyl ether, $(C^3H^3)C^2H^3O$ (*q.v.*) (Liebemann, *Ann. Ch. Pharm.* cxxxi. 123; cxxiv. 266).

ALLYL CHLORIDES. The monochloride, C^3H^3Cl , was obtained by Hofmann a. Cahours in the same manner as the monobromide (i. 142). Oppenheim (*Ann. Ch. Pharm.* cxl. 204) obtains it by heating allyl oxalate to 100° with an alcoholic solution of calcium chloride; calcium oxalate is then precipitated, and the liquid, mixed with water and distilled in the water-bath, yields allyl chloride. An easier mode of preparation is to mix allyl iodide with an equal volume of alcohol, and then with a slight excess of mercuric chloride. Mercuric iodide is then formed, with great evolution of heat, and on adding water to the distillate, a liquid separates containing allyl chloride in the portion boiling between 43° and 50°, and probably allyl-ethyl ether in the portion of higher boiling point. Allyl chloride has a sp. gr. of 0.9340 at 0°, and boils at 44°-45°. The isomeric compound chloropropylene has a sp. gr. of 0.9307 at 0°, and boils at 25-5°. The latter, when heated to 120° with sodium ethylate, is converted into allylene, but allyl chloride is converted by alcoholic potash-solution, even below 100°, into allyl-ethyl ether. The hydrogen in the allyl compounds appears to be more intimately united with the carbon than in the propylene compounds (Oppenheim).

Allyl trichloride, $C^3H^3Cl^3$, prepared by passing chlorine gas into allyl iodide covered with a layer of water, or by digesting the iodide with potassium bichromate and hydrochloric acid, is a colourless liquid having the odour of chloral, and not solidifying at -10°; sp. gr. = 1.41 at 0°. Boiling point between 164° and 167°, like that of the isomeric (or identical) compound, trichlorhydrin. It is not converted into allylene by potash or by sodium ethylate (Oppenheim, *Bull. Soc. Chim.* [2] ii. 97).

ALLYL IODIDE. C^3H^3I , is produced by slowly distilling a mixture of allyl alcohol, iodine, and red phosphorus. As soon as the allyl iodide has passed over, water must be added to distil off the residue; otherwise there will be danger of an

explosion (Tollens a. Henninger, *Bull. Soc. Chim.* [2] xi. 396). Also by distilling glycerin in excess with hydriodic acid:

If, on the other hand, the hydriodic acid is in excess, the chief product is isopropyl iodide (v. 800):

(Erlenmeyer, *Jahresh.* 1861, p. 667; 1866, p. 524). Hydriodic acid gas passed into allyl iodide converts it into isopropyl iodide, with separation of iodine: $C^3H^3I + 2HI = C^3H^3I + I^2$ (M. Simpson, *Proc. Roy. Soc.* xii. 533). Allyl iodide treated at ordinary temperatures with zinc, hydrochloric acid, and alcohol, yields propylene gas (Tollens a. Henninger). Heated to 100° in a sealed tube with zinc-ethyl, it yields diallyl, C^4H^4 , amylene, C^5H^{10} , and amyl hydride, C^5H^{12} . The formation of amylene is represented by the equation $C^3H^3 + C^2H^4 = C^5H^{10}$, and that of amyl hydride probably by the equation

(Wurtz, *Compt. rend.* liv. 387). With cacodyl, allyl iodide forms cacodyl iodide, $As^3(C^3H^3)^2I$ (arsenious ioddodimethide), and crystals of arsenic iodo-dimethyl-diallylido, $As^3(C^3H^3)^2(C^2H^5)^2I$, which when treated with moist silver oxide is converted into the strongly caustic alkaline base $As^3(C^3H^3)^2(C^2H^5)^2(OH)$ (Cahours, *Ann. Ch. Phys.* [3] lxii. 291).

The chloride, bromide, and iodide of allyl exhibit differences of boiling point nearly equal to those observed in the corresponding ethyl compounds; thus:

	Chloride.		Bromide.		Iodide.
Allyl	44.5°	— 25.5° —	70°	— 31° —	101°
	32.5°		30°		29°
Ethyl	12°	— 28° —	40°	— 32° —	72°

On the boiling points of allyl compounds, see also Oppenheim (*Zeitschr. f. Chem.* [2] v. 344); Tollens (*ibid.*).

Allyl Iododichloride, $C^3H^3ICl^2$, is produced by the action of iodine monochloride on allyl iodide:

When purified by washing with dilute potash, distilling, and collecting the portion which passes over between 205° and 210°, it forms a colourless oil, insoluble in water, and having a sweet but biting taste (M. Simpson, *Proc. Roy. Soc.* xiii. 540).

Diallyl Compounds.

Diallyl, C^4H^4 , or *Allyl in the free state*, was first obtained by Berthelot a. De Luca (i. 140) by treating allyl iodide with sodium. It is also produced: 1. Together with other hydrocarbons, by the action of allyl iodide on zinc-ethyl (Wurtz, *Compt. rend.* liv. 387; lvi. 351).—2. By treating allyl iodide with a pulverised alloy of 2 pts. tin and 1 pt. sodium. The action, which begins in the cold, is ultimately assisted by heat, and the crude hydrocarbon thus obtained is purified by heating it for a few hours with sodium, and distilling (Wurtz a. Leclanché, *Ann. Ch. Phys.* [4] iii. 120).—3. By reducing allyl iodide with iron (Linnemann, *Bull. Soc. Chim.* [2] vii. 424).—4. By dry distillation of mercuriallyl iodide (prepared by agitating crude allyl iodide with mercury and a small quantity of iodine):

The diallyl which passes over is purified by repeated rectification over sodium (Linnemann, *Ann. Ch. Pharm.* cxl. 180).

Diallyl is a pungent ethereal liquid boiling at 58° (Wurtz, Buff); sp. gr. = 0.681 at 0°, 0.688 at 17°, 0.6454 to 0.6459 at 58° (Buff, *Ann. Ch. Pharm. Suppl.* iv. 145). Vapour density, obs. = 2.92, calc. = 2.84. It dissolves in strong sulphuric acid, with evolution of heat, the solution on cooling depositing a hydrocarbon differing from diallyl. According to Schorlemmer (*Ann. Ch. Pharm.* cxxxix. 240), it forms with sulphuric acid a pitchy mass, together with hydrocarbons of the series C^2H^{2n-2} , analogous to those obtained from coal-naphtha.

Diallyl belongs to the series C^2H^{2n-2} , but is not a true homologue of acetylene and allylene, because its boiling point is lower than that of hexylene, C^6H^{12} , whereas the

boiling points of acetylene and allylene are above those of the corresponding olefines. Like all the hydrocarbons of the series, it is bivalent and quadrivalent, forming two groups of compounds containing respectively 2 and 4 atoms of univalent radicles.

I. DIALLYL COMPOUNDS CONTAINING TWO ATOMS OF UNIVALENT RADICLES (Wurtz, *Ann. Ch. Phys.* [4] iii. 129; *Jahresb.* 1862, p. 493; 1864, p. 611).—*Diallyl monohydrochloride*, $C^6H^{10}.HCl$, is produced, together with the dihydrochloride, by the action of hydrochloric acid upon diallyl. It is a liquid heavier than water, having a faint aromatic odour, boiling at 130° – 140° .

Monohydriodide, $C^6H^{10}.HI$.—Produced: 1. Together with the dihydriodide (*q.v.*), by the action of hydriodic acid upon diallyl. 2. Together with diallyl, by the action of alcoholic potash on the dihydriodide. Colourless liquid, of sp. gr. 1.497 at 0° , boiling at 164° to 166° . Treated for twenty-four hours with moist silver oxide, it yields, (1) diallyl and hexylene; (2) a liquid boiling at 130° – 140° , and probably identical with diallyl alcohol; (3) a liquid boiling at 180° , the ether of the same alcohol, $(C^6H^{10}.H)^2O$.

Monoacetate, $C^6H^{10}.H.C^2H^3O^2$.—Produced in the preparation of the diacetate, and contained in the liquid which distils at 110° – 160° . When purified by washing with sodium carbonate, drying, and fractional distillation, it is a colourless aromatic liquid, insoluble in water, of sp. gr. 0.912 at 0° , boiling at 150° – 160° . Slowly decomposed by strong boiling potash-ley, more quickly by distillation over solid potassium hydrate. Does not unite with acetic acid when heated with it to 140° .

Diallyl Monohydrate, $C^6H^{10}.H^2O$, or *Pseudo-hexylene Oxide*, $(C^6H^{12})^2O$.—This is the chief product of the action of moist silver oxide on allyl dihydriodide (*infra*). It is a colourless mobile liquid, insoluble in water, having a very pungent odour, a sp. gr. of 0.8387 at 0° , boiling at 92° – 95° . It is strongly attacked by *hydriodic acid* in concentrated aqueous solution, producing a mixture of diallyl dihydriodide, $(C^6H^{10}.HI)^2$, and a body isomeric or identical with hexylene iodhydrin, $C^6H^{12}\begin{Bmatrix} OH \\ I \end{Bmatrix}$, the latter being formed by direct combination. Heated with *acetic anhydride*, it yields a small quantity of diallyl diacetate, $C^6H^{12}O(C^2H^3O)^2O$, or $C^6H^{10}.HI^2(C^2H^3O)^2$. According to these two reactions, the compound may be regarded as pseudo-hexylenic oxide.

Diallyl Alcohol, $C^6H^{10}\begin{Bmatrix} H \\ OH \end{Bmatrix}$.—This compound, isomeric with the last, is produced by treating the monoacetate with solid potash, and is also found among the products of the action of moist silver oxide on the dihydriodide. It is a liquid, insoluble in water, having an aromatic odour, a sp. gr. of 0.8604 to 0.8625 at 0° , and boiling at about 140° . With strong aqueous hydriodic acid it becomes hot, and forms a mixture which, when heated to 100° , yields diallyl dihydriodide.

II. DIALLYL COMPOUNDS CONTAINING FOUR ATOMS OF UNIVALENT RADICLES.—A few of these compounds were obtained by Berthelot a. De Luca; the rest have been discovered and investigated by Wurtz (*loc. cit.*). The *tetrabromide*, $C^6H^{10}Br^4$, and *tetraiodide*, $C^6H^{10}I^4$, discovered by Berthelot a. De Luca, were originally regarded as allyl dibromide and di-iodide, $C^6H^8Br^2$ and $C^6H^8I^2$ (i. 141, 142). *Diallyl Tetranitrylide*, $C^6H^{10}(NO^2)^4$, is formed in white crystals on passing nitrogen tetroxide, N^4O^4 , into a solution of diallyl in anhydrous ether cooled with ice and salt (L. Henry).

Dihydrochloride, $C^6H^{10}.H^2Cl^2$.—Produced, together with the monohydrochloride, by heating diallyl for six or eight hours with fuming hydrochloric acid. The upper layer of liquid thereby produced, yields by fractional distillation, monohydrochloride at 130° – 140° , and dihydrochloride at 170° – 180° . The latter is also produced by heating the monohydrate or dihydrate of diallyl with strong hydrochloric acid. It is a colourless, heavy liquid, insoluble in water (Wurtz).

A *diallylic dichlorhydrin*, $C^6H^{10}\begin{Bmatrix} Cl^2 \\ (OH)^2 \end{Bmatrix}$, is produced by the combination of hypochlorous acid with diallyl. The two bodies unite readily, and with considerable evolution of heat, the diallyl, which is lighter than water, being converted into a heavy oil which sinks to the bottom (L. Henry, *Zeitschr. f. Chem.* [2] v. 479).

Dihydriodide, $C^6H^{10}.H^2I^2$.—Prepared by heating diallyl in a strong sealed flask for five or six hours with excess of highly concentrated hydriodic acid, and purified by washing with alkaline water, drying over calcium chloride, and heating in a vacuum to 130° – 140° , whereupon diallyl and the monohydriodide distil over, and pure dihydriodide remains. It is a transparent amber-yellow liquid, insoluble in water, of sp. gr. 2.024 at 0° , does not decompose or volatilise in a vacuum at 140° ,

but gives off iodine at a higher temperature. Treated with *sodium*, or, better, with an alloy of sodium and tin rich in sodium, it is converted partly into *hexylene*:

partly into diallyl monohydriodide:

the monohydriodide being at the same time resolved into several hydrocarbons of higher boiling point, among which is found the compound $C^{12}H^{22}$, boiling between 190° and 200° : $2(C^6H^{10}HI) + Na^2 = 2NaI + C^{12}H^{22}$. In contact with *alcoholic potash*, the dihydriodide is immediately decomposed, with formation of potassium iodide, diallyl, and the monohydriodide, the two latter distilling over with water:

and

Diacetate, $C^6H^{10}H^{12}(C^2H^3O^2)^2$.—Formed, together with other products, by treating finely divided silver acetate suspended in ether with an equivalent quantity of diallyl dihydriodide for twenty-four hours at ordinary temperatures. On distilling the filtered ethereal liquid, ether and a little diallyl pass over first; then, between 110° and 180° , acetic acid and diallyl monoacetate; afterwards diallyl hydroacetate, $C^6H^{10}H^{12}\{C^2H^3O^2\}$, boiling at about 210° ; and lastly diallyl diacetate, boiling at 225° – 230° . The latter is a thick colourless oil, having a slightly aromatic odour, insoluble in water, and having density of 1.009 at 0° . It is decomposed by potassium hydrate, yielding diallyl dihydrate (Wurtz).

Diallyl Dihydrate or *Pseudo-hexylene Glycol*, $C^6H^{14}O^2 = C^6H^{10}\{H^2(OH)^2\} = C^6H^{12}(OH)^2$, is obtained by decomposing diallyl diacetate, or the crude product of the preparation of that compound distilling between 190° and 230° , with a quantity of recently calcined and pulverised potassium hydrate, just sufficient to saponify the diacetate. Only half this quantity is however added at first, and the mixture, after having been heated for a short time, is distilled in an oil-bath at 300° . The distillate is rectified; the residual portion, boiling above 180° , is carefully treated with the remaining quantity of potash, added in two separate portions, till a distinct alkaline reaction is each time produced; and the product is rectified, the diallyl dihydrate passing over between 210° and 220° . It is a thick colourless syrup, having a sp. gr. of 0.9638 at 0° , and so expansible that its sp. gr. at 65° (referred to water at 0°) is only 0.9202. It boils between 212° and 215° , dissolves in water, alcohol, and ether, and does not decompose even at the boiling point of mercury. With *hydrochloric acid gas* it becomes hot without forming any new product; but when heated in a closed vessel with very strong aqueous *hydrochloric acid*, it forms diallyl dihydrochloride: $C^6H^{10}H^{12}(OH)^2 + 2HCl = 2H^2O + C^6H^{10}H^{12}Cl^2$. With concentrated *hydriodic acid* in like manner it forms diallyl dihydriodide (Wurtz).

Diallyl dihydrate is isomeric with normal hexylene glycol prepared by the usual series of reactions from hexylene (obtained from mannite, or from the hexyl hydride of American petroleum). Hexylene glycol, $C^6H^{12}(OH)^2$, boils at 215° – 220° , that is to say, 10° lower than diallyl-dihydrate; and hexylene diacetate, $C^6H^{12}(C^2H^3O^2)^2$, boils at 207° , or from 5° to 7° lower than diallyl diacetate.

The isomerism between normal hexylene glycol and diallyl dihydrate or pseudo-hexylene glycol may be represented by the following formulæ:

ALLYLAMINE. $(C^6H^3)H^2N$.—This base, discovered by Cahours and Hofmann, who obtained it by distilling allyl cyanate with potash (i. 146), is likewise produced

by the action of zinc and hydrochloric acid on an alkaline solution of allyl sulphocyanate (mustard oil) free from cyanate:

The acid solution freed from alcohol yields with potash a distillate, which, when neutralised with hydrochloric acid, first deposits crystals of sal-ammoniac, and afterwards deliquescent crystals of allylamine hydrochloride, soluble in strong alcohol. The base, $\text{C}^2\text{H}^3\text{N}$, separated from this salt by distillation with potash, forms a colourless, rather mobile liquid, having a burning, sharp taste and a pungent, ammoniacal, faintly allineous odour, which excites sneezing and lachrymation. Boiling point 58° ; sp. gr. = 0.864 at 15° . Burns with bright flame; mixes in all proportions with water, producing rise of temperature; has a strong alkaline reaction, and precipitates aluminic, ferric, mercuric, cupric, and argentic salts, the precipitates formed in the last two cases being soluble in excess of allylamine. Sulphate of allylamine forms feathery crystalline aggregates, permanent in the air. The platino-chloride, $\text{C}^2\text{H}^3\text{N}(\text{PtCl}^4)$, crystallises in orange-yellow monoclinic prisms flattened out into plates (C. Oeser, *Ann. Ch. Pharm.* cxxxiv. 7).

Dimonochlorallylamine, $\text{C}^2\text{H}^3\text{Cl}^2\text{N} = \text{C}^2\text{H}^3\text{Cl} \left\{ \begin{array}{l} \text{C}^2\text{H}^3\text{Cl} \\ \text{H} \end{array} \right\} \text{N}$, is produced, together with sal-

ammoniac, by heating trichlorhydrin, mixed with 7 or 8 vol. alcohol and saturated with ammonia gas, to 130° – 140° under pressure for a few days. The product is saturated with hydrochloric acid, and the hydrochloride of dimonochlorallylamine is dissolved out by absolute alcohol. The base separated from this salt by potash is an oil boiling at about 194° , heavier than water, slightly soluble therein, very soluble in alcohol and ether. The aqueous solution contains enough of the base to precipitate copper and silver salts. The base emits vapours even at ordinary temperatures. The hydrochloride, $\text{N}(\text{C}^2\text{H}^3\text{Cl})^2\text{H}^2\text{Cl}$, is soluble in water and alcohol, and separates from the latter in a mass of small deliquescent needles fusible below 100° . The platinochloride, $[\text{N}(\text{C}^2\text{H}^3\text{Cl})^2\text{H}^2\text{Cl}]^2.\text{PtCl}^4$, is a yellow crystalline precipitate, soluble in water, slightly soluble in alcohol, insoluble in ether (C. Engler, *Bull. Soc. Chim.* [2] ix. 134).

Dimonochlorallylethylamine, $\text{N}(\text{C}^2\text{H}^3\text{Cl})^2(\text{C}^2\text{H}^5)$, is formed by heating the preceding base to 100° in sealed tubes with a large excess of ethyl iodide. Separated by potash from the resulting hydriodide, it forms an oil boiling at a little above 200° , in other respects resembling the preceding. Its hydrochloride also has the aspect of that of dimonochlorallylamine, but it is much less soluble in water and in alcohol. The platinochloride, $[\text{N}(\text{C}^2\text{H}^3\text{Cl})^2\text{C}^2\text{H}^5.\text{HCl}]^2.\text{PtCl}^4$, is crystalline. The base treated with ethyl iodide yields a crystalline mass, probably consisting of $[\text{N}(\text{C}^2\text{H}^3\text{Cl})^2(\text{C}^2\text{H}^5)^2\text{I}]$ (Engler, *loc. cit.*).

ALLYL-ANILINE, $\text{N}(\text{C}^2\text{H}^3)(\text{C}^6\text{H}^5)\text{H}$, is produced by the action of allyl iodide on aniline (iv. 449).

ALLYLENE. C^3H^4 .—This hydrocarbon was discovered by Sawitsch (*Compt. rend.* lii. 399), who obtained it by the action of sodium ethylate on monobromopropylene:

For the mode of preparation see Appendix to vol. i. (p. 1112). It may be obtained in like manner by the action of sodium ethylate on monochloropropylene, $\text{C}^3\text{H}^3\text{Cl}$, produced by treating acetone with phosphorus pentachloride (Friedel, *Bull. Soc. Chim.* 1864, ii. 96). It likewise results from the action of sodium on the dichloride of dichloroacetone (or allylene tetrachloride), $\text{C}^3\text{H}^2\text{Cl}^4$ (Borsche a. Fittig, *Ann. Ch. Pharm.* cxxxi. 111), and on glycidic dichloride or tetrachloride, $\text{C}^3\text{H}^2\text{Cl}^2$ and $\text{C}^3\text{H}^2\text{Cl}^4$ (Pfeffer and Fittig, *ibid.* cxxxv. 257). The reaction in either case is very violent, and, to avoid explosion, it is necessary to mix the chlorine-compound with five or six times its volume of neutral hydrocarbons boiling at 100° – 120° (obtained by rectification of commercial benzol and purified by distillation from sodium). The mixture is gently heated, and the gaseous allylene which is given off is absorbed by an ammoniacal solution of cuprous chloride, from which it is separated by treating the resulting cuprous allylenide with dilute hydrochloric acid.

Allylene is a colourless gas, having an unpleasant odour, and burning with a bright and very smoky flame. It is very soluble in alcohol, and dissolves in water readily enough to render it necessary to add common salt to the water over which it is to be collected. With an ammoniacal solution of cuprous chloride it forms a canary-yellow precipitate; with mercurous nitrate, a dark-grey precipitate, which decomposes without detonation when heated; with silver nitrate, a white precipitate, which is decomposed

by heat, with explosion and production of a reddish flame. Allylene gently heated with sodium is partly decomposed, with formation of acetylene-sodium, separation of charcoal, and increase of the gaseous volume :

The residual gas contains a small quantity of propylene (Berthelot, *Jahresb.* 1866, p. 524). Allylene is absorbed easily and in large quantity by strong sulphuric acid, and may be thereby distinguished from acetylene, which is but slowly absorbed by sulphuric acid (Berthelot).

Allylene differs from the saturated hydrocarbon, propane or propyl hydride, C^3H^8 , by 4 atoms of hydrogen, and therefore acts as a quadrivalent radicle, taking 4 at. Br, Cl, &c., to form saturated compounds; but it can also form unsaturated compounds by combination with 2 at. of a univalent radicle, or 1 at. of a bivalent radicle.

In Hofmann's systematic nomenclature of hydrocarbons (*Proc. Roy. Soc.* xv. 57) allylene is designated as propine :

Bromine-compounds of Allylene (Oppenheim, *Bull. Soc. Chim.* [2] ii. 6; iv. 434).—When allylene is acted upon in the shade by bromine, added in drops or brought in contact with it in the state of vapour, a transparent liquid is formed, which is a mixture of the two bromine-compounds, $\text{C}^3\text{H}^4\text{Br}^2$ and $\text{C}^3\text{H}^4\text{Br}$; if, on the other hand, the action takes place in sunshine, hydrobromic acid is evolved, and a black, partially carbonised liquid is produced. The compounds formed in the shade, may be separated by distillation in a vacuum.

Allylene dibromide, $\text{C}^3\text{H}^4\text{Br}^2$, is a colourless, sweetish liquid, the vapour of which excites a copious flow of tears. Sp. gr. = 2.05 at 0° . It boils in the air without decomposition between 126° and 138° , the greater part distilling over at 132° . It is thereby distinguished from glycidic dibromide or epibromhydrin (ii. 899), which boils at 151° – 152° , and from dibromopropylene, which boils at 120° . It unites with bromine in the shade without elimination of hydrobromic acid.

Allylene tetrabromide, $\text{C}^3\text{H}^4\text{Br}^4$, the chief product of the action of bromine on allylene, is a colourless liquid having an odour of camphor and a sp. gr. of 2.94 at 0° . Under a pressure of 1 centimetre it distils almost completely between 110° and 130° , and under the ordinary atmospheric pressure it boils, with evolution of hydrobromic acid, between 225° and 230° , that is to say, nearly at the same temperature as dibromopropylene dibromide, $\text{C}^3\text{H}^4\text{Br}^2\cdot\text{Br}^2$ (226° according to Cahours). Mercury does not act upon it at 100° , but carbonises it completely at 130° . Heated with an alcoholic solution of potassium acetate, it decomposes in the manner shown by the equation :

Tribromopropylene, the chief product of this reaction, is a very stable, colourless liquid, which boils between 183° and 185° , and is thereby distinguished from the isomeric bromallylene bromide, $\text{C}^3\text{H}^4\text{Br}\cdot\text{Br}^2$, which Liebermann has obtained by the action of bromine on argentic allylene (*infra*), this latter compound being completely decomposed by boiling.

Iodine-compounds of Allylene. *Allylene di-iodide*, $\text{C}^3\text{H}^4\text{I}^2$, is most easily obtained by exposing allylene for two months to the action of a solution of iodine in potassium iodide, in bottles filled with the liquid and exposed to sunshine. After washing with potash it forms a slightly coloured oil, boiling at 198° , and having a sp. gr. of 2.62 at 0° . It turns brown when exposed to light, and is slowly attacked by acetate and oxalate of silver. With an alcoholic solution of potassium acetate it yields allylene and ethyl acetate (Oppenheim, *Bull. Soc. Chim.* [2] iv. 434).

Allylene dihydriodide, $\text{C}^3\text{H}^4\text{H}\cdot\text{I}^2$, isomeric with propylene di-iodide, is produced by direct combination of allylene with concentrated hydriodic acid (Oppenheim, *loc. cit.*; Semenov, *ibid.* [2] v. 446). It is a heavy, peculiar-smelling oil, having a sp. gr. of 2.15 at 0° (Oppenheim), 2.448 at 0° (Semenov). Boils with decomposition between 147° and 148° , but may be easily distilled in a current of steam or of any indifferent gas. It becomes coloured by exposure to air or light, dissolves sparingly in alcohol, easily in ether (Semenov).

The *monohydriodide*, $\text{C}^3\text{H}^4\text{HI}$, isomeric with allyl iodide, cannot be obtained by direct combination, but is produced by treating the dihydriodide with an equivalent quantity of potash in alcoholic solution, and mixing the distillate with water. It is a colourless, strongly refracting liquid, scarcely coloured by light, and having a strong,

but agreeable odour. It boils at 82° (Semenoff), 93° – 103° (Oppenheim), and has a sp. gr. of 1.8346 at 0° , or 1.8028 at 16° (Semenoff).

Chlorine-compounds. The chlorine-compounds of allylene have not been formed by direct combination, but compounds isomeric, or perhaps identical, with them have been obtained from other sources. Thus Borsche and Fittig (*Ann. Ch. Pharm.* cxxxiii. 111; *Jahresb.* 1865. p. 313) by treating acetone with chlorine have obtained compounds containing $C^3H^1Cl^2$ and C^3H^1Cl , the former boiling at 120° and the latter at 153° . The latter is identical with Linnemann's dichloroacetone dichloride (p. 27). By treating glycidic dichlorhydrin (epidichlorhydrin), $C^3H^1Cl^2$ (ii. 899), with chlorine, the same chemists have obtained the compound C^3H^1Cl , isomeric with the preceding, and distilling at 161° . Hübner & Geuther (*Ann. Ch. Pharm.* cxiv. 36), by treating acrolein with phosphorus pentachloride, have obtained a compound, $C^3H^1Cl^2$, which they designate as allylene dichloride. When purified by washing with water, desiccation with calcium chloride, and rectification, it is a colourless oil of sp. gr. 1.17 at 27.5° , having a sweetish ethereal odour, like that of chloroform, and boiling at 84.4° . It is distinguished from epichlorhydrin by not being acted upon by sodium. Another body having the same composition appears to be formed at the same time.

By heating 1 molecule of the chloride just mentioned with 2 molecules of silver acetate, Hübner and Geuther have obtained a compound which they regard as allylene diacetate:

The same compound is obtained by heating equivalent quantities of acrolein and acetic anhydride in closed vessels. It is a colourless liquid, having an acrid taste and fishy odour; sp. gr. = 1.076 at 22° ; distilling at about 130° . It slowly reduces an ammoniacal solution of silver nitrate, and when heated with potash yields potassium acetate and acrolein.

Substitution-derivatives of Allylene.

Argentallylene, C^3H^1Ag , is produced by the action of allylene on an ammoniacal solution of silver nitrate, as a very light white precipitate, altering like silver chloride when exposed to light. Acids decompose it, reproducing allylene. When thrown on bromine or on phosphoric or antimonie chloride, it takes fire, and burns with a hissing noise. It may be dried between 60° and 70° , and detonates at about 150° without previous fusion, but with separation of spongy charcoal (Liebermann, *Ann. Ch. Pharm.* cxxxv. 266). According to Sawitsch, on the contrary, it explodes when heated, with production of flame. It is attacked by a solution of sal-ammoniac, forming a liquid which decomposes on boiling into allylene and silver chloride:

(Berthelot, *Jahresb.* 1866. p. 523).

The precipitates formed by allylene in solutions of other metallic salts appear to be analogous in composition to those formed in the same solutions by acetylene (p. 35), the copper-compound, for example, consisting of cuprosallyl oxide, $(C^3H^1Cu)^2O$; they are, however, much more unstable than the acetylene compounds. Berthelot thinks it probable that the precipitate formed by allylene in ammoniacal silver nitrate may consist in the first instance of argentallyl oxide, $(C^3H^1Ag)^2O$, which quickly changes into argentallylene.

Iodallylene, C^3H^1I , is formed by gently heating argentallylene with a solution of iodine in potassium iodide, and passes over with the aqueous vapour as an oily body, having nearly the sp. gr. of 1.7, and boiling at 98° . It has a pungent odour, attacks the eyes and the mucous membranes, dissolves easily in ether, scarcely at all in alcohol, slightly in water, but easily in acetic acid, from which it is precipitated by water in its original state. It is not attacked by potash-ley, sodium, or sodium ethylate; but by zinc and hydrochloric acid or by zinc-amalgam, it is decomposed with separation of allylene. Bromine cautiously added to cooled iodallylene unites with it, forming the dibromide, $C^3H^1I.Br^2$, a heavy oil which turns yellow when exposed to light. The di-iodide, $C^3H^1I_2$, may also be formed by direct combination, but more easily by agitating dry argentallylene with an ethereal solution of iodine till the colour disappears, and then adding another equal quantity of iodine. The product is then left to itself for a week, the excess of iodine removed by agitation with dilute potash, the ethereal solution evaporated, and the remaining crystals of

Sup.

diallylene-diiodide washed with a little ether. The di-iodide, when crystallised slowly and in the dark, forms colourless lancet-shaped needles, often half an inch long. It is very sensitive to light; may be dried over calcium chloride, but not over oil of vitriol; melts at 64° ; decomposes at about 78° ; and dissolves easily in ether and in chloroform, less easily in benzene, and still less in alcohol. Heated with pulverised potassium hydrate, it is reconverted into iodallylene (Liebermann, *loc. cit.*).

Bromallylene, C^3H^3Br , and products derived from it. *Bromallylene dibromide*, $C^3H^3Br^2 = C^3H^3Br.Br^2$, is produced by adding bromine to argentallylene (not previously dried) suspended in water, and passes over on distillation, together with the aqueous vapour. It is an oily body, which decomposes when distilled alone, yielding hydrobromic acid and allylene bromide, $C^3H^3Br^2$ (?).

Bromallylene, C^3H^3Br , is formed (together with $C^3H^3Br^2$) when allyl tribromide, $C^3H^3Br^3$, or its isomeride, bromopropylene dibromide, $C^3H^3Br.Br^2$, is treated with a considerable quantity of alcoholic potash. By the further action of the alcoholic potash—which acts like potassium ethylate, replacing the bromine by oxethyl—bromallylene is converted into oxethyl-allylene, $C^3H^3(OC^2H^5)$ or $\left. \begin{smallmatrix} C^3H^3 \\ C^2H^5 \end{smallmatrix} \right\} O$:

The univalent radicle C^3H^3 is called by Liebermann propargyl, and the ethereal compound just mentioned is accordingly designated as propargyl ethylate or ethyl propargylate.*

This ether can exchange an atom of hydrogen belonging to the propargyl for silver, forming ethyl argentopropargylate or argentopropargyl ethylate, $C^3H^2Ag(OC^2H^5)$, which is obtained by heating allyl tribromide for a long time with alcoholic potash, then distilling off the alcohol, diluting with water to separate a brominated oil, and pouring the aqueous solution into ammoniacal silver nitrate. The silver-compound then separates as a dazzling white bulky precipitate, which presents no appearance of crystallisation. On the approach of a flame it melts, explodes, and leaves a residue which burns in contact with the air, leaving metallic silver. Acids abstract the silver and convert the compound into ethyl propargylate or oxethyl-allylene, $C^3H^3(OC^2H^5)$. The pure ether thus prepared boils at 72° . Like allylene itself, it unites directly with iodine, forms a yellow precipitate with ammoniacal cuprous chloride, and with ammoniacal silver nitrate a precipitate identical with the silver-compound above described.

Ethyl argentopropargylate or oxethyl-argentallylene, $C^3H^2Ag(OC^2H^5)$, reacts with iodine and bromine in the same manner as argentallylene itself, taking up an atom of iodine in place of silver, and forming the compound $C^3H^2I(OC^2H^5)$ or $\left. \begin{smallmatrix} C^3H^2I \\ C^2H^5 \end{smallmatrix} \right\} O$, which again can take up iodine and bromine, forming the compounds $C^3H^2I(OC^2H^5).I^2$ and $C^3H^2I(OC^2H^5).Br^2$.

Methyl propargylate or propargyl methylate, $C^3H^3(OCH^3)$ or $\left. \begin{smallmatrix} C^3H^3 \\ CH^3 \end{smallmatrix} \right\} O$, is produced by boiling tribromallyl with a solution of potash in methyl alcohol. It forms with ammoniacal silver nitrate a lemon-yellow precipitate, consisting of $C^3H^2Ag(OCH^3)$, from which the pure ether may be obtained by treatment with acids. This silver-compound distilled with a solution of iodine in potassium iodide yields the compound $C^3H^2I(OCH^3)$, which passes over as an oil, and solidifies at a low temperature in fine needles, but does not resume the liquid state till heated to 12° (Liebermann).

Propylphycite, $C^3H^3O^4$, the tetratomic alcohol which Carius obtained by combining epichlorhydrin, $C^3H^3\left\{ \begin{smallmatrix} O \\ Cl \end{smallmatrix} \right.$, with hypochlorous acid, $ClHO$, and treating the resulting compound, $(C^3H^3)^4\left\{ \begin{smallmatrix} (OH)^2 \\ Cl^2 \end{smallmatrix} \right.$, with potash (v. 893), is perhaps identical with allylene alcohol, $(C^3H^3)^4(OH)^4$.

ALLYL-ETHYL. $C^3H^3 = C^2H^3.C^2H^3$.—A hydrocarbon, isomeric with amylene, produced by the action of allyl-iodide on zinc-ethyl. (See AMYLENE.)

ALLYL-ETHYLIC OXIDE. $\left. \begin{smallmatrix} C^3H^3 \\ C^2H^3 \end{smallmatrix} \right\} O$.—This compound, produced by the action

* It is isomeric with the pentatomic radicle propynyl, C^3H^3 , derived from propane by abstraction of 5 atoms of hydrogen.

of ethyl iodide on potassium allylate (i. 142), and by that of alcoholic potash on allyl chloride (Oppenheim, *vid. sup.*), unites directly with bromine (like allyl alcohol), forming the compound $C^3H^5OBr^2$, which distils between 193° and 195° . It is a colourless liquid, which smells like dibromhydrin, becomes coloured when left to itself, and is partially decomposed by distillation. The corresponding chlorine-compound boils at 165° . The bromine-compound does not appear to be decomposed by zinc-methyl in ethereal solution. Sodium-amalgam withdraws the bromine, reproducing allyl-ethyl ether (Morkownikoff, *Jahresb.* 1865, p. 492).

ALLYL-METHYL. $C^3H^5 = C^3H^3.CH^3$, isomeric with butylene (*q.v.*), is produced by the action of allyl-iodide on zinc-methyl (Wurtz).

ALOES. Of this drug there are two principal varieties, viz. a dark, opaque, liver-coloured variety called Aloë hepatica or liver-aloes, and a lighter kind, transparent in thin splinters, called Aloë lucida.

1. Liver-aloes is obtained most abundantly in Barbadoes, from *Aloë vulgaris*; it forms dry blackish lumps, having a dull fatty lustre, easily splitting into angular fragments, and yielding a brown-grey powder. A somewhat different Aloë hepatica is imported from Southern Arabia, by way of Bombay, and is hence called Indian or Bombay aloes. It is of a more brownish black, often indeed of a rather light liver-brown colour, breaks into large angular lumps, and yields a brownish to brownish-yellow or nearly orange-coloured powder.—2. Aloë lucida is produced in largest quantity near Algou Bay, in the Cape Colony, chiefly from the species *Aloë spicata*, *A. africana*, *A. ferox*, and *A. lingua*; it is known in commerce as Aloë capensis and Aloë socotrina. The latter name is derived from the island Socotora, on the coast of Arabia, which was formerly the only source of this kind of aloes, but now yields little or none of it. Aloë lucida when dry forms a nearly uniform mass, having a strong vitreous lustre, translucent in small splinters, nearly black by reflected light, breaking very easily into broadly conchoidal sharp-edged lumps, or into small reddish to light yellow-brown splinters, and yielding a light yellow powder.

All kinds of aloes have a peculiar odour, somewhat like that of myrrh and of saffron, and a bitter disagreeable taste. Pure aloes dissolves completely in alcohol, forming a clear solution; partly in cold water, almost completely in boiling water, liver-aloes however leaving a somewhat larger residue than the translucent variety. The opalescent yellow solution in a small quantity of hot water becomes turbid on the addition of more water, from separation of yellowish resinous drops, which on cooling cohere into a resinous deposit. The clear solution has a slight acid reaction, is coloured dark-brown by alkalis, black by ferric chloride, and forms a yellowish-grey precipitate with leadacetate. Cold water dissolves about half the aloes, forming an acid solution which exhibits the same characters: it is not precipitated by alcohol, and is therefore free from gum (Flückiger, *Lehrbuch der Pharmakognosie des Pflanzenreichs*, Berlin, 1867).

From the experiments of Kosman: (*Bull. Soc. Chim.* 1863, p. 530), which were made upon Cape aloes, it appears that the portion of this drug which is soluble in water (the official *Extractum aloës*) and the insoluble portion (*resin of aloes*) have the same percentage composition, and are both resolvable by boiling with dilute sulphuric acid into glucose and several resinous bodies. He supposes that both these substances are formed, during the concentration of the juice, by oxidation and hydration of aloin, the active principle existing in the laticiferous cells of *Aloë spicata*:

a. Soluble aloes is a yellow amorphous mass composed of agglomerated granules. By boiling with dilute sulphuric acid it is resolved into glucose (amounting to 15.8 per cent. of the soluble aloes) and two resinous acids, one of which, aloëresic acid, is precipitated, together with aloëretin, while the other, aloëretic acid, remains in solution:

and

Aloëresic acid is insoluble in ether, has a yellowish-brown colour, and appears crystalline under the microscope. *Aloëretin*, which is insoluble in ether, is a brown, amorphous resin, not possessing acid properties. *Aloëretic acid*, which remains in

solution together with the sugar, is separated by precipitating it with lead acetate, decomposing the precipitate with hydrogen sulphide, and treating the precipitated lead sulphide with alcohol. It forms a brown shining resin, composed of microscopic rhomboïdal tablets; is nearly insoluble in pure water and in ether, sparingly soluble in alcohol, more frequently in water containing sugar.

β. The portion of Cape aloes which is insoluble in water is yellow, soluble in alcohol, and remains, when the alcoholic solution is evaporated to dryness, in yellow, transparent, shining grains. By boiling with sulphuric acid in alcoholic solution it is resolved into glucose (amounting on the average to 16 per cent.), and a brown resin soluble in alcohol and in sodium carbonate, and separable by ether into aloëresinic acid, $C^{13}H^{16}O^8$, soluble, and aloëretinic acid, $C^{13}H^{16}O^8$, insoluble in that liquid. But these formulae, as well as those of the products previously described, require confirmation.

According to Illasiwetz (*Ann. Ch. Pharm.* cxxxiv. 287; cxxxvi. 31), aloes boiled with dilute sulphuric acid yields paracoumaric acid, $C^8H^6O^3$, from which by fusion with potassium hydrate, paraoxybenzoic acid, $C^8H^4O^3$, is obtained, as also, together with orcin, from aloes itself. Paracoumaric acid appears also to be formed, together with a small quantity of a fragrant volatile oil, a volatile fatty acid, and a volatile base, by boiling aloes with caustic soda-solution (Rochleder a. Czumpelick, *J. pr. Chem.* lxxxiv. 436; *Jahresb.* 1861, p. 743). Aloes heated with nitric acid is converted, first into aloetic acid, $C^8H^2N^2O^3$; then into chrysammic acid, $C^8H^2N^2O^3$; and finally into picric and oxalic acid. Robiquet, by distilling aloes with quicklime, obtained aloïsol (i. 148), a colourless or yellowish oil, smelling like amyl alcohol and bitter almond oil, and remaining liquid at -20° . Rembold (*Ann. Ch. Pharm.* cxxviii. 186) obtained from aloes 1 per cent. of this oil, which he found to be a mixture of xylyl alcohol with acetone and hydrocarbons.

ALOETIC ACID. $C^8H^2N^2O^3$.—This acid, discovered by Schunck, and analysed by him and by Mulder (i. 148), with somewhat discordant results, has been further examined by Finck (*Ann. Ch. Pharm.* cxxxiv. 236), whose results differ from those of both the chemists just named. To prepare the acid, the mixture of chrysammic, aloetic, and a small quantity of picric acid, obtained as a green precipitate by treating aloes with nitric acid, as in Schunck's process, is digested with aqueous potassium acetate till the acetic acid is expelled; and the resulting potassium-salts are treated with cold water, which dissolves only the acetate; the resulting solution, mixed with barium acetate and evaporated, yields warty crystalline crusts of barium aloëate, from which the aloetic acid may be separated by cold dilute nitric acid.

Aloetic acid thus obtained is a yellow amorphous powder consisting of $2C^8H^2N^2O^3 \cdot H^2O$. It dissolves sparingly in cold water, more easily in boiling water and in alcohol, forming purple-red solutions, which become yellow on addition of acids, and red again when neutralised. It has a strongly bitter and acid taste, decomposes carbonates, and forms with the alkalis and alkaline earths, salts which dissolve in water with red colour; with other metallic oxides, sparingly soluble salts. The silver salt contains $C^8HAgN^2O^3$; the barium salt $C^8H^2Ba^2N^2O^6$.

Aloetic acid is converted by boiling with nitric acid, first into chrysammic, then into picric acid. Digested with a solution of potassium or ammonium sulphide containing excess of alkali, it forms an indigo-blue, gelatinous substance, $C^8H^2N^2O^3(?)$, slightly soluble in water, more soluble in alkalis.

ALOÏN. $C^8H^{12}O^7$.—This substance, the purgative principle of aloes, was first isolated by T. and H. Smith (*Chem. Gaz.* 1851, p. 107) from Barbadoes aloes. In *Aloë hepatica* it appears to exist wholly in the crystalline state; in other varieties partly amorphous, partly in an altered condition. Orłowski (*Zeitschr. anal. Chem.* v. 309) prepares it from *Aloë hepatica* [? Indian or Bombay aloes, p. 99] by dissolving the substance in 2 parts of water at 90° – 95° , and leaving the clear decanted liquid to evaporate freely for ten or twelve days. The aloïn, which then separates as a dark-yellow granular mass, is pressed between filter-paper and further purified by crystallisation, first from water, then from alcohol. Barbadoes aloes is treated with only 1 part of water of the temperature above mentioned, the remaining fourth being added after cooling; the whole of the resin then separates after 12 hours. The decanted liquid is treated as above.

Aloïn treated with dilute sulphuric acid is resolved into glucose and rottlerin (*Czumpelick, Jahresb.* 1861, p. 743; *Rochleder, ibid.* 598):

According to Graebe & Liebermann (*Zeitschr. f. Chem.* [2] iv. 503), aloin treated with zinc-dust is converted into anthracene.

ALOSA MENHADEN, OIL OF. See MENHADEN OIL.

ALPHA-TOLUIC ACID, and its derivatives (v. 863).

ALPHA-USNIC ACID (v. 970).

ALPHA-KYLIC ACID (v. 1062).

ALSTONIA. The bark of *Alstonia constricta* (an apocycyaneous tree growing in Australia), which has a bitter taste and slight camphorous odour, contains, according to Palm (*Jahresh.* 1863, p. 615), a neutral resinous bitter principle (similar to caileedrin and taluecunin), a volatile oil smelling like camphor, an iron-greening tannin, gum, resin, fat, wax, protein-substance, oxalic acid and citric acid. The ash, amounting to 6.06 per cent. of the bark, contains in 100 parts:

Na ² O	K ² O	NaCl	CaO	MgO	Fe ² O ³	Mn ² O ³	SO ³	P ² O ⁵	SiO ²	CO ²
0.48	6.96	3.06	32.83	3.61	3.43	0.78	9.33	trace	15.60	23.50.

ALSTONITE. *Bronzite*.—The orthorhombic variety of calcio-baric carbonate, BaCO³.CaCO³, found in the lead mines of Fallowfield in Northumberland, and Bromley Hill, near Alston, in Cumberland. The crystals, derived from a rhombic prism of 118° 50', are double hexagonal prisms, resulting from the interpenetration of six octohedral crystals having a common vertical axis. Basal angles = 122° 30' and 142°; re-entering angle = 178° 51'.

AMANDIN. An albuminous substance, contained, according to Commaillou (*J. Pharm.* [4] iv. 108), in sweet almonds, and obtained by precipitating filtered almond milk with hydrochloric acid, dissolving the precipitate in alkaline water, and again precipitating with hydrochloric acid. Its acidulated solution forms with platinic chloride a precipitate containing 7.02 to 7.45 per cent. platinum. The solution in dilute hydrochloric acid also gives a precipitate with mercuric chloride.

AMARINE. C²¹H¹⁰N².—The sulphate of this base, obtained by direct combination, is described by Laurent (*Ann. Ch. Pharm.* lii. 359) as an acid salt; but according to a recent examination by P. Groth (*ibid.* clii. 122), it appears to be a neutral sulphate, having the composition 2(C²¹H¹⁰N²).7SO⁴.7H²O. It is moderately soluble in water, and gives off its water of crystallisation between 100° and 110°; at 150° it becomes nearly insoluble in water, but does not lose weight. By recrystallisation it is obtained in monoclinic combinations, ∞ P. (∞ P ∞) . ∞ P ∞. (P ∞) . oP. Axes, a : b : c : 0.8537 : 1 : 0.8531. Angle of inclined axes = 97° 12.5'. Cleavage parallel to oP and (P ∞). The plane of the optic axes is perpendicular to the plane of symmetry. Angle of optic axes for the red ray = 60° 33' (Groth).

AMBRITE. C¹⁶H¹⁰O².—A fossil resin occurring in large lumps in the lignite formation of Drury and Hunua, in the province of Auckland, New Zealand. It is amorphous, with conchoidal fracture, semitransparent, brittle, and of yellowish-grey colour. Hardness = 2; sp. gr. = 1.031. Burns with a yellow smoky flame; when heated on platinum-foil it gives off white fumes before melting, and then takes fire. Strongly electric when rubbed. Dissolves in carbon bisulphide, with separation of a white translucent amorphous mass; not in alcohol, ether, turpentine-oil, benzene or chloroform, even at the boiling heat. Fused with potash it turns brown, and floats on the surface as a viscid brown mass. By boiling for some hours with strong nitric acid, it is decomposed, the liquid becoming orange-red, and depositing on evaporation a yellow sticky mass, together with a few microscopic crystals. The ash contains iron, calcium, and sodium (v. Hauser & Maly, *Jahresh.* 1866, p. 1034).

AMMONIA. *Preparation*.—Ammonia prepared from the commercial chloride or sulphate always contains small quantities of compound ammonias. To obtain it quite pure, it is necessary in the first instance to purify the salt from which it is to be evolved. Pure ammonium chloride may be obtained by boiling a saturated solution of commercial sal-ammoniac with $\frac{1}{10}$ th vol. strong nitric acid, till chlorine is no longer evolved, redissolving the salt which crystallises out on cooling, and again heating this solution with $\frac{1}{10}$ th vol. strong nitric acid. Pure ammonium sulphate is obtained by heating the commercial salt with $\frac{2}{5}$ ths of its weight of strong sulphuric acid till decomposition commences, adding a small quantity of nitric acid, and heating the liquid till it is decolorised. The ammonia evolved from either of these pure salts by heating with calcium hydrate has merely a pungent odour, quite different from that of common ammonia.

Absolutely pure ammonia may also be obtained by digesting potassium nitrite (from 1 kilogr. saltpetre) with potash-ley, of sp. gr. 1.25 (15 litres), granulated zinc

free from carbon * (3·5 kilogr.), and iron wire which has been ignited in the air and then reduced in a current of hydrogen (0·5 kils.), and finally distilling the mixture; or better—in order to avoid the rapid disengagement of hydrogen—decanting the liquid from the metal, and distilling it with gentle ebullition (Stas, *Zeitschr. anal. Chem.* vi. 423).

Liquefaction of Gaseous Ammonia.—Loir a. Drion (*Jahresb.* 1860, p. 41) liquefy ammonia gas by means of the cold (-50°) produced by the rapid evaporation of liquid sulphurous oxide. A current of dry air is driven by the bellows of a glass-blower's lamp through several tubes at once into a quantity of liquid sulphurous oxide, in which is immersed the lower bend of a U-tube, traversed by a stream of ammonia gas. The liquefaction is accelerated by a slight increase of pressure.

The sp. gr. of liquid ammonia at 0° is 0·6362, referred to that of water at 0° (Andréeff, *Ann. Ch. Pharm.* cx. 1); according to Jolly (*ibid.* cxvii. 181), it is 0·6234 (mean of three observations). The volumes occupied at different temperatures are, according to Andréeff, as follows:—

Temp.	-10°	0°	$+10^{\circ}$	$+20^{\circ}$
Vols.	0·09805	1·000	1·0215	1·0450

The coefficient of expansion between -11° and 0° is, according to the mean of three observations by Jolly, 0·00155. It appears, then, that at temperatures sufficiently removed from its boiling point, liquid ammonia expands more than the gas.

Liquid ammonia boils under the ordinary pressure at $-35·7^{\circ}$ (Loir a. Drion), at $-38·5^{\circ}$ (Regnault).

The tension of ammonia vapour at various temperatures is, according to Regnault's latest determinations (*Rélation des Expériences*, &c.), as follows:—

Temp.	Tension in millimetres	Temp.	Tension in millimetres
-30°	866·09	$+40^{\circ}$	11595·30
-20°	1392·13	50°	15158·33
-10°	2144·62	60°	19482·10
0°	3183·34	70°	24675·55
$+10^{\circ}$	4574·03	80°	30843·09
20°	6387·78	90°	38109·22
33°	8700·97	100°	46608·24

Combustion of Ammonia.—The combustibility of ammonia in oxygen gas may be strikingly shown by passing a rapid stream of oxygen through boiling concentrated aqueous ammonia; the gas which issues from the mouth of the flask may then be set on fire, and burns with a greenish-yellow flame (Hofmann, *Chem. Soc. Qu. J.* xiii. 78). According to Hointz (*Ann. Ch. Pharm.* cxxx. 102), this experiment may be more safely made by passing a slow stream of oxygen into a flask filled to about $\frac{1}{10}$ th with ammonia, through a tube bent upwards at the end; this tube is introduced only a little way into the mouth of the flask before the gas is set on fire, and afterwards sunk deeper into the body of the flask; the flame then continues to burn quietly as long as a sufficient quantity of ammonia gas is supplied, exhibiting, in fact, a combustion of oxygen in an atmosphere of ammonia. The combustion of ammonia gas and oxygen may also be exhibited by means of a Daniell's jet. If a spiral of platinum wire 0·5 mm. thick, and attached to a long cork, be heated to redness, and suspended within a flask, of the capacity of about 450 cc., containing aqueous ammonia of 20 p. c., the cork lying loosely across the neck, and oxygen be passed into the liquid through a tube 10 mm. wide, the platinum spiral soon rises to a much brighter red heat, and the flask becomes filled, first with white fumes of ammonium nitrate, then with red fumes. If the ammonia be then warmed, the gaseous mixture takes fire with a sharp but not dangerous explosion; and the temperature of the platinum spiral is at the same time reduced below visible redness. After a while, however, it again becomes red hot, again sets fire to the gas, and thus the series of phenomena may be continually repeated (K. Kraut, *Ann. Ch. Pharm.* cxxxvi. 69).

Oxidation by Permanganates.—Ammonia heated with a large excess of permanganate and alkali is wholly converted into nitrate (Wanklyn a. Gamage, *Chem. Soc. J.* [2] vi. 25).

Reaction of Ammonia with Sulphur, Selenium, Tellurium, and Phosphorus.—Flowers of sulphur washed and dried gradually absorb ammonia-gas; if heat be applied, nitrogen is set free, and ammonium sulphide is produced. Aqueous ammonia does not act on pure sulphur at temperatures below 75° , but towards 90° it assumes a

* Stas prepared plumbiferous zinc free from carbon by fusing commercial zinc with 5 p. c. litharge. This alloy reacts with potassium nitrite and iron just like pure zinc, and readily eliminates hydrogen from dilute acids.

yellow colour, in consequence of dissolving a small quantity of sulphur (Brunner, *Dingl. pol. J.* cl. 371). When aqueous ammonia of sp. gr. 0.885 is heated to 100° in a sealed tube for several days with a third of its weight of sulphur, the sulphur dissolves, forming a red-brown liquid which is not viscid and does not fume on exposure to the air. The solution consists mainly of ammonium polysulphides, and the residue left on evaporation is resolved by water into sulphur and ammonium hyposulphite (F. A. Flückiger, *J. Pharm.* [3] xlv. 453). *Selenium* heated with aqueous ammonia in sealed tubes forms a colourless solution of ammonium selenide, together with a small quantity of ammonium selenite. *Tellurium* yields an abundance of tellurite. Amorphous *phosphorus* is not acted on by ammonia; ordinary phosphorus gradually yields hydrogen phosphide and a compound of ammonia with an oxide of phosphorus; if alcoholic ammonia be used, the latter compound appears as a deep black metallic film adhering to the sides of the tube, and not decomposed by boiling sulphuric acid or potash-ley, whereby it is distinguished from the product obtained with aqueous ammonia (Flückiger, *loc. cit.*).

Respecting the action of ammonia on metals, see the several METALS; for its action on the chlorides of sulphur and phosphorus, see vol. iv. pp. 511, 515, 576, 606; v. 535.

Estimation of Ammonia in dilute solutions.—Nessler's reaction (i. 189) was applied by Hadow to the volumetric estimation of ammonia. By Wanklyn, Chapman, & Smith this volumetric determination (which is especially adapted to very minute, and even microscopic quantities of ammonia) has been used in water-analysis, and in a general process for analysing nitrogenous organic substances (*Chem. Soc. J.* [2] vi. 161).

The 'Nessler liquor' is prepared by adding mercuric chloride to a hot concentrated solution of 50 grams potassium iodide till the precipitate no longer redissolves; then filtering; adding 150 grams of potassium hydrate in strong aqueous solution; diluting the liquid to a litre; adding another very small quantity of mercuric chloride; leaving the solution to settle; decanting; and preserving it in a well-closed vessel.

For the application of the 'Nessler liquor' to the quantitative estimation of ammonia, a very weak standard solution of ammonia is required. This is made by dissolving 0.3882 grams of ammonium sulphate (or the equivalent quantity of ammonium chloride) in one litre of water: it contains $\frac{1}{10}$ milligram of ammonia in one cubic centimetre. For general use, the standard may be advantageously diluted with water, so that one cubic centimetre shall contain $\frac{1}{100}$ milligram of ammonia.

The operation of measuring the quantity of ammonia in a given liquid is performed as follows: Two similar cylinders of colourless glass, each holding 100 c.c., and marked accurately at the 100 c.c. measure, are taken and put side by side. Into one is introduced 100 c.c. of the liquid to be tested, into the other the comparison-liquid, containing a measured volume of a standard solution of ammonia; 2 c.c. of 'Nessler liquid' is then to be dropped into each cylinder, and the depth of the resulting coloration observed. If the depth of colour of the comparison-fluid equals the depth of colour in the other glass, the quantity of standard ammonia which has been put into the comparison-fluid is the quantity actually present in the liquid to be tested. If the colour of the comparison-fluid is too high or too low, a fresh comparison-fluid must be made up, and this must be repeated until the right one is obtained.

Different metallic salts interfere with the action of the Nessler test. It is therefore advisable to distil off the ammonia, and apply the test to the distillate, which will contain nothing but ammonia-water.

The strength of ammonia to which the Nessler test is quantitatively applicable ranges from .005 milligram to about 1 milligram per 100 c.c. It works best between 0.005 and 0.20 milligram per 100 c.c.

AMMONIUM ALLOYS. 1. *Ammonium Amalgam.*—Recent experiments on the substance known by this name lead to the conclusion that it is not a true amalgam—that is to say, a compound of mercury with a metallic radicle, NH —but merely a spongy mixture of metallic mercury with bubbles of nitrogen and hydrogen gases. Wetherill (*Sill. Am. J.* [2] xl. 160) finds that its formation may be prevented by certain so-called catalytic influences. When, for example, an ammoniacal salt is electrolysed with a negative pole formed of spongy platinum impregnated with mercury, no ammonium amalgam is formed, but a very brisk evolution of gases takes place. This doubtless arises from the circumstance that the mercury, being held within the pores of the platinum-sponge, is prevented from expanding so as to retain the gases. Landolt (*Zeitschr. f. Chem.* [2] v. 429) has shown that when the so-called ammonium amalgam is immersed in a solution of silver nitrate, ferric chloride, or cupric sulphate, no reduction of the metal or formation of an amalgam takes place, as is the case when an amalgam of potassium or sodium is used, but the ammonium amalgam is decomposed, as under ordinary circumstances, with evolution of nitrogen and hydrogen.

On the other hand, A. H. Gellatlin (*Zeitschr. f. Chem.* [2] v. 607) finds that when ammonium amalgam (prepared with sodium, but freed from excess of that metal) is placed in contact with small pieces of phosphorus, bubbles of phosphoretted hydrogen are evolved: hence he infers that the hydrogen evolved from the amalgam must be in the nascent state, and cannot therefore exist therein as free hydrogen.

But the most decisive experiments bearing on this question are those of Seeley (*Chem. News*, xxi. 265, June 10, 1870), from which it appears that when the amalgam is subjected to varying pressure, its volume changes like that of a gas. Into a tube 20 inches long and fitted with a plunger, mercury containing a little sodium was poured to half an inch in depth, and upon this was poured a strong solution of sal-ammoniac, occupying about two inches of the tube. The ammonium amalgam was completely formed in a few minutes, occupying several inches of the tube. On depressing the plunger, the volume of the amalgam progressively diminished till it closely approached the original volume of the mercury, which at the same time progressively gained fluidity and its usual mirror-like surface. On withdrawing the pressure, the compound resumed its original volume and dull frothy appearance. These results show that the ammonium, or rather its elements, NH^3 and H, exists in the amalgam, not as liquid, but as gas. The particles of the ammonia and hydrogen gases set free all over the surface of the mercury adhere to it, and as fresh particles of mercury are brought to the surface by the internal movements, they become enfilmed and carried inwards till the mixture becomes a homogeneous froth. Loew's so-called *hydrogenium amalgam*, obtained by agitating a dilute zinc amalgam with aqueous platonic chloride, is doubtless a mass of similar character.

Pfeil a. Lippman (*Compt. rend.* lxii. 426) have endeavoured to prepare ammonium amalgams corresponding to the compound ammonias. A saturated solution of trimethylamine hydrochloride reacts with sodium amalgam just like a solution of sal-ammoniac, and the spongy amalgam produced quickly decomposes, with evolution of hydrogen, and formation of trimethylamine, which remains in solution. Saturated solutions of the hydrochlorides of aniline, conine, morphine, and quinine, also of rosaniline acetate, treated with sodium amalgam, give off large quantities of hydrogen, but do not form any product resembling ammonium amalgam. Hence also it appears that the physical properties of the ammonium amalgam are due to imprisoned gas-bubbles, and that those compound ammonias which are solid or liquid at ordinary temperatures do not form such amalgams. Pfeil a. Lippman also find that sodium amalgam does not act upon solid sal-ammoniac till a drop of water is added.

2. *Ammonium-bismuth* (?).—Gellatlin (*loc. cit.*) describes an alloy of ammonium and bismuth, prepared by pouring water in a fine rapid stream on an alloy of bismuth and sodium in contact with sal-ammoniac. The bismuth then swells up, becomes pasty and porous, and solidifies, giving off considerable quantities of hydrogen and ammonia. The compound immersed in a solution of copper quickly becomes covered with metallic copper, a property exhibited also by sodium-bismuth, but not by metallic bismuth. [The precipitation was perhaps due to sodium still present in the mass.] The ammonium-bismuth after drying in a vacuum over sulphuric acid gave off, when heated in a vacuum, 27 times its volume of gas consisting of hydrogen and nitrogen.

On Ammonium alloys, see also vol. v. pp. 328, 329.

AMPHITHALITE. A mineral from the Hartsjöberg in Wernland, Sweden, occurring in hard, dense, milk-white veins or nodules, infusible, and not attacked by hydrochloric acid till after fusion with alkalis. Contains $(\text{Ca} : \text{Mg})^2\text{P}^2\text{O}^7\text{Al}^2\text{P}^2\text{O}^{13} + 10\text{aq.}$, and therefore approximates in constitution to lazulite (Igelström, *J. pr. Chem.* c. 126; *Bull. Soc. Chim.* [2] viii. 41).

AMYGDALIN, $\text{C}^{20}\text{H}^{27}\text{NO}^{11}$, and **AMYGDALIC ACID**, $\text{C}^{20}\text{H}^{25}\text{O}^{12}$.—Schiff (*Zeitschr. f. Chem.* [2] v. 708) finds that seven of the hydrogen-atoms in amygdalin may be replaced by acid radicles, such as acetyl and benzoyl; hence he assigns to this compound a rational formula similar to that of arbutin, viz.,

Heptacetylamygdalin, $\text{C}^8\text{H}^{14}\text{O}^4 \left\{ \begin{array}{l} (\text{OC}^2\text{H}^3\text{O})^7 \\ \text{C}^2\text{H}^4\text{CN} \end{array} \right.$, is obtained by heating dehydrated amygdalin with excess of acetic anhydride to the boiling point of the latter. It

crystallises from alcohol in long colourless anhydrous needles, having a silky lustre. At lower temperatures, acetylated amygdalins are formed, in which smaller numbers of hydrogen-atoms are replaced by acetyl.

Amygdalin cannot be supposed to contain the radicle benzoyl, C^7H^5O : for when treated with phosphorus pentachloride it yields only cyanogen chloride, benzeno chloride, and chlorinated derivatives of the latter, but no chloride of benzoyl; whereas the true benzoylated amygdalins, obtained by treating amygdalin with benzoyl chloride, reproduce the latter when subjected to the action of phosphorus pentachloride. Similar results are obtained by the action of bromine on amygdalin and benzoyl-amygdalin.

Amygdalin heated with *aniline* to 160° – 180° is converted into amygdalanilide, $C^{12}H^{14}O^2(NC^6H^5)^2 \left\{ \begin{smallmatrix} (OH)^1 \\ C^7H^5.CN \end{smallmatrix} \right.$, an uncrystallisable substance, decomposed even by solution in boiling water into amygdalin and aniline. The acetyl-amygdalins likewise yield anilides.

Amygdalin is not the amide of amygdalic acid, but is related to the latter in the same manner as methyl cyanide to acetic acid:

Amygdalic acid treated with acetic anhydride is converted into a tetra- or a hepta-acetyl compound according as the reaction takes place at a lower or a higher temperature:

Amygdalic acid is easily obtained in the form of a deliquescent crystalline mass. Its acetyl derivatives are insoluble in water and uncrystallisable, and are readily decomposed even by weak bases.

The formulæ of amygdalin and amygdalic acid above given afford a ready explanation of the formation of mandelic (formbenzoic) acid, $C^7H^5 \left\{ \begin{smallmatrix} (OH) \\ CO^2H \end{smallmatrix} \right.$, by heating amygdalin with hydrochloric acid (iii. 800).

AMYL. C^5H^{11} , and in the free state $C^{10}H^{22}$.—The isolated radicle is now more generally called diamyl. It is identical with decyl hydride, and when treated with chlorine yields chlorodiamyl or decyl chloride, $C^{10}H^{21}Cl$.

Diamyl is not attacked by nitric acid at ordinary temperatures, but at a gentle heat it is violently attacked by fuming nitric acid, and less energetically by acid of sp. gr. 1.4, yielding succinic acid, together with a liquid distillate, which appears to contain capronitrile, $C^{10}H^{19}N$, together with ceanthyllic, valeric, and caproic acids (Schorlemmer, *Proc. Roy. Soc.* xvi. 372).

Wurtz obtained diamyl by the action of sodium on amyl iodide; and in like manner, amyl-ethyl, $C^5H^{11}.C^2H^5$, and amyl-butyl, $C^5H^{11}.C^4H^9$, by the action of sodium on a mixture of amyl iodide with ethyl iodide or butyl iodide (ii. 525; v. 732). Similarly, a mixture of the iodides of amyl and isopropyl treated with sodium (the mixture being cooled at first, and gently heated towards the end) yields amyl-

isopropyl, $C^5H^{11}.CH(CH^3)^2$ or $C^5H^{11} \left\{ \begin{smallmatrix} H \\ CH^3 \\ CH^3 \\ C^3H^7 \end{smallmatrix} \right.$ Amyl-isopropyl boils at 109° – 110° ; its

specific gravity is 0.6980 at 16.5° , and 0.6712 at 49° . It is probably identical with dibutyl, $C^4H^9.CO^2H^3$, which, according to Kopp, boils at 109° , and has a sp. gr. of 0.7001 at 16.4° . (Respecting the constitutional formulæ of all these bodies, see HYDROCARBONS.)

Chlorine converts amyl-isopropyl into the chloride $C^8H^{17}Cl$, a colourless liquid which has an odour of oranges, like its isomeric, octyl chloride, a sp. gr. of 0.8634 at 10.5° , 0.8617 at 36° , and boils at 165° . With *iodine chloride* amyl-isopropyl forms a number of substitution-products, amongst which the chloride $C^8H^{17}Cl$ appears to be the most abundant. A solution of *chromic acid* attacks amyl-isopropyl very slowly, the only oxidation-products formed being carbonic and acetic acid (Schorlemmer, *Proc. Roy. Soc.* xvi. 37).

AMYL ALCOHOLS. $C^5H^{12}O$.—Of these alcohols there are eight possible varieties, viz. four primary, three secondary, and one tertiary.

Primary.

Secondary.

Tertiary.

Primary. Normal Amyl alcohol or Butyl carbinol, $\text{C} \begin{cases} \text{CH}^2\text{CH}^2\text{CH}^2\text{CH}^3 \\ \text{H}^3 \\ \text{OH} \end{cases}$, has been quite recently obtained by Lieben a. Rossi (*Compt. rend.* lxxi. 370) by a synthetical process from normal butyl alcohol, $\text{C} \begin{cases} \text{CH}^2\text{CH}^2\text{CH}^3 \\ \text{H}^3 \\ \text{OH} \end{cases}$ (p. 63), which had been prepared from normal butyric acid. The butyl alcohol was transformed into the cyanide, and from the latter, normal valeric acid, boiling at 185° , was prepared. The calcium salt of this acid was mixed with calcium formate and distilled, and the valeral thus obtained was hydrogenated with sodium amalgam, and thereby converted into the alcohol. The amyl alcohol thus produced boils at 137° under a pressure of 744 mm. (ordinary amyl alcohol boils at about 132°); the chloride, bromide, iodide, and acetate obtained from it likewise boil at higher temperatures than the corresponding ordinary amyl-compounds. In most respects, however, normal amylic alcohol resembles the alcohol from fusel-oil. By oxidation it yields a valeric acid, which is the normal acid, $\text{C} \begin{cases} \text{CH}^2\text{CH}^2\text{CH}^2\text{CH}^3 \\ \text{O} \\ \text{OH} \end{cases}$, boiling at 185° and smelling somewhat like butyric acid.

Isobutyl Carbinol. $\text{C} \begin{cases} \text{CH}^2\text{CH}(\text{CH}^3)^2 \\ \text{H}^2 \\ \text{OH} \end{cases}$.—This, as shown by Erlenmeyer, is the constitution of the ordinary amylic alcohol of fermentation, which is therefore the true homologue of Wurtz's butylic alcohol, itself likewise a product of fermentation. The latter yields by oxidation with chromic acid, not normal butyric, but isobutyric acid, $\text{CH}(\text{CH}^3)^2.\text{CO}^2\text{H}$. (See BUTYL ALCOHOLS.) Now the butyl cyanide, $\text{CH}^2\text{CH}(\text{CH}^3)^2.\text{CN}$, prepared from this fermentation butyl alcohol, is converted by boiling with alcoholic potash into a valeric acid, $\text{CH}^2\text{CH}(\text{CH}^3)^2.\text{COOH}$, identical in every respect with ordinary valeric acid, obtained from valerian root, or by oxidation of ordinary amyl alcohol. This alcohol must, therefore, contain the same radicle as the valeric acid prepared from butyl cyanide, that is to say, it must consist of isobutyl carbinol (Erlenmeyer, *Ann. Ch. Pharm. Suppl.* v. 337; *Jahresb.* 1867, p. 580).

But ordinary fusel-oil, as shown some years ago by Pasteur (i. 205), contains two isomeric amyl alcohols, one active, the other inactive, to polarised light. Both of these are primary alcohols, yielding valeric acid by oxidation, the acid thus obtained being, however, optically active or inactive, according as it is obtained from the active or inactive alcohol. The question then arises, Are these two alcohols merely physically isomeric, or are they metameric, the one containing normal butyl, the other isobutyl? This question has not yet been answered with certainty; but from the recent experiments of Pedler (*Chem. Soc. J.* [2] vi. 74) it appears that the two alcohols exhibit the closest resemblance to one another in all their physical properties, excepting their relation to polarised light. They have the same smell and taste, and their boiling

points differ by only one degree, the active alcohol boiling at 128° , the inactive alcohol at 129° (according to other authorities the boiling point of amylic alcohol is 132°). The active alcohol rotates a yellow ray of polarised light 17° to the left in a tube 50 centimetres long. The close resemblance of the two alcohols in all other physical properties points rather to physical than to chemical isomerism, being probably indeed the kind of isomerism which exists between the several varieties of turpentine oil (which are in like manner distinguished from one another chiefly by their behaviour to polarised light), and being due to differences of arrangements in the molecules of the body, rather than to differences of constitution in the molecules themselves.

In their behaviour with oxidising agents, however, the two amylic alcohols exhibit a certain amount of difference. The inactive alcohol when heated with potassium dichromate and dilute sulphuric acid yields nothing but ordinary inactive valeric acid, whereas the active (lævogyrate) alcohol heated with the same oxidising mixture is converted into acetic and carbonic acids; in the cold, however, it is oxidised to *dextrogyrate* valeric acid, producing a rotation of 43° in a tube 50 centimetres long.

From these results it may be concluded that inactive amyl alcohol certainly consists of isobutyl carbinol, $\text{CH}^3\text{CH}(\text{CH}^3)_2\text{CH}^2\text{OH}$; but whether the active alcohol consists of the third or fourth modification above enumerated, or is merely a physical modification of the inactive alcohol, is a question requiring further investigation; but, as already observed, the latter supposition appears to be the more probable of the two.

Chapman & Smith (*Proc. Roy. Soc.* xvii. 308) find that the separation of the active and inactive amyl alcohols may be effected much more easily than by Pasteur's method (i. 203), by dissolving soda, potash, or chloride of calcium in crude amyl alcohol at the boiling heat, and distilling the saturated solution, the non-rotating alcohol being then to a great extent retained, while the rotating alcohol distils off. Almost any salt easily soluble in amyl alcohol might be used for the purpose, but the substance which answers best is caustic soda. The amyl alcohol is boiled with caustic soda, and the hot solution is decanted into a flask and distilled from an oil-bath, the temperature being kept below 200° . The alcohol distils off quickly at first, afterwards more slowly, and, finally, the contents of the flask solidify, after which it becomes very difficult to distil off any more amyl alcohol. On now adding water and again distilling, amyl alcohol comes over of about half the rotating power of the alcohol employed. By a sufficient number of repetitions of this process it is possible to effect a separation of the alcohols, and very easy to obtain considerable quantities of the non-rotating alcohol quite pure.

Chapman has subsequently found that the rotating alcohol is actually converted into the non-rotating alcohol by repeated distillation over caustic soda.

Schorlemmer (*Proc. Roy. Soc.* xv. 131) has shown that the amyl-compounds obtained from fusel-oil and from American petroleum agree so nearly in specific gravity and boiling point that they may be regarded as identical. The results are given in the following table:

	From fusel-oil		From petroleum	
	B. P.	Sp. gr.	B. P.	Sp. gr.
Amyl hydride, C^4H^{12}	—	—	34°	0.6263 at 17°
Amyl chloride, $\text{C}^4\text{H}^{11}\text{Cl}$	101°	0.8750 at 20°	101°	0.8777 at 20°
Amyl acetate, $\text{C}^4\text{H}^{11}\text{C}^2\text{H}^3\text{O}^2$	140°	0.8733 at 15°	140°	0.8752 at 15°
Amyl alcohol, $\text{C}^4\text{H}^{10}\text{O}$	132°	0.8148 at 14°	132°	0.8199 at 14°

Lastly, Wurtz has shown that valeral, $\text{C}^4\text{H}^9\text{COH}$, treated for fifteen days with sodium amalgam and water, takes up 2 at. hydrogen and is converted into a primary amyl alcohol (*Ann. Ch. Pharm.* cxxxiv. 301).

The following statements all relate to the amylic alcohol of fermentation:—

Solubility.—1 pt. of amylalcohol dissolves in 3.9 pts. water at 16.5° , forming a liquid of sp. gr. 0.998. On the other hand, 1 pt. of water mixes with 11.625 pts. amyl alcohol at 16.5° , forming a clear liquid of sp. gr. 0.8350 (Wittstein, *Jahresb.* 1862, p. 408). Amyl alcohol dissolves in all proportions of acetic acid diluted with an equal quantity of water, and may be thereby separated from neutral amylic ethers which are not soluble in acetic acid (Berthelot & St. Gilles, *Jahresb.* 1862, p. 409). It dissolves $3\frac{1}{2}$ vol. acetylene at 18° (Berthelot, *Ann. Ch. Phys.* [4] ix. 425).

Reactions.—1. Vapour of amyl alcohol is decomposed by the passage of electric sparks in a barometric vacuum, with formation of acetylene (De Wilde, *Bull. Soc. Chim.* [2] vi. 267).—2. The vapour passed through a tube heated to low redness is resolved into a mixture of gases, chiefly propylene (Reynolds, i. 203), together with ethylene, butylene, liquid hydrocarbons (Wurtz, *Ann. Ch. Phys.* [3] li. 84), and a small quantity of acetylene (Caventou, *Bull. Soc. Chim.* [2] v. 162). If the heat is very strong, the product consists almost wholly of marsh gas (Reynolds).—3. Amyl

alcohol exposed to the air, either in direct sunshine or in diffused daylight, is gradually oxidised, yielding hydrogen dioxide and an acid, probably valeric acid (Schönbein, *J. pr. Chem.* xcviii. 261). When shaken up with ozonised air, it is oxidised to valeraldehyde and valeric acid (Gorup-Besanez, *Ann. Ch. Pharm.* cx. 103).

4. When nitric acid of sp. gr. 1.5 is covered with a nearly equal volume of amyl alcohol, the two being separated by a layer of water, and the whole left to itself for a month, amyl valerate is formed, together with oxalic acid and a yellow colouring matter (Claus, *J. pr. Chem.* cii. 384). Amyl alcohol heated to 90° absorbs nitrogen tetroxide, forming amyl nitrite and nitric acid:

and the nitric acid thus formed converts part of the amyl alcohol into amyl nitrate, and by oxidation into hydrogen valerate (valeric acid) and amyl valerate. Vapour of nitrous acid (from starch and nitric acid) passed into amyl alcohol forms amyl nitrite and ammonium nitrate, which separate in crystals (N. Bunge, *Zeitschr. f. Chem.* [2] ii. 82).

5. Solutions containing 3 to 8 p. c. potassium dichromate and a sufficient quantity of sulphuric acid oxidise amyl alcohol to valeric acid and amyl valerate; but the more volatile portion of the distillate obtained by fractional distillation from a sample of commercial amyl alcohol yielded, when thus treated, valeric, butyric, and carbonic acids, probably owing to the presence of a secondary amyl alcohol in the commercial product (Chapman a. Thorp, *Chem. Soc. J.* [2] iv. 477).

6. When amyl alcohol is boiled with sulphur, a small quantity of hydrogen sulphide is evolved; sulphuretted products are obtained in larger quantity by passing the vapour of the alcohol into boiling sulphur (Brian, *Jahresh.* 1863, p. 467).

7. When chlorine gas is passed into amyl alcohol, the liquid becomes hot, giving off hydrochloric acid and amyl chloride; if the action be prolonged (with a few ounces of the alcohol it goes on for eight or ten days), the ultimate product is the compound $\text{C}^5\text{H}^7\text{Cl}^3$, and intermediate products are formed agreeing approximately with the formulae $\text{C}^5\text{H}^8\text{ClO}^2$ and $\text{C}^5\text{H}^9\text{ClO}^2$; the latter when decomposed with alcoholic potash yields valeric acid. The compound $\text{C}^5\text{H}^7\text{Cl}^3$ treated with alcoholic potash yields a liquid, $\text{C}^5\text{H}^7\text{Cl}^4$, boiling above 200° (Barth, *Ann. Ch. Pharm.* cxix. 216).

8. Amyl alcohol distilled with water and chloride of lime yields, besides chloroform, a liquid which boils at 70°, has a density of 0.88 at 0°, and exhibits the composition of butyl chloride, $\text{C}^4\text{H}^9\text{Cl}$ (F. Gerhard, *Ann. Ch. Pharm.* cxxii. 363).

9. With phosphorus trichloride, amyl alcohol yields amyl chloride and amyl phosphorous chloride, $\text{PC}^5\text{H}^{11}\text{OCl}^2$ (Menschutkin, *Ann. Ch. Pharm.* cxxxix. 343). (For the action of PCl^3 , see i. 201.) Phosphorus cyanide acts strongly on amyl alcohol, forming amyl phosphite and hydrocyanic acid (Wehrhane a. Hübner, *Ann. Ch. Pharm.* cxxiii. 283).

10. With chlorine disulphide, S^2Cl^2 , amyl alcohol mixes to a yellow liquid which evolves hydrochloric acid and sulphurous oxide, and when heated deposits sulphur, gives off amyl chloride, then becomes carbonised and gives off stinking sulphuretted products. With excess of amyl alcohol, the products are chloride, sulphite, and sulphhydrate of amyl (Carius a. Fries, *Ann. Ch. Pharm.* cix. 1):

and

With sulphur dichloride, SCl^2 (a mixture of chlorine disulphide and sulphur tetrachloride, v. 535), amyl alcohol forms hydrochloric acid, sulphurous oxide, amyl chloride, and chlorine disulphide (Carius a. Fries):

With thionyl chloride, amyl alcohol forms hydrochloric acid and amyl sulphite (Carius, *Ann. Ch. Pharm.* cxi. 98).

11. Amyl alcohol distilled with zinc chloride gives off, in addition to amylene and amyl hydride, other hydrocarbons homologous with these, varying in boiling point from below 50° to above 400°, and leaves an undistillable carbonaceous residue (Wurtz). If the distillation be interrupted at 140°–160°, the residue contains triamylene and tetramylene (Bauer, *Zeitschr. Ch. Pharm.* 1861, p. 645). On distilling amyl alcohol for 24 hours with 1½ pts. of recently fused and pulverised zinc chloride, separating the portion of the oily distillate which boils below 60° and contains amylene and amyl hydride, treating the portions of higher boiling point once more

with *sine chloride*, and further with sodium, to remove unaltered amyl alcohol, a liquid is obtained which yields by fractional distillation, (a) between 60° and 70°, hexylene and hexyl hydride; (b) between 80° and 85°, heptylene and heptyl hydride; (c) between 120° and 130°, octylene and octyl hydride; (d) between 135° and 150° nonylene and nonylhydride; (e) diamylene and diamylhydride; and, lastly, thick oily hydrocarbons boiling above 400°. The greater number of these hydrocarbons are however formed, not from the amyl alcohol itself, but from small quantities of other alcohols mixed with it (Wurtz, *Bull. Soc. Chim.* 1863, p. 461; *Ann. Ch. Pharm.* cxxviii. 316).

12. Amyl alcohol boiled with solution of *platinic chloride* yields amylene platinosochloride, $2(C^5H^{10}.HCl).Pt.Cl^4 + 2aq.$, together with valeraldehyde and chlorinated products (Birnbäum, *Ann. Ch. Pharm.* cxlv. 67).

13. When 10 pts. amyl alcohol are added to 2 pts. *mercury* dissolved in 12 pts. *nitric acid*, a brisk reaction takes place and oxalic acid is formed, but no product analogous to fulminating mercury; the cooled liquid deposits crystals of a double salt of mercurous oxalate and mercuric nitrate (v. Gilm, *Jahresb.* 1858, p. 402).

14. When amyl alcohol is heated with *ethyl acetate* (α), *iodide* (β), or *oxalate* (γ), there is formed, by double decomposition between the amyl alcohol and a portion of these ethers: α. Amyl acetate and ethyl alcohol; β. Amyl iodide, ethyl alcohol, and ethyl-amyl oxide; γ. Amyl oxalate and ethyl-amyl oxalate (Friedel & Crafts, *Ann. Ch. Pharm.* cxxx. 198; cxxxi. 55).

Sodium Amylate or *Amylene-sodium Hydrate*. $C^5H^{11}NaO$.—The crystalline body produced by the action of sodium on amyl alcohol (i. 205) is commonly regarded as sodium amylate, $C^5H^{11}\left\{ \begin{smallmatrix} O \\ Na \end{smallmatrix} \right\}$, derived from amyl alcohol, $C^5H^{11}\left\{ \begin{smallmatrix} O \\ H \end{smallmatrix} \right\}$, by substitution of sodium for the typical hydrogen. But from recent investigations by Wanklyn (*Phil. Mag.* [4] xxxvii. 117, 175), it appears that this crystalline body, when dried at 100°, has the composition $C^5H^{11}NaO.3C^5H^{12}O$, that is, 1 mol. sodium amylate with 3 mol. amyl alcohol, and that when heated to about 200° it gives off the whole of the amylic alcohol, leaving pure or absolute sodium amylate, $C^5H^{11}NaO$. This same compound may be obtained by the action of amyl alcohol on sodium ethylate:

Moreover, from numerous considerations relating to the constitution and chemical functions of sodium compounds, Wanklyn infers that sodium is not univalent, as commonly supposed, but trivalent, sodium hydrate consisting of $Na^{\prime\prime\prime}\left\{ \begin{smallmatrix} H \\ O \end{smallmatrix} \right\}$, sodium acetate of $Na^{\prime\prime\prime}\left\{ \begin{smallmatrix} C^2H^3O \\ O \end{smallmatrix} \right\}$, &c. (See SODIUM.)

In accordance with this view, sodium amylate, $C^5H^{11}NaO$, must be regarded as amyleno-sodium hydrate, and represented by the formula

Amylene-sodium hydrate treated with *ethyl valerate* is converted into amyleno-sodium valerate and ethyl alcohol:

Amylene sodium acetate, $\overbrace{C^5H^{10}-O-C^2H^3O}^{Na^{\prime\prime\prime}}$, is obtained in like manner.

This salt, or ether, is isomeric with sodium cœnanthylate, $C^5H^{12}NaO^2$, and the valerate above mentioned with sodium rutate or caprate, $C^5H^{10}NaO^2$. These ethers react with *water* in such a manner as to yield an ordinary salt of the acid whose radicle they contain, together with amyl alcohol; e.g.,

All these reactions have been more closely studied with the ethylene sodium compounds (*q.v.*).

Sodium amylate treated with *chloroform* yields sodium chloride and a triamylie ether, analogous in constitution to the tri-alcoholic glycerides (Williamson & Kay, *Chem. Soc. Qu. J.* vii. 224):

Thallium Amylate, $\text{C}^5\text{H}^{11}\text{TlO}$, described amongst thallium compounds (*v. 757*),

may be regarded in like manner as $\text{Tl}^{'''}$ $\left\{ \begin{array}{c} \text{C}^5\text{H}^{11} \\ | \\ \text{O} \\ | \\ \text{H} \end{array} \right.$.

Compound of Amyl Alcohol with Stannic Chloride.—When anhydrous stannic chloride is poured, with careful exclusion of air, into pure amyl alcohol cooled to between -10° and -17° , a nearly colourless mass is formed, consisting of the amyl alcoholate of stannic chloride, $\text{SnCl}_4 \cdot 2\text{C}^5\text{H}^{12}\text{O}$. This compound forms colourless tabular crystals, which deliquesce rapidly on exposure to the air, and are instantly decomposed by water into stannous chloride, hydrochloric acid, and amyl alcohol. It dissolves in benzol, chloroform, and carbon bisulphide, and may be recrystallised from these solutions over sulphuric acid in a vacuum, though not without partial decomposition. Heated to 100° in a sealed tube and then distilled, it yields, together with a yellow liquid, white feathery crystals of the hydrate of stannic chloride, $\text{SnCl}_4 \cdot 3\text{H}_2\text{O}$, described by Casselmann (*v. 808*). The yellow liquid, after washing with dilute alkali, yields by fractional distillation, from 40° to 100° , moderately pure amylene; from 100° to 170° , chiefly amylene chloride, $\text{C}^5\text{H}^{12}\text{Cl}_2$; and from 170° to 400° , polymerides of amylene, mixed with a small quantity of chlorinated amylenes. The decomposition of the amyl-alcoholate of stannic chloride by heat may therefore be represented essentially by the following equation:

Primary Amylic Haloid Ethers.

Amyl Bromide, $\text{C}^5\text{H}^{11}\text{Br}$, is best prepared by saturating amyl alcohol with gaseous hydrobromic acid, mixing the saturated solution with an equal volume of the aqueous acid of sp. gr. about 1.5, and digesting slowly at the heat of the water-bath, either in a flask with a vertical condensing tube, or in a closed vessel. The amyl bromide which rises to the surface must be decanted, washed with water, and distilled from under a solution of sodium carbonate. The distillate consists of water and the bromide, which has then to be dried over calcium chloride and fractionally distilled. If the amyl alcohol was pure, the bromide boils quite constantly; if not, it fractionates very easily. The pure bromide boils at 121° (at 118.7° according to Mendelejeff, *Jahresb.* 1860, p. 7), and has a sp. gr. of 1.217 at 16° (1.058 at 0° , Pierre; 1.2059 at 15.7° , Mendelejeff). It is very strongly attacked by sodium at temperatures near its boiling point (Chapman & Smith, *Chem. Soc. J.* [2] vii. 198).

Amyl Chloride, $\text{C}^5\text{H}^{11}\text{Cl}$, is produced by treating 90 pts. amyl alcohol with 200 pts. brown chloride of sulphur (a mixture of S^2Cl_2 with SCl_4 , *v. 535*). The action is very violent at first, hydrochloric acid and sulphurous oxide being given off, for the complete removal of which the mixture must be heated to 101° . At 110° amyl chloride distils over, amounting, after washing with weak soda-ley, drying, and rectifying, to 100 pts. (Carius & Fries, *Ann. Ch. Pharm.* cix. 1).

Boiling point 101.75° under pressure of 752.4 mm. (Pierre, *Jahresb.* 1851, p. 51); 98° (Rossi, *Ann. Ch. Pharm.* cxxxiii. 176); corr. 100.9° , under pressure of 745.6 mm. (Kopp; Carius & Fries). Sp. gr. 0.8625 at 25.1° ; 0.8559 at 0° (Kopp, *Jahresb.* 1855, p. 35); 0.8958 at 0° (Pierre); 0.8744 at 15.7° (Mendelejeff, *ibid.* 1860, p. 7).

Amyl chloride is very slowly decomposed by water at 100° into hydrochloric acid and amyl alcohol (Butlerow, *Ann. Ch. Pharm.* cxliv. 34). Chlorine passed through it converts it into carbon trichloride, C^2Cl_6 (Gerhard, *ibid.* cxxii. 363). With strong sulphuric acid it yields hydrochloric and amyl-sulphuric acids (Oppenheim, *J. pr. Chem.* cii. 339). With *alcoholic potash* it forms ethyl-amyl oxide (Reboul & Truchet, *Compt. rend.* lxi. 1243). Heated with *sodium acetate* or *benzoate*, it forms amyl acetate or benzoate, together with a small quantity of amylene (Berthelot, *Ann. Ch. Pharm.* cxxvii. 69).

When chlorine is passed in diffused daylight and at ordinary temperatures through amyl hydride from American petroleum, a mixture of chlorinated products is formed, from which by fractional distillation an amyl chloride may be separated boiling at 98° – 103° . This chloride, treated with sulphhydrate and monosulphide of

potassium, and with alcoholic ammonia, yields amyl-compounds; but with alcoholic potash it yields a large quantity of amylene (Pelouze & Cahours, *Ann. Ch. Phys.* [4] i. 13); from this it appears probable that a secondary amyl chloride is formed simultaneously with the primary chloride.

Amyl Iodide. $C^5H^{11}I$.—Produced, together with ethyl alcohol, by heating amyl alcohol with ethyl iodide; the decomposition, however, is only partial; and, on the other hand, ethyl alcohol and amyl iodide react partially, producing amyl alcohol and ethyl iodide (Friedel & Crafts, *Ann. Ch. Pharm.* cxxx. 198).

According to Grimm (*J. pr. Chem.* lxii. 385), the directions usually given for the preparation of this compound prescribe too large a proportion of amyl alcohol. Grimm uses 5 parts iodine to 4 parts amyl alcohol. The alcohol mixed with 4 to 5 per cent. water is saturated with iodine; the decanted solution is heated to 50° and decolorised with phosphorus, then decanted from the phosphorus, and poured back on the undissolved iodine, again decolorised with phosphorus, and so on, till the whole of the iodine is used up. The fuming liquid is distilled after 24 hours, the distillate shaken up with water and iodine, as long as the colour of the iodine is thereby destroyed, then washed, dried, and rectified, the pure amyl iodide passing over at 149° .

Sp. gr.	Boiling point (corr.)	Observers
1.5087 at 15.8° (referred to water at 4°)		Mendelejeff (<i>Compt. rend.</i> 1. 52).

Reactions.—Amyl iodide is slowly oxidised to valeric acid by a 5 per cent. aqueous solution of potassium dichromate and sulphuric acid (Chapman & Thorp, *Chem. Soc. J.* [2] iv. 477). Heated with moist silver oxide to 100° , it forms silver iodide and amyl alcohol, together with small quantities of amyl oxide and amylene (Wurtz, *Ann. Ch. Phys.* [3] xlv. 223).

When 2 at. silver cyanide and 1 at. amyl iodide are heated together to the boiling point of the latter, a very violent action takes place, equal volumes of amylene and hydrocyanic acid being given off, and a black mass remaining, which consists of silver iodide and a compound of silver cyanide with amyl cyanide, and when further heated gives off hydrocyanic acid, amylene, and amyl cyanide (Hofmann, *Zeitschr. f. Chem.* [2] iii. 665).

For the reactions of amyl iodide with sodium, see i. 202; with sodium ethylate and methylate, i. 205; with zinc, iv. 219; with sodium stannide, v. 835; with sodium plumbide, iii. 560; with sodium amalgam in presence of acetic ether, iii. 924; with cacodyl, i. 411; with ethyl oxalate, amyl oxalate, &c., and zinc, iv. 278.

Secondary Amyl Alcohols. The secondary alcohol $C^4H^9.CH(OH).C^2H^5$ or $C^5H^{10}.H^2O$ admits of the three following modifications:

The first two of these are actually known.

PROPYL-METHYL CARBINOL is produced: 1. By combining ethyl-allyl, $C^2H^5.C^3H^5$, with hydriodic acid, and distilling the resulting secondary amyl iodide, $C^5H^{10}.HI$, with silver oxide and water, or, better, by converting the iodide into the corresponding acetate, $C^5H^{10}.H.C^2H^3O^2$, by means of silver-acetate, and distilling the purified acetate at 120° with very strong potash-ley and sticks of potash. The passage from the ethyl-allyl through the iodide to the alcohol may be represented by the following structural formulae:—

(Wurtz, *Zeitschr. f. Chem.* [2] iv. 490).

2. By decomposing propyl-methyl ketone (obtained by distilling a mixture of calcium butyrate and acetate) with sodium amalgam and water (Friedel, *ibid.* v. 486).

Propyl-methyl carbinol has an odour like that of ordinary amyl alcohol, but less pungent; sp. gr. = 0.8249 – 0.8260 at 0°; boiling point 120° under a pressure of 759 mm. (Wurtz), 120° – 123° (Friedel); insoluble in water; oxidised by *potassium permanganate*, yielding a neutral liquid which unites with acid sodium sulphite, and when separated from that combination boils at 103°, and exhibits nearly the composition of propyl-methyl ketone, $C^3H^{10}O$. Acetic and propionic acids are likewise produced in the oxidation. The alcohol treated with *chromic acid* does not yield carbon dioxide (Wurtz). Treated with *iodine* and *phosphorus*, it yields the corresponding iodide, $C^3H^{10}HI$, which when decomposed by silver acetate, yields amylene, together with the corresponding amyl acetate, $C^3H^{10}.H.C^2H^3O^2$.

ISOPROPYL-METHYL CARBINOL, $CH(CH^3)^2.CH(OH)$, or AMYLENE MONOHYDRATE, $C^3H^{10}.H^2O$, discovered by Wurtz (*Ann. Ch. Phys.* [4] iii. 137), is produced by combining amylene (from ordinary amyl alcohol) with hydriodic acid, adding the resulting hydriodide by small quantities at a time to an equivalent quantity of moist silver oxide in a vessel surrounded with ice, then leaving the mixture to itself for a while, and distilling. The alcohol then passes over with the water; afterwards the boiling point rises to about 160°, and above that temperature the corresponding ether, $C^3H^{10}.H(OC^2H^3)$, passes over. Ordinary amylene hydriodide is decomposed by silver oxide much more easily than the isomeric compound ethyl-allyl hydriodide.

The passage from amylene through the iodide to the alcohol is represented by the following formulae:

Isopropyl-methyl carbinol is a light, colourless, very mobile liquid, boiling at 105° (bar, 768 mm.) (Wurtz), at 108° (Kolbe), i.e. from 12° to 15° lower than methyl-propyl carbinol. Heated for some hours to 200°, it splits up into amylene and water. It absorbs *hydriodic acid* rapidly and with rise of temperature, forming water and amylene hydriodide; with *bromine* it forms chiefly amylene dibromide; with *chlorine*, amylene dichloride and hydrochloride. When shaken up with *sulphuric acid*, it becomes hot and yellow, and is converted, not into amylsulphuric acid, like the primary alcohol, but into amylene and hydrocarbons polymeric therewith. With *sodium* it forms sodium amylenate, $C^3H^{10}.Na(OH)$ [probably identical with Wanklyn's hydrate of amylene-sodium, p. 109], which when treated with amylene hydriodide reproduces the secondary alcohol and amylene:

When oxidised by *potassium dichromate* and *sulphuric acid*, it gives off carbon dioxide, volatile acids, chiefly acetic acid, a mixture of ketones, &c.; with *potassium permanganate*, the same products (Wurtz). According to Kolbe (*Ann. Ch. Pharm.* cxxxii. 102; *Jahresh.* 1864, p. 502), the oxidation is of a more definite character. On gradually pouring the alcohol into a hot aqueous solution of 2 pts. potassium dichromate mixed with 3 pts. sulphuric acid, there distils over, together with acetic acid, a fruity-smelling oil, which is a mixture of the unaltered alcohol with a ketone; $C^3H^{10}O$, convertible by further oxidation into acetic and carbonic acids. This body is doubtless isopropyl-methyl ketone, or methyl-isobutyryl, $CO \begin{Bmatrix} CH^3 \\ CH(CH^3)^2 \end{Bmatrix}$.

Secondary Amylic Ethers.

These ethers, as well as the corresponding alcohols, are distinguished from the primary amylic compounds by the facility with which they are resolved into amylene (or isoamylenes) and the corresponding acids. They may in fact be regarded as amylenes compounds intermediate in composition between the primary amylic compounds and the amyleno-glycolic compounds. (See ALCOHOLS, p. 66.) The chloride, bromide, and iodide are formed by direct combination of amylene or isoamylenes with the haloid acids.

Propyl-methyl-carbinyl Acetate or Iso-amylenes Acetate,

is prepared by adding the corresponding iodide to an equivalent quantity of silver acetate suspended in ether, distilling after 24 hours, agitating the distillate with aqueous sodium carbonate, drying with calcium chloride, and rectifying. It is a colourless liquid, having a pleasant aromatic odour, but not smelling of pears like ordinary amyl acetate. Sp. gr. 0.9222 at 0°. Boils at 133°-135°. Decomposed with some difficulty by caustic potash, yielding propylmethyl-carbinol (Wurtz).

Isopropyl-methyl-carbinyl Acetate or Amylenes Acetate,

Produced by the action of amylene hydriodide on silver acetate. Colourless liquid, lighter than water, boiling at 125°. When kept for some time at 200°, it is resolved into acetic acid and amylene (Wurtz).

Isopropyl-methyl-carbinyl Amylate, C¹⁰H²²O = $\begin{matrix} \beta\text{C}^2\text{H}^7 \\ \text{CH}^2 \end{matrix} \left\{ \text{CH}(\text{OC}^2\text{H}^{11}), \right.$ or *Diamylenes Hydrate* = (C²H¹⁰)².H²O, is obtained, as above mentioned, together with the corresponding alcohol, by the action of moist silver oxide on the hydriodide, but in variable quantity. It is an aromatic liquid, differing in odour from its isomeride, primary amylic oxide, and boiling at 160°-165° (the primary ether boils at 176°). Sp. gr. = 0.876 at 0°. Insoluble in water. Resolved by heat into amylene and amylenes monohydrate; by gaseous hydriodic acid into water and amylenes hydriodide (Wurtz).

Isopropyl-methyl-carbinyl Ethylate, $\begin{matrix} \beta\text{C}^2\text{H}^7 \\ \text{CH}^2 \end{matrix} \left\{ \text{CH}(\text{OC}^2\text{H}^5); \right.$ *Ethylene-amylenes Hydrate or Amylenes Ethylate,* $\begin{matrix} \text{C}^2\text{H}^4 \\ \text{C}^2\text{H}^{10} \end{matrix} \left\{ \text{H}^2\text{O} \right.$.—Formed by heating amylenes hydrobromide with excess of alcoholic potash (amylenes being however the principal product), and separated by washing with water and rectification, finally over sodium. Boils at 102°-103° under a pressure of 742 mm. (the isomeric ethyl-amylic ether, (C²H⁵)(C²H¹¹)O, at 112°), and has a sp. gr. of 0.759 at 21°. Heated with hydrobromic acid, it yields primary and secondary amylic bromides (Reboul a. Truchot, *Compt. rend.* lxi. 1243).

Isopropyl-methyl-carbinyl Benzoate or Amylenes Benzoate,

prepared like the acetate, is a colourless, rather mobile liquid, soluble in water, having a slight benzoic odour, and a faint but disagreeable taste. Sp. gr. 1.007 at 0°. Boils at about 240° (Wurtz).

Isopropyl-methyl-carbinyl Bromide or Amylenes Hydrobromide:

Prepared like the hydrochloride, which it also resembles in its properties. Sp. gr. 1.227 at 0°. Boils at 113° (corr.). Its vapour-density at different temperatures exhibits variations similar to those of the hydriodide (p. 115) as shown by the following numbers, determined by Wurtz:

Temp. (corrected)	V.D.	Temp. (corrected)	V.D.	Temp. (corrected)	V.D.
153°	5.37	193.2°	4.84	262.5°	3.09
158.8	5.18	195.2	4.66	272	3.11
160.5	5.32	205.2	4.39	295	3.19
165	5.14	215	4.12	305.3	3.19
171.2	5.16	225	3.68	314	2.98
173.1	5.18		3.83	319.2	2.88
182.3	5.15	236.5	3.30	360	2.81
185.5	5.12	248			

Now the calculated vapour-density of the compound, referred to air, is $\frac{60 + 11 + 80}{2}$

$\times 0.0693 = 5.23$. Hence the compound exhibits a normal vapour-density as high as about 185°, or 72° above its boiling point; but above that temperature the vapour-density diminishes, rapidly between 193° and 250°, and at 360° it is reduced to little more than the half of the calculated density, showing that the compound is resolved at these high temperatures into a mixture of amylene and hydrobromic acid. At the same temperatures hydrobromic acid vapour and amylene may be mixed together without uniting, the mixture not being attended by any perceptible increase of heat. If mixed at 215°–225°, they combine to a small amount, producing a rise of temperature amounting to 0.6°; if mixed between 120° and 130°, they combine in larger proportion, producing a rise of 4° to 6°; and if mixed at 40°, they unite immediately, producing a considerable rise of temperature. All these phenomena show that the anomaly in the vapour-density of this and of similar compounds at high temperatures is due to dissociation (Wurtz, *Compt. rend.* lx. 728; lxx. 1182).

Isopropyl-methyl-carbinyl Chloride, or Amylene Hydrochloride.

$\text{BC}^{\text{H}^7}\text{CHCl} = \text{C}^{\text{H}^9}\text{HCl}$.—Produced by the direct combination of amylene vapour and hydrochloric acid gas, the action being attended with evolution of heat; also by dissolving amylene at ordinary temperatures in 4 vols. absolute alcohol saturated with hydrochloric acid gas, and distilling off the upper layer of liquid after 24 hours (Berthelot, *Compt. rend.* lvi. 700). It is a colourless mobile liquid, having an ethereal odour, boiling at about 90°. Sp. gr. = 0.833 at 0°. Vapour-density at 193° = 3.68 (calc. for a two-volume condensation, 3.688); but at a somewhat higher temperature dissociation occurs, and at 290° the density of the vapour is reduced to that of a mixture of amylene and hydrochloric acid, namely, to 1.808. The amylene and hydrochloric acid recombine in great part on cooling (Wurtz). Amylene hydrochloride treated with aqueous *potash* yields amylene hydrate or isopropyl-methyl carbinol and amylene; with *sodium benzoate* it yields amylene and a large quantity of isopropyl-methyl benzoate; with *sodium acetate*, amylene in rather large quantity, and the corresponding acetate (Berthelot).

Isopropyl-methyl-carbinyl Cyanate, or Amylene Cyanate,

obtained by treating amylene hydriodide with recently prepared and cooled silver cyanate, is a liquid boiling between 100° and 120°, and having an irritating odour. In contact with *ammonia*, it forms secondary amyl-urea, $\text{C}^{\text{H}^9}\text{H.N}^{\text{O}} = \text{CON}^{\text{H}^2}(\text{C}^{\text{H}^7})(\text{C}^{\text{H}^9})$ [primary amyl-urea being $\text{CON}^{\text{H}^2}(\text{C}^{\text{H}^{11}})$]. This compound crystallises in splendid needles, and when treated with very strong aqueous *potash* yields carbon dioxide, ammonia, and secondary amylamine or iso-amylamine (p. 116). By *water* or caustic *potash*, amylene cyanate is converted into a mass of crystals, consisting of secondary diamyl-urea, $\text{C}^{\text{H}^9}\text{H.N}^{\text{O}} = \text{CON}^{\text{H}}(\text{C}^{\text{H}^7})(\text{C}^{\text{H}^9})(\text{C}^{\text{H}^{11}})$ [primary diamyl-urea being $\text{CON}^{\text{H}^2}(\text{C}^{\text{H}^{11}})^2$] (Wurtz).

Propyl-methyl Carbinyl Iodide, $\text{BC}^{\text{H}^7}\text{CHI}$, or Iso-amylene Hydri-

odide, $\text{C}^{\text{H}^9}\text{H.I}$, is produced by heating ethyl-allyl (isoamylene) with hydriodic acid, or by the action of iodine and phosphorus on propyl-methyl carbinol (p. 112). It has a sp. gr. of 1.587 at 0° and 1.5219 at 11°. Boils at 129° (Wurtz).

Isopropyl-methyl-carbinyl Iodide, $\text{BC}^{\text{H}^7}\text{CHI}$, or Amylene Hydri-

odide, $\text{C}^{\text{H}^9}\text{H.I}$, is produced by heating ordinary amylene with concentrated

hydriodic acid. It boils at 130° under the ordinary atmospheric pressure (primary amyl iodide at 146°), and at 50°-55° in a vacuum. Sp. gr. = 1.522 at 0°. Its vapour-density, even at temperatures but little above its boiling point, falls below the calculated number, indicating a commencement of decomposition, and at higher temperatures the vapour-density approaches continually to that of a mixture of amylene and hydriodic acid; thus:

Temperature	Vapour-density	
	Air = 1. Hydrogen = 1.	
160°	5.73	82.7
210°	4.06	67.3
262°	4.38	63.2

Half the molecular weight of the compound $C^5H^{11}I$ is $\frac{60 + 11 + 127}{2} = 99$.

With *sodium*, amylene hydriodide yields chiefly amylene and hydrogen. With *silver-acetate* mixed with ether, a brisk reaction takes place, even at 0°, the liquid becoming hot, and yielding secondary amyl acetate, together with amylene and acetic acid:

and

Moist *silver oxide* acts in a similar manner, forming silver iodide, secondary amyl alcohol, amylene, and water. *Aqueous ammonia* heated with the hydriodide to 100° in a closed tube displaces the amylene, and forms only a small quantity of the hydriodide of an organic base, which yields a platinochloride crystallising in golden yellow scales. *Alcoholic potash* liberates amylene (Wurtz).

Tertiary Amyl Alcohol or Ethyl-dimethyl Carbinol. $C\begin{Bmatrix} (CH^3)^3 \\ OH \end{Bmatrix} =$

$(CH^3)^2(C^2H^5).COH$ (Popoff, *Ann. Ch. Pharm.* cxlv. 292).—A mixture of 1 mol. chloropropionyl and 1 mol. zinc-methyl yields needle-shaped crystals of the compound $(CH^3)^2(C^2H^5).CCl$, from which by decomposition with water the tertiary alcohol is obtained, the reaction being precisely analogous to that by which tertiary butyl alcohol is prepared from zinc-methyl and acetyl chloride (p. 66). The alcohol is separated by distillation and addition of a strong solution of potassium carbonate, shaken up with a concentrated solution of acid sodium sulphite, and dried with fused potash and caustic baryta. It boils between 98.5° and 102°, smells very much like trimethyl carbinol, does not solidify at -17°, merely becoming more viscid and syrupy. By oxidation with potassium dichromate and dilute sulphuric acid it yields nothing but acetic acid.

AMYL HYDRIDE or QUINTANE. C^5H^{12} .—This saturated hydrocarbon, the fifth of the paraffin or marsh-gas series, C^5H^{12+2} , is found in American petroleum, of which it constitutes the portion boiling at 30° (Pelouze a. Cahours); it is also found in Boghead naphtha (C. Gr. Williams, *Chem. Soc. J.* xv. 130), and in light coal-tar oil obtained from Wigan cannel-coal (Schorlemmer, *ibid.* 419). It is produced: *a.* By the action of water on zinc-amyl:

β. By heating equal volumes of amyl iodide and water to 140° in a sealed tube with excess of zinc (Frankland, *Ann. Ch. Pharm.* lxxiv. 47):

γ. Together with amylene and its polymerides by heating amyl alcohol with zinc chloride.—*δ.* Together with amylene, as a product of the decomposition of diamyl, in the action of zinc on dry amyl iodide:

The mixture of amyl hydride and amylene formed in these and other reactions may be separated by means of fuming sulphuric acid, which dissolves the amylene, but not the amyl hydride.

Amyl hydride from American petroleum has a sp. gr. 0.628 at 18° and boils at 80° (Pelouze a. Cahours); sp. gr. 0.6263 at 17°, boiling point 84° (Schorlemmer, *Proc. Roy. Soc.* xv. 131). Amyl hydride readily absorbs *chlorine*, forming (together with

more highly chlorinated products) amyl chloride, $C^5H^{11}Cl$, boiling at 102° , like that obtained from amyl alcohol (Pelouze & Cahours). By prolonged action of the chlorine a thickish liquid is obtained, which begins to boil at 180° , and yields between 230° and 240° a liquid having the composition $C^5H^8Cl^4$, and converted by alcoholic potash into trichloramylene, $C^5H^3Cl^3$ (Bauer, *Compt. rend.* li. 572).

AMYL SULPHOXIDE. $C^{10}H^{22}SO = (C^5H^{11})^2SO$.—Produced by carefully dropping amyl sulphide, $(C^5H^{11})^2S$, into fuming nitric acid, and precipitating the solution with water. It then separates as a light yellow oil, solidifying, when washed with sodium carbonate, to a crystalline mass, which may be washed with water and recrystallised from ether. On leaving the still coloured crystals to drain in a funnel, the coloured portion runs away, and the purer compound remains. It forms stellate groups of needles melting at 37° – 38° , insoluble in water, easily soluble in strong sulphuric and in fuming nitric acid, from which solutions it is precipitated by water; easily soluble also in alcohol and in ether. It gives off acid vapours at 100° , and is decomposed by distillation, evolving stinking sulphuretted products; is completely oxidised by heating with chromic acid, iodic acid, and other oxidising agents; reduced by zinc and dilute sulphuric acid to amyl monosulphide. Hydriodic acid decomposes it at ordinary temperatures, and more readily when heated, with separation of iodine, and formation of a brown oil insoluble in water. Not altered by ethyl iodide, amyl iodide, or zinc-ethyl (Saytzeff, *Ann. Ch. Pharm.* cxxxix. 364).

AMYLAMINES. Ordinary amylamine, $C^5H^{11}N$, being derived from the amylie alcohol of fermentation, contains the radicle isobutyl $CH^2CH(CH^3)^2$, and is represented by the formula

It is produced, together with formic acid, by the action of acids—hydrochloric acid for example—on amyl cyanide (Hofmann, *Jahresb.* 1867, p. 364):

According to Limpricht (*Bull. Soc. Chim.* [2] viii. 363), a mixture of amyl cyanate and cyanurate, decomposed by potash, forms an oily and a watery layer, the former consisting of amyl alcohol, the latter of a mixture of amylamine, diamylamine, and triamylamine.

Secondary Amylamine or Isoamylamine. $C^5H^{11}N = C \begin{pmatrix} CH(CH^3)^2 \\ CH^2 \\ H \\ NH^2 \end{pmatrix}$ or

$N \begin{pmatrix} CH(CH^3)^2[CH(CH^3)^2] \\ H \\ H \end{pmatrix}$.—This base, discovered by Wurtz (*Bull. Soc. Chim.* [2] vii.

243), is produced by heating secondary amyl urea (p. 113) in a flask of very hard glass with strong potash mixed with solid potassium hydrate, decanting the liquid which takes the place of the crystals of the urea, and distilling it over caustic baryta. The isoamylamine then distils over at 78.5° . Its density at 0° is 0.755. It has an ammoniacal odour, precipitates cupric salts, but does not redissolve the precipitated cupric hydrate. Its vapour strongly heated in contact with baryta yields combustible gases and a small quantity of barium cyanide. Bromine in contact with excess of the concentrated solution of this base forms a hydrobromide of the base and a heavy yellow brominated liquid, $C^{10}H^{12}BrN$, which cannot be distilled. The *hydrochloride*, $C^5H^{11}N.HCl$, crystallises in efflorescent scales, and may be obtained in rather large quadratic octohedrons by pouring ether into the concentrated alcoholic solution. The *platinichloride*, $2C^5H^{11}N.Cl.PtCl^4$, is very soluble in water and in alcohol, and forms fine crystals, derived from a monoclinic prism. The *aurochloride*, $C^5H^{11}N.AuCl^3$, forms large yellow crystals, also belonging to the monoclinic system.

AMYLENE or QUINTENE. C^5H^{10} .—This hydrocarbon, originally obtained by dehydrating amyl alcohol with zinc chloride, is also produced: in the decomposition of amyl chloride by melting potash, or by passing the vapour of that compound over lime heated to dull redness:

in the decomposition of amyl iodide by zinc amalgam in sealed tubes; of amylene

hydrate or secondary amyl alcohol by heat; of amylene hydriodide by moist silver oxide, ammonia, silver acetate, &c. (p. 116); of amylene dibromide, by copper and water under certain circumstances; in the dry distillation of amyl sulphates, acetates, and butyrates, also of oleic acid, resin, Boghead coal, and other organic bodies.

To prepare amylene, 1 pt. of fused zinc chloride is drenched with $\frac{1}{2}$ pt. amyl alcohol, and the liquid, after several days' contact and frequent agitation, is distilled, the action beginning at 70° – 80° , and the distillation being continued till the temperature rises to 130° – 140° and the liquid begins to froth. The distillate contains amylene, water, undecomposed amyl alcohol, and polymerides of amylene; it is redistilled in the water-bath, and the distillate is dehydrated, and rectified over sodium. The residue contains di-, tri-, and tetra-amylene (Bauer, *Wien. Akad. Ber.* xlv. [2] 87; *Jahresb.* 1861, p. 659). See also Linnemann (*Ann. Ch. Pharm.* cxliii. 350).

Amylene boils at 33° to 34° . Sp. gr. = 0.66277 at 0° ; 0.6549 at 10° (Buff, *Ann. Ch. Pharm. Suppl.* iv. 143).

Iso-amylene or Ethyl-allyl, $C^2H^3.C^2H^3$, a hydrocarbon isomeric with the amylene above described, is produced by the action of zinc-ethyl on allyl-iodide:

When a mixture of 1 mol. zinc-ethyl and 2 mol. allyl-iodide is heated to 100° in a sealed tube, a violent action takes place, zinc iodide separates out, and on opening the tube a large quantity of gas escapes, whilst the iodide is saturated with a liquid. On distilling off this liquid, heating it for some days in a sealed tube with potassium, and then subjecting it to fractional distillation, allyl passes over first, forming the principal product, then between 25° and 32° chiefly amyl hydride, and between 32° and 39° ethyl-allyl or iso-amylene mixed with amyl hydride. These two hydrocarbons are separated by treatment with bromine and distillation, the amyl hydride, which does not unite with the bromine, passing off at a comparatively low temperature, the bromisoamylene at about 175° (Wurtz, *Ann. Ch. Pharm.* cxxiii. 202).

The constitution of iso-amylene is shown by its mode of formation; ordinary amylene has not been formed synthetically, but its formation from primary amyl alcohol, and its conversion into secondary amyl alcohol or methyl-isopropyl carbinol (p. 112) show that it has the constitution of vinyl-isopropyl: $C^2H^3.C^2H^3$.

Amylene differs by 2 at. hydrogen from the saturated hydrocarbon C^4H^{12} , and is capable of uniting directly with 2 at. bromine, chlorine, and other univalent radicles, also with 1 mol. HCl, HBr, &c., and thereby forming saturated compounds of the type C^4H^{12} . It is therefore a diatomic or bivalent radicle; but, like most other radicles of this class, it possesses considerable stability in the free state, and is capable of giving up a portion of its hydrogen in exchange for other radicles, thereby forming substitution-products of its own type, e.g. C^4H^9Cl , C^4H^9Br , &c.; and these again can take up Cl^2 , Br^2 , HCl, &c., also forming saturated compounds. On the other hand, amylene bromide, $C^4H^{10}Br^2$, heated with alcoholic potash, gives up 2 mol. hydrobromic acid, and is reduced to quinine or valerylene, C^4H^8 , which is a quadrivalent radicle capable of forming saturated compounds, like $C^4H^8Br^2$, and unsaturated (bivalent) compounds, like $C^4H^6Br^2$; moreover, this last-mentioned compound is reduced by treatment with alcoholic potash to quinine or valerylene, C^4H^8 , which is a sexvalent radicle (v. 982). The following reactions relate chiefly to ordinary amylene; those of iso-amylene, so far as they have been studied, are analogous:—

1. Amylene is not altered at 300° , but decomposes partially when heated in a glass vessel to the softening point of the glass, yielding traces of acetylene and tar, also hydrocarbons of the series C^2H^{2n+2} , viz. propylene and butylene, and others belonging to the series C^2H^{2n+2} (Berthelot, *Ann. Ch. Phys.* [4] ix. 442). Acetylene is also formed in the imperfect combustion of amylene (Berthelot).

2. Amylene is not decomposed by heating to 300° with aqueous zinc chloride, but fused zinc-chloride at 100° converts it partially into diamylene and other polymerides (Bauer, Berthelot).

3. Strong sulphuric acid acts in a similar manner, but more quickly (Bauer), the liquid dividing into two portions, the lower of which contains an acid isomeric with amylsulphuric acid, and another corresponding to isethionic acid (Berthelot, *Ann. Ch. Pharm.* cxxviii. 311). At 100° part of the amylene is carbonised (Bauer).

4. Amylene heated with a solution containing 4 to 8 per cent. potassium dichromate and a sufficient quantity of sulphuric acid is oxidised to acetic and carbonic acids (Chapman a. Thorp). Wurtz obtained from amylene by this mode of oxidation the same products as from amylene hydrate (p. 112). Potassium permanganate acts in the same manner as the chromic acid mixture (Chapman a. Thorp). Truchot (*Compt. rend.* lxiii. 274) obtained formic, acetic, and propionic acids; he also observed an odour of butyric acid. According to Berthelot (*Compt. rend.* lxiv. 36), a cold solution of potassium permanganate produces volatile acids, oxalic, malonic, succinic, and perhaps pyrotartaric acid. When amylene is left for a week in contact with a highly concentrated solution of hydrogen dioxide in hydrochloric acid, amylene hydrochloride is produced, and may be extracted by ether. The remaining liquid, when freed from hydrochloric acid by silver oxide and concentrated, forms a bitter syrup, which when treated with chlorine bisulphide, yields amylene hydrochloride, and therefore contains hydrated oxide of amylene (Carius, *Ann. Ch. Pharm.* cxxix. 167). Respecting the action of fuming nitric acid and nitrogen tetroxide on amylene, see i. 208, 209.

5. With bromine, amylene forms chiefly amylene bromide, $C^3H^{10}Br_2$ (Reboul, *Compt. rend.* lviii. 105-8).

6. Amylene cooled at first to -15° , and afterwards gently heated, quickly absorbs chlorine, with slight evolution of hydrochloric acid, and the product, washed with dilute alkali and dried by calcium chloride, yields on fractional distillation the following compounds: 1. Chloramylene, C^3H^9Cl , of sp. gr. 0.9992 at 0° , and boiling at 90° - 95° (in small quantity).—2. Amylene dichloride, $C^3H^{10}Cl_2$, of sp. gr. 1.2219 at 0° , boiling at 145° (in larger quantity).—3. Chloramylene dichloride, $C^3H^9Cl_3$, by cooling of the portion which goes over between 160° and 190° : white feathery crystals purifiable by sublimation.—4. Dichloramylene chloride, $C^3H^8Cl_4$, a limpid liquid of sp. gr. 2.4292, boiling at 220° - 230° ; produced in considerable quantity by the action of chlorine on amylene at 100° ; not completely dechlorinated even by heating with alcoholic potash to 120° - 130° (Bauer, *Zeitschr. f. Chem.* 1866, pp. 380, 667).

7. Stannic chloride heated with excess of amylene to 100° in a sealed tube, is reduced to stannous chloride, and converts a portion of the amylene, partly into chloramylene, partly into amylene dichloride. The excess of amylene is at the same time converted into polymeric modifications (Bauer a. Klein, *Zeitschr. f. Chem.* [2] iv. 380).

8. Amylene unites with hydrochloric and hydrobromic acids less readily than propylene (Berthelot, *Compt. rend.* xlv. 1350); also with hydriodic acid (Wurtz). According to Morkownikoff (*Zeitschr. f. Chem.* [2] ii. 502), it absorbs hydrobromic and hydriodic acids as rapidly as water, hydrochloric acid less quickly; unites also with hydrocyanic acid.

9. It combines readily with hypochlorous acid, $ClOH$, forming amylenic chlorhydrin, $C^3H^{10}Cl(OH)$ (Carius, p. 121). On agitating it with iodine, mercuric oxide, and water, hypiodous acid is produced, which converts the amylene into amylenic iodhydrin, $C^3H^{10}I(OH)$ (Lippmann, p. 121).

10. With carbonyl chloride (phosgene) amylene becomes hot and forms white fumes, condensing to a pungent liquid, which is not decomposed by contact with water for several days. This liquid yields by distillation amylene and dichloramylene, formed by the free chlorine in the phosgene gas, and between 90° and 100° a very strong-smelling product, consisting of leucic chloride, $C^3H^{10}OCl_2$, formed by direct addition of carbonyl chloride: $C^3H^{10} + COCl_2 = C^3H^{10}OCl_2$ (Lippmann, *Ann. Ch. Pharm.* cxxix. 81).

11. With phosphorus pentachloride, amylene becomes heated, and converted, without evolution of hydrochloric acid, into a nearly dry mass containing phosphorous acid, hydrochloric acid, and dichloramylene (Guthrie, *Ann. Ch. Pharm.* cxxi. 108). With chlorine bisulphide it unites directly, forming the compound $(C^3H^{10})_2S^2Cl^2$; with brown chloride of sulphur, $(S^2Cl^2 + SCl^2)$, it forms $C^3H^{10}S^2Cl^2$ (Guthrie, i. 209).

12. Cyanogen iodide heated with excess of amylene, decomposes it, forming brown products (Erlenmeyer, *Zeitschr. Ch. Pharm.* 1865, p. 546).

COMPOUNDS OF AMYLENE.

The additive compounds of amylene may be divided into two groups, viz.,

a. Those formed by addition of 1 molecule of a haloid acid, HCl , HBr , &c., and others formed therefrom by substitution of hydroxyl, OH , acetyl, $\text{OC}^2\text{H}^3\text{O}$, &c., for the haloid element. These are the secondary amylic compounds, discovered by Wurtz, e.g.,

Amylene Hydrochloride, or Methyl-isopropyl-carbinyl Chloride . $\text{C}^2\text{H}^{10}\text{HCl}$
 Amylene Monohydrate, or Methyl-isopropyl Carbinol . $\text{C}^2\text{H}^{10}\text{HOH}$
 Amylene Mono-acetate or Methyl-isopropyl-carbinyl Acetate . $\text{C}^2\text{H}^{10}\text{HOC}^2\text{H}^3\text{O}$

They have already been described, together with the corresponding methyl-propyl compounds derived from iso-amylene or ethyl-allyl, under **AMYL ALCOHOLS** and **ETHERS** (pp. 111-115).

β . Compounds formed by addition of 2 at. bromine, chlorine, or other univalent radicles, or 1 at. oxygen, sulphur, or other bivalent radicles, to 1 mol. amylene: these are the amylene-glycolic compounds, e.g.,

Amylene Dichloride	$\text{C}^2\text{H}^{10}\text{Cl}^2$
Amylene Hydrato-chloride or	}	$\text{C}^2\text{H}^{10}\left\{\begin{array}{l}\text{Cl} \\ \text{OH}\end{array}\right.$
Amylenic Chlorhydrin		
Amylene Dihydrate or	}	$\text{C}^2\text{H}^{10}(\text{OH})^2$
Amylenic Glycol		
Amylene Acetato-chloride or	}	$\text{C}^2\text{H}^{10}\left\{\begin{array}{l}\text{Cl} \\ \text{OC}^2\text{H}^3\text{O}\end{array}\right.$
Amylenic Aceto-chlorhydrin		
Amylene Diacetate	$\text{C}^2\text{H}^{10}(\text{OC}^2\text{H}^3\text{O})^2$
Amylene Oxide	$\text{C}^2\text{H}^{10}\text{O}$

Several of these compounds are described in vol. i. pp. 208, 209; the following have been more recently discovered, or further investigated.

Amylene Dibromide. $\text{C}^2\text{H}^{10}\text{Br}^2$.—Produced by the action of bromine on amylene (Cahours, *Compt. rend.* xxxi. 291), or on amylene monohydrate (Wurtz). To prepare it, bromine is added in a fine stream to amylene till the colour remains constant. The product, after washing with dilute potash, then with water, and drying, passes over on distillation, mostly between 170° and 180° , but not without loss of hydrobromic acid, so that it is best to interrupt the distillation at 160° ; the residual impure bromide may then be used for the preparation of amylene glycol (Wurtz, *Ann. Ch. Phys.* [3] lv. 458).

Amylene bromide is converted by alcoholic potash, chiefly into monobromamylene (Cahours), but a very small portion is converted by loss of Br^2 into amylene, and another small portion by loss of H^2Br^2 into valerylene, C^2H^8 (Reboul, *Ann. Ch. Pharm.* cxxxiii. 84). With *silver-acetate* it forms amylene diacetate (Wurtz). An alcoholic solution of *potassium acetate* acts upon it at 100° only after addition of glacial acetic acid, and even then but slowly, forming chiefly bromamylene, $\text{C}^2\text{H}^9\text{Br}$, with a small quantity of amylene diacetate (Bauer, *Bull. Soc. Chim.* 1860, p. 148). With *sodium ethylate* it yields bromamylene and amyl alcohol; with *zinc, sodium, or potassium*, bromamylene, amylene, and hydrogen (Bauer). Treated with *silver oxalate* under petroleum, it yields amylene, carbon dioxide, and silver bromide:

(Golowkinsky, *Ann. Ch. Pharm.* cxi. 252).

Derivatives of Amylene Dibromide.

Monobromamylene, $\text{C}^2\text{H}^9\text{Br}$, formed by heating amylene dibromide with alcoholic potash, is a colourless mobile liquid turning brown on exposure to the air, boiling at 100° – 110° (Bauer, *Ann. Ch. Pharm.* cxx. 187; *Zeitschr. Ch. Pharm.* 1861, p. 590); at 117° – 118° ; sp. gr. 1.22 at 19° (Linnemann, *Ann. Ch. Pharm.* cxliii. 351). It unites with 2 at. bromine, forming $\text{C}^2\text{H}^9\text{Br}^2$, and with chlorine, forming the compound $\text{C}^2\text{H}^9\text{Br}^2\text{Cl}^2$ in white crystals, but many other products are formed at the same time (Bauer). *Alcoholic potash* at 140° abstracts HBr , and forms valerylene, C^2H^8 (Reboul). Bromamylene distilled with *silver cyanate* yields a compound which forms with ammonia crystals of a *myl-urea* (Cahours & Hofmann, *Ann. Ch. Pharm.* civ. 309). *Zinc-ethyl* heated with bromamylene to 130° for 96 hours forms a small quantity of zinc bromide, a gas, and a few drops of a liquid boiling below 40° , probably amylene (Wurtz, *ibid.* cxxiii. 202). Olevisky (*Zeitschr. Ch. Pharm.* 1861, p. 674) obtained a light liquid having an alliaceous odour and boiling at 70° – 80° .

Bromamylene Dibromide. $C^8H^8Br^2 = C^8H^8Br.Br^2$.—On dropping bromine into bromamylene, the liquid solidifies, with hissing and evolution of heat, to a red-brown mass, which may be purified by pressure and recrystallisation from ether (Bauer, *loc. cit.*). This compound is also formed, together with amylene dibromide, on treating amylene with bromine (Reboul, *Compt. rend.* lviii. 1058). It forms white needles having the odour and taste of camphor. When heated it sublimes, with partial decomposition, but without fusion.

Treated with alcoholic potash, it yields bromamylene, C^8H^8Br , dibromamylene, $C^8H^8Br^2$, and an ethylate, $\begin{matrix} C^8H^8Br \\ C^2H^5 \end{matrix} \bigg\} O$, which boils at 177° – 180° , and is capable of taking up 2 at. bromine. The body thus formed, $\begin{matrix} C^8H^8Br^2 \\ C^2H^5 \end{matrix} \bigg\} O$, is converted

by alcoholic potash into another ethylate, $\begin{matrix} C^8H^8 \\ C^2H^5 \end{matrix} \bigg\} O$, a liquid lighter than water, boiling at 125° – 130° , and uniting with bromine, iodine, and concentrated haloid acids (Reboul).

The alcoholic solution of bromamylene dibromide heated with silver acetate yields the diacetate $\begin{pmatrix} C^8H^8O \\ C^2H^5Br \end{pmatrix}^2 O$, which when saponified by fused and pulverised potassium hydrate, yields bromamylene dihydrate, or bromamylene glycol, $\begin{matrix} C^8H^8Br^2 \\ H^2 \end{matrix} \bigg\} O^2$; and this last body heated to 100° in a sealed tube with potash yields amyleic glycerin, $\begin{pmatrix} C^8H^8 \\ H^2 \end{pmatrix} O^3$ (Bauer, *Zeitschr. Ch. Pharm.* 1861, p. 673).

Amylene Dibenzoate, $C^8H^{10}.(C^6H^5O^2)^2$, produced by the action of silver benzoate on amylene dibromide, forms large colourless shining laminae, soluble in alcohol and ether, melting at 123° (Meyer, *Compt. rend.* lix. 444).

Amylene Dichloride. $C^8H^{10}Cl^2$ (Guthrie, *Chem. Soc. Qu. J.* xiv. 128; Bauer, *Zeitschr. f. Chem.* [2] iv. 380, 667).—1. A mixture of phosphorus pentachloride and amylene forms a nearly dry mass, from which water, after twelve hours' standing, separates amylene dichloride as an oily layer, while hydrochloric and phosphorous acids remain in solution. The amylene dichloride is purified by washing, drying, and rectification (Guthrie).—2. The dichloride may also be prepared by passing chlorine through amylene, cooled at first to -15° , and then gradually heated to the boiling point of the resulting liquid. The product, washed with alkaline water, dried, and subjected to fractional distillation, gives off between 90° and 95° , monochloramylene, and at about 145° amylene dichloride, which at higher temperatures becomes mixed with more highly chlorinated products (Bauer, p. 118).—3. It is formed, together with polymerides of amylene, by the action of stannic chloride on amylene and on amyl alcohol (Bauer a. Klein, p. 118).

Amylene dichloride is a liquid of sp. gr. 1.058 at 9° (Guthrie); 1.2219 at 0° (Bauer). Boils at 141° – 147° (Guthrie); at 145° (Bauer).

When valeraldehyde is heated with rather more than an equivalent quantity of phosphorus pentachloride, and the product is mixed with water, washed, dried, and distilled, there passes over a light mobile oil consisting of an isomeride of amylene dichloride. This compound has a sp. gr. of 1.05 at 21° , and boils at 130° . It is insoluble in water, soluble in alcohol and ether, and is decomposed by alcoholic potash (Ebersbach, *Ann. Ch. Pharm.* cvi. 265).

Chloramylene, C^8H^8Cl , is formed, together with other chlorine-compounds (p. 118), by the action of chlorine on amylene. It boils at 90° – 95° , has a sp. gr. of 0.9992 at 0° ; vapour-density = 3.82 (calc. 3.62) (Bauer).

Chloramylene Dichloride, $C^8H^8Cl.Cl^2$, is produced, together with chloramylene and amylene dichloride, by the action of chlorine upon amylene, and constitutes the portion of the product which boils between 160° and 190° . This distillate yields on cooling white feathery crystals, which may be purified by pressure and sublimation. The mother-liquor exhibits the same proportion of chlorine as the crystals, and therefore perhaps contains an isomeric compound (Bauer, *J. pr. Chem.* c. 42).

Dichloramylene Dichloride. $C^8H^8Cl^2.Cl^2 = C^8H^8Cl^3$.—Produced by prolonged treatment of amyl hydride with chlorine, and separated from the very viscid product by fractional distillation, passing over between 230° and 250° , but is decomposed by repeated distillation. It is a thick, heavy, colourless liquid decomposed by alcoholic potash, with formation of trichloramylene. Soluble in alcohol and ether, insoluble in water (Bauer, *Jahresh.* 1860, p. 405).

A compound isomeric or identical with this is formed, together with amylene

dichloride and other products, by the action of chlorine on amylene, and passes over on fractional distillation between 220° and 230°. It is a transparent colourless liquid, of sp. gr. 1.4292 at 0°; decomposes partially on distillation. Alcoholic potash separates from it a large quantity of potassium chloride, but does not form a non-chlorinated and distillable product even at 130° (Bauer, *J. pr. Chem.* c. 43).

Trichloramylene, $C^8H^{10}Cl^3$, is produced by treating dichloramylene dichloride with alcoholic potash, and boils at about 200° (Bauer).

Amylenic Chlorhydrin, $C^8H^{10}\begin{Bmatrix} Cl \\ OH \end{Bmatrix}$, described at p. 208, vol. i., as produced by the action of hydrochloric acid on amylene glycol, is also readily formed by direct addition of hypochlorous acid, $ClOH$, to amylene. A solution of hypochlorous acid of 1 or 2 p. c. $ClHO$ (containing also mercuric oxychloride and excess of mercuric oxide) is gradually mixed in a glass vessel having a ground stopper, with amylene in the proportion of rather more than 1 molecule of the latter to 2 at. chlorine. As soon as the odour of the acid ceases to be perceptible, the aqueous solution of the amylenic chlorhydrin is filtered, freed from dissolved mercury by hydrogen sulphide, then neutralised with sodium carbonate, and shaken up with ether. The ethereal solution dehydrated with potassium carbonate, and freed from ether by evaporation over the water-bath, leaves the amylenic chlorhydrin as a colourless liquid, which may be further purified by standing over oil of vitriol, and one subsequent distillation. It has a powerful odour, like that of valeric acid, is heavier than water, and soluble therein, and is precipitated from the aqueous solution by salts. It distils easily with aqueous vapour, boils, when quite pure at 155°, and has a vapour density of 4.218 (calc. 4.245). It dissolves mercuric chloride in considerable quantity, and cannot be separated by distillation from this solution without decomposition, inasmuch as mercurous chloride is produced on heating the liquid (also from the aqueous solution). By potash it is resolved into potassium chloride and amylene oxide (Carius, *Ann. Ch. Pharm.* cxxvi. 195).

Amylenic Iodhydrins.—When amylene is shaken up with iodine and mercuric oxide, mercuric iodide and hypoiodous acid, HIO , are formed, which latter combines directly with the amylene, forming an iodhydrin, which is heavier than water, is decomposed by distillation, and when treated with silver acetate yields acetic acid, silver iodide, and amylene oxide. When iodine, mercuric oxide, and amylene are introduced into absolute alcohol, the iodine disappears, forming mercuric iodide and several iodhydrins which cannot be distilled except in a vacuum. An iodhydrin thus prepared was found to contain $\begin{Bmatrix} (C^8H^{10})^2O \\ C^8H^{10} \end{Bmatrix} I$; another, which could not be distilled, gave, with silver acetate, a mixture of amylenic acetates, from which, by fractional distillation, the following compounds were separated:

A: boiling at 150°.

B: boiling at 165°.

The body B, which was formed in the largest quantity, yielded, by heating with hydriodic acid to 150°, the iodides of ethyl and amyl (Lippmann, *Zeitschr. Ch. Pharm.* 1867, p. 17).

Amylene Iodocyanide, $C^8H^{10}ICy$, is obtained in an impure state, by adding amylene drop by drop to cyanogen iodide. It is a brown liquid, which distils over with water, and may be decolorised by acid sodium sulphite. With alcoholic potash at the boiling heat it yields ammonia and leucic acid, or an isomer thereof:

(Erlenmeyer, *Zeitschr. Ch. Pharm.* vi. 545).

Amylene Bisulphide, $C^8H^{10}S^2$, is produced by boiling diamylene sulphochloride for some hours with zinc-granules in a flask provided with a reflux condenser. On distilling off the greater part of the alcohol, and washing the residue with water, the bisulphide rises to the surface as an oil, which may be dried and rectified. The pure compound is a colourless oil, having a sp. gr. of 0.907 at 13°, and boiling at about 200° (Guthrie, *Chem. Soc. Qu. J.* xiv. 128).

Amylene Sulphocarbonate, $C^8H^{10}CS^2$, obtained by the action of an alcoholic solution of amylene bromide on sodium sulphocarbonate, is a somewhat viscid liquid of more or less yellow-brown colour, and sp. gr. = 1.073 (Hüsemann, *Jahresb.* 1862, p. 484).

AMYLENES, POLYMERIC. *Diamylene.* $C^{10}H^{20}$ (Balard, *Ann. Chim. Phys.* [3] xii. 320; Bauer, *Rép. Chim. pure*, 1862, p. 3; *Bull. Soc. Chim.* 1863, p. 332; 1867, viii. 341; Berthelot, *Chimie organique fondée sur la Synthèse*, ii. 700; and *Compt. rend.* lvi. 1242).—This body, representing a double molecule of amylene, was discovered by Balard, who named it *paramylene*. It is produced, together with other hydrocarbons, by the action of strong sulphuric acid or zinc chloride on amyl alcohol, or on amylene. It also occurs amongst the products of the action of zinc-ethyl on allyl iodide. It is a liquid having a sp. gr. of 0.7777 at 0°, and boiling at 165°.

When bromine is added to a cooled ethereal solution of diamylene, a bromide, $C^{10}H^{18}Br^2$, is obtained, very easily decomposed by heat. On adding the ethereal solution of this bromide by small portions to dry silver acetate mixed with acetic acid, and heating the mixture in the water-bath, a mixture of the *acetin* and *diacetin* of diamylenic glycol is obtained, viz.,

When the acetate thus obtained by distillation is heated with pulverised potassium hydrate, it yields diamylene oxide, $C^{10}H^{20}O$ (isomeric with capric aldehyde), in the form of a light liquid boiling at 170°–180°, and having a vapour-density of 5.361 (calc. 5.401). This oxide is insoluble in water, soluble in alcohol and ether, reduces ammoniacal silver nitrate, and has an odour of rue (Bauer). When diamylene cooled to –17° is treated with a current of *chlorine*, the temperature being gradually raised to 11° and ultimately to 140°, the liquid, which had at first turned brown, becomes colourless, and when washed with alkaline water and distilled, yields at 240°–250° chlorinated diamylene chloride, $C^{10}H^{18}Cl_2$, soluble in alcohol and ether, and having a density of 1.1638 at 0°. This chloride heated in closed vessels with alcoholic potash yields chlororutylene, $C^{10}H^{17}Cl$, and if the action of the potash be repeated on this body, potassium chloride is again separated, indicating the formation of the compound $C^{10}H^{16}$ (Bauer).

Diamylene directly treated with bromine forms an unstable oil, $C^{10}H^{18}Br.Br^2$. By oxidation with *potassium dichromate* and *sulphuric acid*, it yields a green oxygenated non-acid oil, boiling between 130° and 200°, an acid product containing acetic acid and an oily acid, and a tarry residue, which appears to contain an acid boiling between 215° and 225° (Walz, *Zeitschr. f. Chem.* [2] iv. 315).

Diamylene disulpho-dichloride, $C^{10}H^{20}S_2Cl_2$.—This compound, obtained by treating chlorine disulphide with excess of amylene, was discovered by Guthrie, and is described in vol. i. p. 209 as *disulphochloride of amylene*. The formula there given contains an uneven number of univalent atoms, and should therefore be doubled.

The compound chars when heated, giving off hydrochloric acid, sulphuric acid, and other sulphuretted products. The alcoholic solution heated with *zinc* forms amylene bisulphide, $C^{10}H^{16}S^2$; if an acid is present, sulphur is likewise removed. Fuming *nitric acid* attacks it violently, forming sulphuric, hydrochloric, oxalic, and a sulpho-acid; and by incomplete action, a heavy green oil agreeing approximately with the formula $C^{10}H^{16}S(NO)^4$.

With *potassium acetate*, diamylene sulphochloride appears to form the compound $C^{10}H^{20}(C^2H^3O)^2S^2$. With *zinc-ethyl* it forms a compound whose composition is approximately represented by the formula $(C^{10}H^{18})^2S^2$ (? heptyl bisulphide).

With alcoholic *potassium cyanide* it forms diamylene dithiodicyanide, $C^{10}H^{16}Cy^2S^2$, a liquid having a sp. gr. of 1.07 at 13°. With alcoholic *potassium sulphocyanate* it yields diamylene tetrathiodicyanide, $C^{10}H^{16}Cy^4S^4$, a liquid of sp. gr. 1.16 at 13° (Guthrie, *Chem. Soc. J.* xiii. 35; xiv. 128).

Triamylene, $(C^{10}H^{20})^3$, is produced, together with several other products, by heating amyl alcohol or amylene with zinc chloride (p. 117). On removing the products which distil below 160°, and dissolving the residue in water, an oil rises to the surface which when distilled yields triamylene between 240° and 250°, and tetramylene between 390° and 400°. Both these products must be rectified over sodium.

Triamylene is a colourless oil having an odour of turpentine, a sp. gr. of 0.8139, and boiling at 248°. Vapour-density = 7.6 (calc. 7.4). It is insoluble in water, soluble in alcohol, but not in all proportions, insoluble in ether. Burns with a white sooty flame. Reacts with bromine like diamylene. The bromide, $C^{10}H^{18}Br^2$, acts violently on silver acetate even at –15°, producing triamylene acetate, $C^{10}H^{20}(C^2H^3O)^3$, which is decomposed by potash, yielding potassium acetate, water, and benylene, $C^{10}H^{20}$ (Bauer, *Wien. Akad. Ber.* xlv. [2] 87; *Jahresb.* 1861, p. 559; *Ann. Ch. Pharm.* cxxvii. 249). Triamylene bromide is also converted into benylene by heating

to 100° with alcoholic potash: $C^{10}H^{16}Br^2 + 2KOH = 2KBr + 2H^2O + C^{10}H^{18}$. The formation of benylene from triamylene is similar to that of rutylene from diamylene (Bauer & Verson, *Zeitschr. f. Chem.* [2] iv. 501).

Tetramylene. ($C^{10}H^{16}$).—Discovered by Balard (*Ann. Ch. Phys.* [3] xii. 320), who named it *metamylene*. It is formed simultaneously with triamylene in the reactions above mentioned, and purified by rectification in a vacuum. It is a thick brownish oil, having a sp. gr. of 0.871 at 0°, and boiling between 390° and 400°. Dissolves with difficulty in alcohol, more easily in ether (Bauer).

AMYL-ETHYL SULPHIDE. $\left. \begin{matrix} C^8H^{11} \\ C^2H^3 \end{matrix} \right\} S$. *Amyl sulphethylate* or *Ethyl sulphamylate*.—This compound, prepared by the action of amyl alcohol on ethyl disulphophosphate (ii. 548), was found by Carius to boil at 132°–132.5°. Linnemann prepared it by the action of amyl iodide on potassium sulphide in alcoholic solution, and found it to boil between 130° and 140°. According to Saytzeff (*Zeitschr. f. Chem.* [2] vi. 105), it boils at 158°–169°, whether prepared by the heating amyl chloride with sodium sulphethylate (mercaptide) or ethyl iodide with sodium sulphamylate. It is oxidised by nitric acid to amyl-ethyl sulphoxide, (C^8H^{11})(C^2H^3)SO, a thick, yellowish, oily liquid, which is not distillable without decomposition, and solidifies in a freezing mixture to a crystalline mass, melting even below 0°. By zinc and dilute sulphuric acid the sulphoxide is reduced to amyl-ethyl sulphide (Saytzeff, *Ann. Ch. Pharm.* xxxix. 354).

AMYLUMIC ACID. See **MYRTHULMIC ACID**, iii. 984.

AMYLIN. A constituent of arbol-a-brea resin (i. 354), and probably also of elemi resin (ii. 483).

ANACAHUITA. A wood of unknown botanical origin, lately imported into Europe from Mexico, and said to yield preparations useful in pulmonary disorders. The bark and wood yield to alcohol and cold water only a small quantity of extractive matter, together with iron-greening tannin. The aqueous decoction yields on standing a large quantity of calcium oxalate, which is deposited in the parenchyma cells, and may likewise be isolated by agitating the bast with ether. The wood leaves 2.9 p. c., the bast about 20 p. c. ash, consisting almost wholly of calcium carbonate (A. Buchner, *Chem. Centr.* 1861, p. 447). The wood is said also to contain a volatile oil which unites with acid sodium sulphite, a tannic acid resembling catechutannic acid, gallic acid, a yellowish resin, arabin, uncrystallisable sugar, grape-sugar, a tasteless volatile body which crystallises in warty masses, and a bitter substance crystallising in white needles which does not precipitate platonic chloride or phosphomolybdic acid (*Jahresb.* 1861, p. 771).

ANÆROBES. Pasteur's name for those infusoria which live, or at least act as ferments, only when excluded from the air: they are also called *zymic ferments* (from *ζύμη*, yeast); on the other hand, those which, like *Monas* and *Bacterium*, require the presence of oxygen, are called *Ærobes* or *Azymic ferments*.

ANALYSIS, INORGANIC. *Disintegration of Insoluble Substances.*—The ordinary method of treating substances insoluble in water and acids, by fusion with an alkaline carbonate in a platinum or porcelain crucible, involves the risk either of destroying the platinum vessel by the action of reducible metals which may possibly be present, or of contaminating the fused mass with silica and alumina derived from the porcelain crucible; moreover, with an ordinary gas-burner or blowpipe it is not easy to raise a porcelain crucible to the high temperature required for the fusion. These inconveniences may be avoided by a method introduced by Bloxam (*Chem. Soc. J.* [2] iii. 226), which consists in causing the heat to be applied *inside* the mass to be fused. For this purpose the substance under examination is intimately mixed with 2 pts. sodium carbonate and 14 pts. of a mixture composed of 1 pt. finely pulverised charcoal and 6 pts. saltpetre; the mixture is placed in a thin porcelain dish or clean iron tray, and set on fire with a glowing slip of wood. The deflagration is completed in two or three seconds, and a well-fused mass remains, which is easily detached from the cooled dish, and may then be boiled, first with water, and then with acids for the extraction of the soluble constituents. This method is effectual for the disintegration of quartz-sand, pipe-clay, fluor-spar, and indeed of all insoluble substances, except chrome-iron ore. Barium sulphate (heavy spar) is so completely decomposed by it that the process may be advantageously applied to the preparation of soluble barium salts. Tin-stone, flint-glass, crown-glass, silver chloride, lead sulphate, and cryolite are also perfectly decomposed, felspar only partially. In cases when it is not desired to search for sulphates, the disintegration may also be advantageously effected by deflagrating a

mixture of 1 pt. of the insoluble substance with 4 pts. sodium carbonate, 4 pts. salt-petre, and 10 pts. of finely pulverised gunpowder.

To search for alkalis, the insoluble substance is deflagrated with seven times its weight of a mixture of 1 pt. sulphur and 6 pts. barium nitrate in a porcelain crucible; the cooled mass is well boiled with water; and the filtrate, after being freed from the dissolved baryta, is examined for alkalis in the usual way. Flint-glass, felspar and cryolite thus treated give up the whole of their alkali.

W. Clarke (*Sill. Am. J.* [2] xlv. 173) disintegrates refractory minerals, such as chrome-iron ore, rutile, &c., by mixing them, finely pulverised, with 3 pts. sodium fluoride in a platinum crucible, covering the mixture with a layer of acid potassium sulphate (12 pts.) and heating the crucible over a Bunsen's lamp till the mixture attains a state of tranquil fusion. The fused product is almost always perfectly soluble in water, especially if it be moistened after cooling with sulphuric acid, and heated again. When the presence of alumina does not interfere with the analysis, cryolite may be used instead of sodium fluoride. The author prepares sodium fluoride by boiling cryolite with caustic soda in an iron vessel, washes the gelatinous sodium fluoride thereby separated with cold water, and purifies it by crystallisation.

Schönn (*Zeitschr. f. Chem.* [2] v. 664; vi. 279) decomposes insoluble substances by fusing them in a steel crucible with potassium or sodium. For the detection of iron, however, a separate portion must be fused in a glass tube.

Qualitative Analysis of Metallic Solutions containing only the more ordinary metals without the use of Hydrogen Sulphide or Ammonium Sulphide (Zettnow, *Pogg. Ann.* cxxx. 324).—1. Lead, silver, and mercurous are precipitated by hydrochloric acid, and the chlorides are separated in the usual way.

2. The filtrate is treated with sulphuric acid, which throws down lead, calcium (in part), strontium, and barium. Calcium sulphate is extracted from the precipitate by water; the small quantity of lead sulphate may be dissolved out by ammonium tartrate; and the strontium and barium sulphates may be separated by known methods.

3. One-fourth of the liquid filtered from the precipitated sulphates is treated with barium hydrate, the liquid boiled, and the vapour tested for ammonia; on precipitating the excess of barium by ammonium carbonate, then evaporating the filtered solution, and calcining, a residue is obtained containing the fixed alkalis.

4. The remaining portion of the liquid filtered from the sulphates is treated with zinc in a flask fitted with a gas-delivery-tube, drawn out at the end, and the evolved hydrogen is tested for arsenic and antimony. The zinc at the same time precipitates tin, antimony, mercury, copper, cadmium, and bismuth [also gold, platinum, and the allied metals], in the metallic state; this precipitation is much facilitated by placing a piece of platinum foil in contact with the zinc. The precipitated metals, after being washed, are treated with nitric acid, which dissolves them all, except tin and antimony, which are converted into stannic and antimonious acids [and gold, platinum, &c., which remain in the metallic state]. One portion of the resulting solution is tested for mercury with stannous chloride; the rest is boiled with soda; and the resulting precipitate is treated, after washing, with ammonia and sal-ammoniac, which dissolves copper and cadmium, and leaves bismuth in the state of hydrate. The ammoniacal filtrate contains copper and cadmium, which are easily recognised, the former by potassium ferrocyanide, the latter by caustic soda.

5. The solution containing the metals not precipitated by zinc is oxidised with nitric acid. Iron may then be recognised by treating one portion of the liquid with potassium sulphocyanate. Another portion is neutralised by ammonia, and shaken up with barium carbonate, which precipitates chromium and aluminium as hydrates: the precipitate is boiled with soda, a small quantity of potassium permanganate being added to oxidise the chromic hydrate; and the filtered solution is examined for chromic acid and alumina in the usual way. (If the liquid contains phosphoric or boric acid, ferric chloride is added before precipitating with barium carbonate.)

6. The solution filtered from the barium carbonate is treated with sulphuric acid to remove dissolved barium, then treated with ammonium carbonate, which precipitates manganese, together with any remaining portion of lime; the filtrate still retains magnesium, nickel, and cobalt. The magnesium is precipitated by sodium phosphate; the filtrate is evaporated to dryness; the residue dissolved in hydrochloric acid; the cobalt precipitated by potassium nitrite and acetic acid; and the nickel from the filtrate by soda.

7. To search for zinc, the solution separated from the chlorides and sulphates (1, 2) is boiled with caustic soda; the filtrate is treated with ammonium chloride and carbonate as long as ammonia continues to escape; and the liquid again filtered is examined for zinc with potassium ferrocyanide.

J. Thomson (*Zeitschr. anal. Chem.* vi. 183) recommends the following method for the qualitative separation of the metals which are not precipitated by hydrogen sulphide from solution in hydrochloric acid (iron, aluminium, chromium, zinc, nickel, cobalt, manganese, barium, strontium, calcium, and magnesium). The solution, containing excess of hydrochloric acid, and heated with nitric acid or potassium chlorate, is first mixed with dilute sulphuric acid, which separates barium and strontium as sulphates. The filtrate, mixed with a large quantity of sodium acetate, yields, on addition of sodium phosphate (containing free acetic acid) in the cold, a precipitate containing nothing but ferric and aluminic phosphates. From the filtrate, hydrogen sulphide throws down the zinc, and after approximate saturation with sodium carbonate, also the cobalt and nickel. The solution, again filtered, is boiled with sodium hypochlorite, whereby manganese dioxide is precipitated (together with lime and magnesia), while chromic acid remains dissolved. The precipitated manganese dioxide is freed from lime and magnesia by dilute acetic acid.

Influence of Fixed Organic Substances on the Precipitation of Metallic Oxides from Saline Solutions by Alkalis.—The following results have been obtained by H. Grothe (*J. pr. Chem.* xcii. 175):—1. The alterations produced in the reactions of different metallic solutions with alkalis by the presence of fixed organic bodies exhibit great diversities, scarcely any two metallic bodies being similarly affected, so that these alterations do not afford properties characteristic of groups of metallic oxides, but rather of individual oxides.—2. Of non-volatile organic substances, citric acid acts most strongly in modifying these reactions; then follows tartaric acid; then sugar, starch, and gum, which, however, act but feebly, and require to be added in large excess.—3. The precipitating action of ammonia is diminished by these bodies much more than that of sodium carbonate.—4. Solutions which are not precipitated in presence of fixed organic bodies by alkaline hydrates or carbonates are for the most part precipitated by alkaline orthophosphates, pyrophosphates, arsenates, and borates.—5. Sodium orthophosphate may be used as a reagent in nearly all cases in which the precipitation of a metallic oxide is hindered by the presence of non-volatile organic substances.

The table on the following page exhibits the reactions of the more important metallic salts with ammonia, and with carbonate, borate, phosphate, pyrophosphate, arsenate, and borate of sodium, in presence of tartaric acid, citric acid, and sugar: 'p.' denotes perfect precipitation; 'i.' imperfect precipitation; a dash, no precipitation.

ANALYSIS, INORGANIC, BY FLAME REACTIONS. (Bunsen, *Ann. Ch. Pharm.* cxxxviii. 257; *Phil. Mag.* [4] xxxii. 81.)—Almost all the reactions which can be performed by means of the blowpipe may be accomplished with far greater ease and precision in the flame of the non-luminous gas-lamp. This flame, moreover, possesses several peculiarities which render it available for reactions by which the smallest traces of many substances occurring mixed together can be detected with certainty when the blowpipe and even still more delicate methods fail.

I. THE STRUCTURE OF THE NON-LUMINOUS GAS-FLAME.

The gas-lamp with non-luminous flame used for these reactions is represented in fig. 1, and must be made, exactly to scale, $3\frac{1}{2}$ times as large as the drawing. It must be furnished with a cap at *a* for closing and opening the draught-holes, so as to regulate the supply of air for every dimension of the flame. The conical chimney *d d d* (fig. 2) must also be made of such a size that the flame burns perfectly steady. Fig. 2 represents this flame of half its natural size. It is composed of the following three chief divisions:—A. *The dark cone*, *a a a*, containing the cold unburnt gas mixed with about 82 per cent. of atmospheric air. B. *The flame-mantle*, *a o a b*, formed of the burning coal-gas mixed with air. C. *The luminous point*, *a b a*, not seen when the lamp is burning with the draught-holes open, but obtained of the size required for the reactions by closing these holes up to a certain point.

The following six points in the flame are used in the reactions:—

1. *The base of the flame* lies at *a*; its temperature is comparatively very low, as here the burning gas is cooled by the upward current of cold air, and much heat is absorbed by the cold end of the metal tube. If mixtures of flame-colouring substances are held in this part of the flame, it is often possible to vaporise the most volatile constituent, and thus in the first few moments to obtain tints which cannot be observed at higher temperatures, because they then become masked by colours produced by the volatilisation of the remaining substances.

Table of Precipitation referred to on p. 125.

2. *The zone of fusion* lies at β , somewhat above the first third of the flame in height, and midway between the inner and outer limits of the mantle at the point where the flame is thickest. This is the point in the flame which possesses the highest temperature, and it is therefore used in testing substances as regards their melting-point, their volatility, their emissive power, as well as for all processes of fusion at high temperatures.

3. *The lower oxidising flame* lies at γ , in the outer margin of the zone of fusion, and is especially suitable for the oxidation of substances dissolved in beads of fused salts.

4. *The upper oxidising flame* at ϵ is formed by the highest point of the non-luminous flame, and acts most powerfully when the draught-holes of the lamp are wide open.

FIG. 2.

This flame is suited for the oxidation of larger portions of substance, for roasting off volatile oxidation-products, and generally for all those cases of oxidation in which an excessively high temperature is not needed.

5. *The lower reducing flame* lies at δ , on the interior edge of the mantle next to the dark central zone. As the reducing gases at this point are mixed with unburnt atmospheric oxygen, many substances remain here unaltered which become deoxidised on exposure to the upper reducing flame. This point of the flame gives, therefore, very valuable reactions which cannot be obtained with the blowpipe. It is especially available for reductions on charcoal, and in beads of fused salts.

6. *The upper reducing flame* is formed by the luminous point γ , produced over the dark zone when the admission of air is lessened by the gradual closing of the draught-holes (fig. 1, a). If this luminous point is made too large, it will be found that a test-tube filled with cold water and held there becomes covered with a film of lamp-black: this ought never to occur. This flame contains no free oxygen, is rich in finely divided incandescent carbon, and hence it possesses far greater reducing powers than the lower reducing flame. It is especially available for reducing metals when it is desired to collect them in the form of films.

II. METHOD OF EXAMINATION IN THE VARIOUS PARTS OF THE FLAME.

A. Behaviour of the Elements at High Temperatures.—This is one of the most important reactions which can be employed for the detection and separation of substances. The possibility of producing, with the flame of the lamp alone, a temperature as high as or higher than that of the blowpipe, depends upon the condition that the radiating surface of the heated body be made as small as possible. The arrangement for bringing the substances into the flame must therefore be on a very small scale. The platinum wire upon which the substance is heated must scarcely exceed the thickness of a horsehair, and one decimetre in length of the wire must not weigh more than 0.034 grm. It is impossible to obtain the results hereafter detailed if a thicker wire than this is employed. Substances which act upon platinum, or which will not adhere to the moistened surface of the metal, are held in the flame upon a thin thread of asbestos, of which a hundred may be obtained from one splinter of the mineral. These threads must not exceed in thickness one-fourth of that of an ordinary lucifer-match. Decrepitating substances are ground to the finest powder on a porcelain plate with an elastic knife-blade, and drawn up on to a moistened strip of one square centimetre of filter-paper. If the paper is then burnt, being held with the platinum forceps, or, better, between two rings of fine platinum wire, the sample remains as a coherent crust, which now may without difficulty be heated in the flame.

If the substance requires to be heated in the flame for a long time, the holder (fig. 3) is used. The arm *a* is fastened to the carrier A, so fixed on the stand by a spring (as seen at B) that it can be moved both horizontally and vertically. The glass tube (fig. 4) is held on this arm *a*, and the fine platinum wire fused on to the tube is thus held in the flame. The splinters of asbestos are stuck into the glass tube which slips into the holder, and may then be moved with the carrier A. The carrier carries a spring-clamp for holding test-tubes which have to be heated for a considerable time in a particular part of the flame. The little turntable C contains nine upright supports to hold the wire tubes (fig. 4) employed in the experiments. By means of these arrangements a particle of the substance under examination is brought to the flame, and its behaviour in the coldest and hottest parts of the flame is ascertained, the substance being examined with a lens after each change of temperature.

The following six different temperatures can be obtained in the flame, and these points may be judged of by observing the tints attained by the thin platinum wire:—

1. Below a red heat. 2. Commencing red heat. 3. Red heat. 4. Commencing white heat. 5. White heat. 6. Strong white heat.

It is scarcely necessary to remark that these different temperatures must not be ascertained by the glow of the substances themselves, as the luminosity of different bodies depends not only upon the temperature, but also mainly upon their specific power of emission.

The following phenomena are observed when a sample of a substance is heated:—

1. *Emission of Light.*—The emissive power of substances is ascertained by placing them on the platinum wire in the hottest part of the flame. The sample is of weak emissive power when it is less luminous than the platinum wire, of a mean emissive power when both appear about equally luminous, and of strong emissive power when the intensity of the light which it emits is greater than that from the platinum. Most solid bodies emit a white light, others (as, for instance, ceria) coloured light.

Some bodies, such as many osmium, carbon, and molybdenum compounds, volatilise and separate out finely divided solid matter, which renders the flame luminous. Gases and vapours always exhibit a smaller power of emission than fused substances, and these generally less than solid bodies. The form of the substance under examination must always be noted, as the emissive power depends upon the nature of the surface; thus compact alumina, obtained by slowly heating the hydrate, possesses only a moderate emissive power, whereas the porous oxide prepared by quick ignition of the sulphate possesses a high power of emission.

2. *The melting point* is determined by using the six different temperatures already mentioned. At every increase of temperature the bead is examined with the lens to see whether the volume is decreased or increased, whether bubbles are given off on melting, whether, on cooling, the bead is transparent, and what changes of colour it undergoes during the action of the heat or on afterwards cooling.

3. *The volatility* is ascertained by allowing equally heavy beads of the substance, placed on a platinum wire, to evaporate in the zone of fusion, and observing the time,

by means of a metronome, which the bead takes to volatilise. The point at which the whole of the substance is converted into vapour can be ascertained with great accuracy, often to a fraction of a second, by the sudden disappearance of the coloration of the flame. The platinum wire upon which the substance is weighed is protected from the moisture of the air by insertion in a tube. If we know the weight of the tube and wire, the right weight of substance can easily be attached, either by volatilising a portion or by fusing some more substance on to the bead, and thus making it lighter or heavier. The experiments are best made with one centigramme of substance. The position in the flame where the highest constant temperature exists can be found by

FIG. 3.

FIG. 4.

moving a fine platinum wire, fixed on a stand and bent at its point at a right angle, slowly about the zone of fusion, and noting the point where it glows most intensely. The beads to be volatilised are then most carefully brought into the flame at the same distance from the point of this wire. Care must also be taken that the dimensions of the flame do not undergo change from alterations in the pressure of the gas whilst the experiments are going on. As a measure of volatility, it is convenient to take the time needed to evaporate one centigramme of sodium-chloride. If we call this time t' , and the time of volatilisation of the same weight of another substance t'' , the volatility of this substance, compared with that of common salt, is

$$v = \frac{t'}{t''}.$$

The following examples are taken from experiments of Dr. Hurtzig, to which are added the chlorides of cesium and rubidium :—

Sup.

K

	Time of evaporation	Volatility
Sodium chloride	84.25	1.000
Sodium sulphate	1267.0	0.066
Lithium carbonate	736.5	0.124
Potassium sulphate	665.2	0.127
Sodium carbonate	632.0	0.133
Potassium carbonate	272.0	0.310
Lithium chloride	114.0	0.739
Potassium chloride	65.4	1.288
Sodium chloride	48.8	1.727
Potassium bromide	41.0	2.055
Rubidium chloride	38.6	2.183
Sodium iodide	35.7	2.360
Cesium chloride	31.3	2.717
Potassium iodide	29.8	2.828

It must not be forgotten that the relations of these numbers are altered if the temperature of evaporation and the weight of the substance are changed.

4. *Flame Coloration*.—Many substances which volatilise in the flame may be detected by the peculiar kinds of light which their glowing gases emit. These colorations appear in the upper oxidising flame when the substance causing them is placed in the upper reducing flame. Mixtures of various flame-colouring substances are tested in the lowest and coldest part of the flame; and here it is often possible to obtain for a few moments the peculiar luminosity of the most volatile of the substances unaccompanied by that of the less volatile constituents.

B. *Oxidation and Reduction of Substances*.—In order to recognise substances by the phenomena exhibited in their oxidation and reduction, and to obtain them in a fit state for further examination, the following methods are employed:—

1. *Reduction in glass tubes* is especially employed for the detection of mercury, and for the separation of sulphur, selenium, phosphorus, &c., when in combination with sodium or magnesium. A stock of very thin glass tubes is prepared, each 2 to 4 millims. in width and 3 centims. in length: forty of these are easily made out of one ordinary-sized test-tube, by softening the glass before the blowpipe, and then drawing it out until the requisite size of tube is obtained. This long tube is then cut up with a diamond into pieces 6 to 8 centims. long, each of which is again divided into two over the lamp, and the closed ends are neatly rounded. The sample having been finely powdered with a knife-blade on a porcelain plate, is treated in a tube either by itself, or with a mixture of carbon and soda, or with sodium or magnesium. A piece of magnesium wire a few millims. in length is for this purpose pushed down into the powdered sample contained in the glass tube; and the sodium is carefully freed from rock-oil and rolled out between the fingers to a small cylinder, which is then surrounded by the powdered substance. The best form of carbon is the soot from turpentine, which has been deposited upon the outside of a basin filled with cold water. As soon as the small tube containing the perfectly dry sample has been heated to the point of fusion of the glass, when generally an ignition inside the tube is noticed, it is allowed to cool and then placed upon the porcelain plate, covered with a piece of paper, and crushed to powder with the knife, for the purpose of further examining the products of reduction.

2. *Reduction on Splinters of Charcoal*.—In this way the metal can be obtained in small globules, or as a porous mass, from quantities often less than a milligramme of the sample.

A transparent crystal of sodium carbonate is brought near to the outside of the flame, and a common wooden lucifer-match is rubbed over two-thirds of its length with the drops of fused salt. If the match is then turned upon its axis through the flame, the carbonised wood becomes surrounded with a crust of solid sodium carbonate, which, on heating in the zone of fusion, melts and is absorbed by the carbon. A splinter of charcoal is thus obtained, which is prevented from burning by its glass of soda. A mixture of the substance is then made with the knife upon the hand with one drop of the melted soda-crystal, and a portion of this, of the size of a mustard-seed, is placed upon the point of the splinter. As soon as this has been melted in the lower oxidising flame, it is passed through a part of the dark interior zone to the hotter portion of the lower reducing flame. The point at which the reduction occurs is easily seen by the violent effervescence of the soda; and this is after a time stopped by bringing the splinter into the dark zone. In order to isolate the reduced metal, the end of the splinter is broken off and rubbed up with a few drops of water in a small agate mortar, when the metallic particles are generally visible without removal of the

carbon. For further examination, the carbon and soda can be easily removed by several careful washings, and the particles transferred to a small piece of curved glass cut out from an old flask,* in which they are again washed by decantation, the last drops of water removed by suction with a piece of filter-paper, and the metallic particles dried at a moderate heat. A few tenths of a milligramme of the metal is generally sufficient to yield a solution with which all the characteristic precipitations can be accomplished, the reagents being contained in capillary glass threads, dropped into the solution by the milligramme, and the effect thus produced ascertained by examination with a lens. Iron, cobalt, and nickel, which do not fuse to globules on the splinter, are withdrawn from the agate mortar by means of the point of a magnetised blade, washed with water, and dried high above the flame on the point of the knife. If the blade be then tightly drawn between the upper part of the thumb and the lower part of the first finger, and if the point of the blade be then approached to the metallic particles on the finger, they jump from the hand to the blade, forming a brush-like bundle which can be conveniently examined by the lens, and by touching with a melted borax-bead can be transferred in suitable quantities. The portion of metal remaining on the knife is rubbed on to a small piece of filter-paper, a drop of acid added, and the paper warmed over the flame so as to allow the metal to dissolve; this solution can then be further examined with various reagents.

3. *Films upon Porcelain.*—Those volatile elements which are reduced by carbon and hydrogen can be deposited from their compounds as films on porcelain either in the elementary state or as oxides. Such films can be very easily converted into iodides, sulphides, and other compounds, and thus may be made to serve as most valuable and characteristic tests. The films are composed in the centre of a thicker layer, which gradually becomes thinner on all sides until the merest tinge is reached; it is therefore necessary to distinguish between 'thick' and 'thin' parts of the films. Both exhibit in their variation of thickness all the tints of colour characteristic of the substance under different circumstances of division. One-tenth up to one milligramme is in many cases sufficient for these reactions. Many surpass Marsh's arsenic test in delicacy and certainty, and approach in this respect the spectrum-analytical methods.

The following films can be obtained:—

a. *Metallic films* are prepared by holding in one hand a particle of the substance on an asbestos-thread in the upper reducing flame, which must not be too large, whilst with the other hand a glazed porcelain basin, 1 to 2 decimetres in diameter, filled with cold water, is held close above the asbestos-thread in the upper reducing flame. The metals separate out as dead black or brilliantly black films of varying thickness. Even lead, tin, cadmium, and zinc yield in this way films of reduced metal which by mere inspection cannot be distinguished from the soot separated out on the porcelain by a smoky flame. By means of a glass rod, these films can be touched with a drop of dilute nitric acid containing about 20 per cent. of real acid; and the various degrees of solubility of the films serves as a distinguishing characteristic.

b. *Oxide films* are obtained by holding the porcelain basin filled with water in the upper oxidising flame, the rest of the operation being the same as in the production of the metallic films. If only a very small quantity of the sample can be employed, care must be taken to lessen the size of the flame, in order that the volatile products may not be spread over too large a surface of porcelain.

The film of oxide is examined as follows: a. The colour of the thick and thin film is carefully observed.—b. The reducing action or otherwise of a drop of stannous chloride is noted.—c. If no reduction occurs, caustic soda is added to the stannous chloride until the precipitated hydrate redissolves, and then it is to be observed whether a reduction occurs.—d. A drop of perfectly neutral silver nitrate is rubbed over the film with a glass rod, and a current of ammoniacal air is blown over the surface from a small wash-bottle containing ammonia solution, and having the mouth-tube dipping under the liquid and the exit-tube cut off close below the cork. If a precipitate is formed, the colour is observed, and the solubility or alteration, if any, noticed which occurs when the current of alkaline air is continued, or when a drop of ammonia liquor is added.

c. *Iodide films* are obtained from the oxide films by breathing on the latter upon the cold basin, which is then placed upon a wide-mouthed well-stoppered glass containing fuming hydriodic acid and phosphorous acid derived from the gradual deliquescence of phosphorous iodide. When the mixture no longer fumes, owing to absorption of moisture, it is easy to render it again fuming by adding a little anhydrous phosphoric acid. Other films, often containing both iodides of a metal, and therefore frequently less regular in colour and appearance, may be easily obtained

* Watch glasses crack much too readily to be used for such experiments.

by smoking the oxide film with a flame of alcohol containing iodide in solution, placed upon a bundle of asbestos-threads and held under the basin. If any iodine be condensed on the basin with the hydriodic acid, it can easily be removed by gentle warming and blowing.

The examination of the film is conducted as follows: *a.* The solubility of the film is examined simply by breathing upon it when the basin is cooled; the colour then either changes or entirely disappears, the film being dissolved in the moisture of the breath. If the basin be gently warmed, or if it be blown upon for some distance, the film again becomes visible by the evaporation of the moisture in the current of air.—*β.* The ammonia compound of the iodide is formed by blowing ammoniacal air upon it and noticing whether the colour of the thick and thin films alters quickly, slowly, or not at all. The different colours reappear at once if the basin be held for a few moments over an open bottle containing fuming hydrochloric acid.—*γ.* The iodide films generally give the same reactions as the oxide films with silver nitrate and ammonia, with stannous chloride, and with caustic soda.

d. The sulphide film is most easily obtained from the iodide film by blowing upon it a current of air saturated with ammonium sulphide, and removing the excess of sulphide by gently warming the porcelain. It is advisable to breathe on the film from time to time whilst the current of sulphuretted air is being blown on the basin. The experiments to be made with this film are: *a.* The solubility or insolubility in water is ascertained by breathing on it, or by adding a drop of water. The sulphides often possess the same colour as the iodide films; they may, however, generally be distinguished by their insolubility on breathing.—*β.* The solubility of the sulphide in ammonium sulphide is ascertained by blowing or dropping.

4. *Films on Test-tubes.*—Under certain circumstances it is advisable not to collect the film on porcelain, but upon the outside of a large test-tube; this method is especially useful when it is needed to collect larger quantities of the reduction film for the purposes of further examination. The fine asbestos-thread with the sample of substance is held on the glass tube before the lamp so that it is placed at the height of the middle of the upper reducing flame, and the test-tube fixed so that the lowest point is just above the end of the asbestos-thread. If the lamp be now pushed under the test-tube, the substance and the asbestos-thread are in the reducing flame. By repeating this operation the film can be obtained of any wished-for thickness; some pieces of marble are in this case placed in the test-tube, to prevent the water from being thrown out of the tube by percussive boiling.

III. THE REACTIONS OF THE ELEMENTS.

The elements, which can easily be recognised by their flame reactions, are arranged in the following groups and subgroups according to their behaviour in the reducing and oxidising flames:—

A. Elements reducible to metal and deposited in films:

1. Films scarcely soluble in cold dilute nitric acid—tellurium, selenium, antimony, arsenic.
2. Films slowly and difficultly soluble in cold dilute nitric acid—bismuth, mercury, thallium.
3. Films instantly soluble in cold dilute nitric acid—cadmium, zinc, indium.

B. Elements reducible to the metallic state, giving no film:

1. Not fusible to a metallic bead.
 - a.* Magnetic—iron, nickel, cobalt.
 - b.* Non-magnetic—palladium, platinum, rhodium, iridium.
2. Fusible to metallic beads—copper, tin, silver, gold.

C. Elements most easily separated and recognised as compounds—tungsten, titanium, tantalum and niobium, silicon, chromium, vanadium, manganese, uranium, sulphur, phosphorus.

In the special descriptions of the flame-reactions, the following abbreviations will be used: Fl. c., flame-coloration; Vl., volatilisation; R. f., reduction-film; M. f., metallic-film; O. f., oxide-film; I. f., iodide-film; S. f., sulphur film; Ch. sp., charcoal splinter with soda.

1. *Tellurium compounds.*—Fl. c.: In the upper reducing flame pale blue, whilst the upper oxidising flame appears green. Vl. unaccompanied by any smell. R. f. black, thinnest part blackish brown, dead or bright; heated with concentrated sulphuric acid gives splendid carmine-red colour. O. f. white, invisible or nearly so; stannous chloride colours it black from reduced tellurium; silver nitrate, after blowing with ammoniacal air, yellowish-white. I. f. blackish-brown, thinnest part

brown; disappears momentarily on breathing on it, but not when slightly warmed; reappears on exposure to hydrochloric acid; blackened by stannous chloride. S. f. blackish-brown to black; does not disappear by breathing; soluble in sulphuretted air; reappears on warming or by dry blowing. Ch. sp. yields a sodium-telluride, which, when moistened, leaves a black mark on a silver coin; and if the sample contains much tellurium, gives off a smell of telluretted hydrogen when moistened with hydrochloric acid.

2. *Selenium compounds*.—Fl. c. the bright blue of the corn-flower. VI. burns, giving off the peculiar putrid smell of selenium. R. f. brick-red to cherry-red, sometimes dead, sometimes bright; heated with strong sulphuric acid, gives an olive-green solution. O. f. white; on addition of stannous chloride, brick-red from liberated selenium; the red colour becomes darker on addition of caustic soda; silver-nitrate gives a white not easily visible coloration, which disappears in a current of ammoniacal air. I. f. brown, contains some reduced selenium, and hence cannot be completely removed either by blowing with ammoniacal air or by breathing. S. f. yellow to orange-red, insoluble in water, soluble in ammonium-sulphide. As the sulphide is prepared from the iodide, it also contains free selenium, and does not give very clear reactions. Ch. sp. gives sodium-selenide, producing a black mark on a silver coin when moistened, and giving rise, if the quantity be not too small, when touched with hydrochloric acid, to red selenium and a smell of seleniuretted hydrogen.

3. *Antimony compounds*.—Fl. c. by treatment in the upper reducing flame, pale green, unaccompanied by smell. VI. black, sometimes dead, sometimes bright. O. f. white; moistened with perfectly neutral silver-nitrate solution and then blown on by ammoniacal air, it gives a black spot which does not disappear in ammonia. It is unaltered by stannous chloride, either with or without caustic soda. I. f. orange-red, disappearing by breathing, and reappearing by blowing or warming; blown on with ammoniacal air it disappears, but does not return; generally it gives the same reactions as the oxide. S. f. orange-red; the film is difficult to blow away with sulphide of ammonium; returns on blowing with air; insoluble in water. Ch. sp. gives no black stain on silver, but yields a white brittle metallic bead.

4. *Arsenic compounds*.—Fl. c. in upper reducing flame pale blue, giving the well-known arsenical smell. VI. black, dead or brilliant, thin film brown. O. f. white, touched with perfectly neutral silver-nitrate and then blown with ammoniacal air, it gives a canary-yellow precipitate, soluble in ammonia. Together with the lemon-yellow precipitate, a brick-red one of silver-arsenate occurs when the film has previously been treated with bromine vapour. Stannous chloride with or without soda produces no change. I. f. deep yellow; disappears transiently on breathing, permanently in ammoniacal air; reappears unaltered after the action of hydrochloric acid. S. f. lemon-yellow, disappears easily on blowing with ammonium-sulphide, and reappears on warming or blowing; insoluble in water, and does not disappear on breathing. Ch. sp. yields no metallic bead.

5. *Bismuth compounds*.—Fl. c. bluish, not characteristic. R. f. black, dead or brilliant; thin portion of film brownish black. O. f. light yellow; unaltered by silver-nitrate with or without ammonia; gives no reaction with stannous chloride, but yields black precipitate of bismuth suboxide on addition of caustic soda. I. f. very characteristic, and remarkable for the number of tints which it assumes; the thick part is of a brown or blackish-brown colour, with a shade of lavender-blue; the thin film varies from flesh-coloured to light pink; it easily disappears on breathing, and appears again on blowing; in a stream of ammoniacal air it passes from pink to orange, and on blowing or warming it again attains a chestnut-brown colour; it resembles the oxide-film in its behaviour to stannous chloride and caustic soda. S. f. of a burnt-umber colour, the thin parts of a lighter coffee-brown colour; does not disappear on blowing, and is not soluble in ammonium-sulphide. Ch. sp. metallic bead, yielding, when rubbed in the mortar, bright shining yellowish splinters of metal soluble in nitric acid. The solution gives, with stannous chloride and caustic soda, black bismuth suboxide.

6. *Mercury compounds*.—M. f. mouse-grey, non-coherent, and spreads over the whole basin. To obtain small traces of mercury in the reduced state, the sample is mixed with soda and saltpetre and filled into a thin test-tube 5 to 6 millims. wide and 10 to 20 millims. long. This is held by a platinum wire in the flame, whilst the bottom of the basin filled with cold water is placed close above the open end of the tube. If the quantity of mercury is considerable, the metal collects in the form of small globules which can be seen with a lens, and collected into larger drops by wiping the basin with a piece of moistened filter-paper. O. f. not obtainable. I. f. obtained by breathing on the metallic film and then placing it over a vessel containing moist bromine. It first becomes black and then disappears, but not until

after some time, as mercuric bromide is formed. If the basin be now placed above a vessel of fuming hydriodic acid, a very characteristic carmine-coloured film of mercuric iodide is produced: this is often accompanied by mercurous iodide; but neither of these disappears on breathing, or when blown with ammoniacal air. S. f. black, not altered by breathing or by blowing with ammonium-sulphide. Ch. sp. no reaction.

7. *Thallium compounds*.—F. c. bright grass-green. M. f. black; thin parts coffee-coloured. O. f. colourless; with stannous chloride and soda, as well as with silver-nitrate with or without ammonia, no alteration. I. f. lemon-yellow, does not disappear on breathing, or on blowing with ammoniacal air, or on addition of liquid ammonia. S. f. formed from the oxide, black, and the thin parts bluish-grey; insoluble in liquid ammonium-sulphide. Ch. sp. reduced to a white ductile bead, which quickly oxidises in the air, and is acted upon by hydrochloric acid with difficulty. In addition to the foregoing, there are two metals, viz. tin and molybdenum, which may be classed under the group A 2. These two metals, however, cannot be reduced from all their compounds, and the reduction never takes place easily, owing to their slight volatility; so that it will be better to class them under the groups B 2, B 1, b, as they can be best distinguished by the reactions which are characteristic of these groups.

8. *Lead compounds*.—Fl. c. pale blue. R. f. black, dead or brilliant. O. f. bright yellow-ochre coloured; no coloration with stannous chloride and caustic soda, or with silver-nitrate or ammonia. I. f. orange- to lemon-yellow, insoluble on breathing or on moistening; disappears on blowing with ammoniacal air, and appears again on warming. S. f. brownish-red to black; not altered by blowing or moistening with ammonium-sulphide. Ch. sp. grey, very soft ductile metallic bead, soon tarnishing, and slowly but completely soluble in nitric acid.

9. *Cadmium compounds*.—M. f. black; the thin parts brown. O. f. brownish-black, shading off through brown to a white invisible film of suboxide, which is not altered by stannous chloride either alone or with soda, but gives with silver-nitrate a characteristic blackish-blue coloration of reduced metal; does not alter by ammonia. I. f. white, not changed by ammonia. S. f. lemon-yellow, insoluble in sulphide ammonium. Ch. sp., imperfect reduction to a silver-white ductile bead.

10. *Zinc compounds*.—R. f. black, in the thin parts brown. O. f. white, and therefore invisible. To test it, a square centimetre of filter-paper moistened with nitric acid is rubbed over the surface and then rolled up on two rings of fine platinum wire, 3 millims. in diameter, and burnt. If the paper is burnt in the upper oxidising flame at as low a temperature as possible, the ash forms a small solid mass about a square millimetre in area, which can be ignited without fusion, and becomes yellow on gently heating, appearing, however, white on cooling. If this be moistened with a few milligrammes of a very dilute cobalt solution and ignited, it appears of a beautiful green colour on cooling. I. f. white, not easily recognisable either by itself or after blowing with ammoniacal air. S. f. also white, not easily recognised either with or without blowing with ammonium-sulphide. *The reduction of the metal* cannot be accomplished, owing to the volatility of zinc.

11. *Indium compounds*.—Fl. c. intense, and pure indigo-colour. M. f. black, the thin parts brown, either dead or brilliant; instantly disappears in presence of nitric acid. O. f. yellowish-white, scarcely visible; gives no reaction with stannous chloride and silver solution. I. f. also yellowish-white, not visible either with or without ammonia, if present in small quantities only. S. f. also yellowish-white, difficult to see; unaltered by ammonium-sulphide. Ch. sp.; reduction difficult; gives silver-white ductile globules slowly soluble in hydrochloric acid.

12. *Iron compounds*.—Ch. sp., no metallic bead or ductile lustrous particles; the finely divided metal forms a black brush on the end of the magnetised knife-blade; this, when rubbed off on paper and dissolved in a drop of aqua regia, yields a yellow spot when warmed over the flame, which, when moistened with potassium-ferricyanide, gives a deep coloration of prussian-blue. The yellow spot moistened with caustic soda and then held for a few moments in a vessel with bromine-vapour gives, on a second addition of soda, no coloration of a higher oxide. *Borax bead*.—In the oxidising flame, when hot, yellow to brownish-red; when cold, yellow to brownish-yellow; reducing flame bottle-green.

13. *Nickel compounds*.—Ch. sp.: On pulverising the charcoal the metal is obtained in white, lustrous, ductile particles, forming a brush on the magnetised blade. The metal dissolved in nitric acid on paper gives a green solution, which on moistening with soda, exposure to bromine-vapour, and subsequent addition of soda, gives a blackish-brown spot of nickel-sesquioxide. The ash of the paper, from which the excess of soda has been washed out, can be used for the borax-bead test.

Borax bead.—Oxidising flame greyish-brown or dirty-violet. Upper reducing flame grey from reduced nickel, which often collects to a spongy mass of metal, rendering the bead colourless.

14. **Cobalt compounds.**—By pulverising the charcoal, as with nickel, white ductile lustrous metallic particles are obtained, which form a brush on the magnetic blade. The metal, rubbed off on paper, gives a red solution when moistened with nitric acid; this yields a green colour on addition of hydrochloric acid and drying, which disappears again on moistening. The paper moistened with soda, brought into bromine-vapour and again moistened with soda, yields a blackish-brown spot of cobalt-sesquioxide. This reaction is plainly seen with a few tenths of a milligramme of metal. The paper can also be used, after washing out the soda and burning, for the coloration of the borax bead.

Borax bead.—In the oxidising flame a bright-blue bead, unaltered in the lower reducing flame. The bead when held for some time in the most powerful upper reducing flame, becomes colourless, owing to the separation of metallic cobalt: this separation takes place more rapidly in presence of platinum-ammonium-chloride, when an alloy of nickel and platinum is formed.

15. **Palladium compounds.**—In the upper oxidising flame these compounds, heated on a fine platinum wire with soda, yield a grey mass resembling spongy platinum; this yields on trituration silver-white lustrous particles, the red solution of which in nitric acid forms, with a drop of mercuric cyanide, when blown upon by ammoniacal air, a white precipitate soluble in excess of ammonia. The solution is coloured blue, green, and brown by stannous chloride, according to the quantity of the reagent added.

16. **Platinum compounds** yield in the oxidising flame with soda a grey spongy mass, giving on trituration white, ductile, lustrous particles. These are insoluble in either nitric or hydrochloric acid alone, but dissolve in a mixture of these acids, forming, if the platinum is pure, a light-yellow solution, which is of a darker colour if rhodium, iridium, or palladium is present. The solution in nitro-muriatic acid gives with mercuric cyanide and ammonia, not a white precipitate, but a light-yellow crystalline precipitate of platinum-ammonium-chloride. Stannous chloride colours platinum compounds yellowish-brown.

17. **Iridium compounds** are likewise reduced to metal when heated with soda in the upper reducing flame, yielding a grey non-lustrous powder, which is not the least ductile, and is insoluble even in aqua regia.

18. **Rhodium compounds** can be distinguished from those of iridium only by the fact that the metallic powder, insoluble in aqua regia, when fused with hydropotassic sulphate, is partially oxidised, giving a rose-coloured solution.

19. **Osmium compounds** give, in the oxidising flame, fumes of volatile osmic acid, possessing an acrid chlorine-like smell and attacking the eyes powerfully.

20. **Gold compounds.**—Traces of gold mixed with large quantities of matrix, can be concentrated and detected only by the old gold-test.* In other cases, however, a few tenths of a milligramme can be detected by reduction with soda on a charcoal splinter. The yellow lustrous ductile globules thus obtained can be flattened out to larger golden particles; these do not dissolve in nitric or hydrochloric acid, but are pretty easily dissolved in aqua regia, yielding a light-yellow solution, which, if it is absorbed by a small piece of filter-paper, yields the purple of Cassius when moistened with stannous chloride.

21. **Silver compounds.**—If silver occurs only in traces in slags or complex ores, it can only be detected by the well-known method of cupellation.† If, however, the silver compound is not mixed with a very large amount of foreign matter, it can be detected in very minute quantities by reduction with soda on the charcoal splinter. The white ductile beads dissolve easily on warming in dilute nitric acid, and yield silver-chloride with hydrochloric acid, which can then readily be recognised by its behaviour with nitric acid and ammonia. Less than one-tenth of a milligramme of silver can thus be easily detected with certainty.

22. **Copper compounds** yield on the charcoal splinter with soda a ductile lustrous metallic bead, easily recognisable by its red copper colour, and by the reaction of its nitric acid solution with potassium ferrocyanide. *With Borax on Platinum Wire.*—Blue bead, not altered to cuprous oxide when heated in the lower reducing flame alone, but on addition of very little tin-salt, forms a reddish-brown bead. If this bead be frequently oxidised and reduced in the flame, a ruby-red transparent bead is obtained; this occurs most readily when the bead is allowed to oxidise very slowly.

23. **Tin compounds.**—On the charcoal splinter the tin compounds are easily reduced to white lustrous ductile metallic beads. The flattened particles, transferred to the

* C. F. Plattner's *Probierkunst*, bearbeitet v. Th. Richter, 1865, p. 541.

† *Ibid.* p. 512.

curved glass dissolve slowly in hydrochloric acid; and the solution, when absorbed by paper, gives a red precipitate with stannous, and a black precipitate with tellurous acid dissolved in hydrochloric acid. If to the solution a trace of bismuth-nitrate be added, an excess of soda gives a black precipitate of bismuthous oxide. The metal acted on by nitric acid yields a white powder of insoluble stannic acid. A borax bead, containing enough copper-oxide to render it faintly blue, serves as a delicate test to ascertain with certainty the presence of a trace of a tin compound, as the bead placed in the lower reducing flame, as explained above, turns reddish-brown, or forms a clear ruby-red glass.

24. *Molybdenum compounds.*—On a charcoal splinter with soda molybdenum is reduced, though with great difficulty, to a grey powder. In the same way some molybdenum compounds give in the upper reducing flame a film on porcelain which it is very difficult to obtain. Molybdenum is best detected as follows. The sample, finely pulverised with the knife on the porcelain plate, is mixed on the hand with soda, obtained in a pasty state by melting a crystal. The mixture is then transferred to a spiral of fine platinum wire and fused in the flame; the liquid fused mass is then knocked off the wire and allowed to fall upon the plate, when it is digested with two or three drops of water, and the clear supernatant liquid absorbed by three or four strips of filter-paper a few millimetres in breadth. *a.* One of these strips, on moistening with hydrochloric acid, does not change colour, but on addition of a drop of potassium-ferrocyanide it is coloured reddish-brown. *β.* If one of the strips be gradually moistened with a few milligrammes of stannous chloride, it is coloured blue either at once or on gently heating; if the tint be yellow or light brown, a few drops of soda solution must be added by a capillary tube until the blue colour appears. *γ.* A drop of ammonium-sulphide added to the third strip produces a brown coloration; and on addition of hydrochloric acid a brown precipitate is formed, the paper, at the circumference of the drop, often being coloured blue. *δ.* The yellow phosphate precipitate produced by the nitric acid solution of ammonium-molybdate can also be readily obtained. The borax bead is not very characteristic; in the oxidising flame it is colourless, and in presence of much molybdenum it becomes opaque; in the reducing flame it is dark from reduced molybdenum.

25. *Tungsten compounds.*—The reduction of tungsten can likewise be made on the charcoal splinter with soda, but this method is not available for the detection of the metal. The tungsten compounds are therefore best examined in the mode described under molybdenum, by absorbing the liquid obtained by fusion with soda on some strips of filter-paper. *a.* One strip is moistened with hydrochloric acid; it remains white, but on heating turns yellow; moistened with ferrocyanide it is unaltered. *β.* A second strip, touched with stannous chloride, is coloured blue in the cold or on heating. *γ.* A drop of ammonium-sulphide causes no precipitate either by itself or after addition of hydrochloric acid; the paper becomes, however, blue- or greenish, coloured, especially on warming.

26. *Titanium compounds* give with microcosmic salt in the oxidising flame a colourless bead which turns of a pale amethystine colour in the reducing flame. On addition of ferrous sulphate the bead assumes in the reducing flame the peculiar red colour of venous blood, whilst in the oxidising flame the light-brown colour of ferric oxide can be obtained at pleasure. The titanium compounds form with soda a bead which at first effervesces, and is colourless and transparent while hot, but becomes opaque on cooling. If to the hot bead stannous chloride be added, and if it then be heated in the lower reducing flame, a grey mass is formed, which dissolves on heating in hydrochloric acid, yielding a pale-amethystine-coloured solution.

27 & 28. *Tantalum and Niobium compounds* exhibit the same reactions as titanium.

29. *Silica compounds.*—*a.* Treated with soda in the oxidising flame, the silicates dissolve with more or less effervescence. The mass treated whilst hot with stannous chloride and fused does not yield a trace of blue colour on solution in warm hydrochloric acid; and the silicates may thus be distinguished from the compounds of titan, tantal, or niob acids. The blood-red colour obtained with ferric oxide from these acids is also not yielded by silicates. Gelatinous silica separates out when the fused mass is carefully treated with water and acetic acid on the lamp-plate. Fine particles of any silicate yield, on fusion in a bead of microcosmic salt, a mass of gelatinous silica when fused, which on cooling forms a solid opaque mass swimming in the transparent bead.

30. *Chromium compounds.*—*a.* In the spiral of platinum wire with soda the chromium compounds give, when fused with repeated additions of nitre, a yellow mass, which, when pulverised on the plate and treated with water, yields a light yellow solution exhibiting the well-known reactions of chromic acid.

31. *Vanadium compounds* (*a*) treated with nitre and soda in the platinum spiral

yield a bright yellow mass, the solution of which, on addition of silver nitrate and acidification with acetic acid, yields a yellow precipitate. The fused mass when evaporated with aqua regia gives a yellow instead of a green solution, which becomes blue on addition of stannous chloride. If the mass contains much vanadium, the solution gives a yellowish-brown colour or precipitate on addition of an excess of cold concentrated hydrochloric acid.

32. *Manganese compounds* give an amethystine-coloured bead in the oxidising, and a colourless bead in the reducing flame; with soda and a little nitre, a green bead, the green aqueous solution of which turns red on addition of acetic acid, and then often becomes colourless, with separation of brown flocculi.

33. *Uranium compounds* give in the oxidising flame a yellow bead, which becomes green in the reducing flame, especially on addition of stannous chloride. These colours closely resemble those of the iron compounds, but may easily be distinguished, at least if no other colouring metallic oxide is present, by the fact that the uranium bead, when incandescent, emits a bluish-green light analogous to that which the uranium compounds exhibit when fluorescing. Beads of lead-oxide, stannic oxide, and a few other substances exhibit a similar phenomenon when incandescent, but they none of them yield, like the uranium compounds, a coloured bead on cooling. Insoluble uranium compounds may be decomposed by gentle heating on the platinum spiral with acid potassium sulphate. On powdering the melted substance with a few particles of sodium carbonate, absorbing the moistened mass with filter-paper, and adding a drop of potassium ferrocyanide, a brown spot is formed.

34. *Phosphorus compounds*.—The presence of phosphorus may easily be detected, even when mixed with large quantities of other substances, as follows:—The sample having been ignited, is rubbed fine on the porcelain plate, and introduced into a small glass tube of the thickness of a straw; into this tube, which is closed at the bottom, a piece of magnesium wire, about one-fourth of an inch in length, is placed so that it is covered by the powder. On heating the tube, magnesium-phosphide is formed with incandescence. The black contents of the tube powdered on the plate give, on moistening with water, the highly characteristic smell of phosphuretted hydrogen. A piece of sodium can be equally well used if magnesium cannot be procured. If it has been ascertained that the sample does not yield any film on porcelain in the upper oxidising flame, the phosphates may be recognised by heating on platinum with borax and a thin piece of iron wire in the hottest part of the reducing flame, when a bright molten bead of iron-phosphide is obtained which can be extracted with the magnetised knife on crushing the bead under paper.

35. *Sulphur compounds* give with soda on the charcoal splinter a fused mass, which leaves a black stain when brought on to moistened silver. As selenium and tellurium give rise to the same reaction, the absence of these substances must first be ascertained by seeing that no film of selenium or tellurium is deposited on porcelain. In the case of metallic sulphides, and not of sulphates, the simple ignition of the sample in the flame is sufficient to produce the peculiar smell of burning sulphur.

The following examples are given to illustrate the value of these methods in analysis:—

1. *A mixture of the Sulphides of Arsenic, Antimony, and Tin*.—If in a mixture of these three sulphides containing only traces of antimony and tin, they are separated according to the ordinary rules of qualitative analysis, by dissolving in alkaline sulphides and reprecipitation with acids, the detection of these two metals by the regular tests is extremely uncertain and troublesome. By the following method, however, their detection is rendered easy and certain when the proportion of tin is only a few thousandths, and that of the antimony only a few hundredths, of the total weight of the mixture.

Three decigrammes of the sulphides are roasted on a curved piece of glass, small enough to be altogether surrounded by the flame, and the residue, weighing only a few milligrammes, is scraped together with a knife. The moistened mass is then collected on the end of a thread of asbestos, and a strong metallic film obtained on the test-tube (see p. 132). In order to prevent the deposition of any carbon with the metals, which would act injuriously in the subsequent operations, the upper reducing flame is made so small that the luminous point is only just visible. The film is next dissolved in a drop or two of nitric acid, and the solution is evaporated below the boiling-point by gently warming and blowing, so as to obtain the solid residue in as small a space as possible. A drop of neutral silver solution is now brought on to the residue at the moment when it becomes solid; and on blowing with ammoniacal vapour a characteristic black stain is formed, whilst the reaction of arsenic is also generally noticed. In

Table of Volatile Elements which

White.	White.	White.	Does not disappear.	
Yellowish white.	Yellowish white.	White.	Does not disappear.	

order to detect tin, a few scarcely visible particles of the roasted sulphides are fused on a borax bead which has been very slightly tinted with cupric oxide. If the bead is now brought into the lower reducing flame, it assumes a ruby-red colour from reduced cuprous oxide. If the oxide be present in too large a quantity, the bead can be obtained transparent by the process described under the reactions of the copper compounds. This reaction can be obtained only in the lower reducing flame of the non-luminous gas-lamp, as in the ordinary blowpipe-flame the cupric oxide is reduced to cuprous oxide without the presence of tin-salt.

2. *Black Tellurium, containing Tellurium, Selenium, Antimony, Lead, Gold, and Sulphur.*—After the sulphur has been detected by the smell on roasting, the metallic film is obtained on a test-tube, which is then placed inside a wider and shorter tube containing a few drops of concentrated sulphuric acid, so that the metallic film is surrounded by the acid. If the temperature be now gradually raised, the presence of tellurium is at once ascertained by the formation of a bright carmine-colour. If the temperature be still further raised, the tellurium oxidises, and the olive-green colour of selenium becomes visible; the cooled solution, on dilution with water, then no longer exhibits the black precipitate of tellurium, but is coloured yellowish red from the selenium. If this substance is present in small traces only, it can be best detected by looking down the length of the test-tube upon a sheet of white paper. As common commercial sulphuric acid not unfrequently contains traces of selenium, it is well to make a blank experiment to assure one's self of its absence. The antimony is detected exactly as described in the preceding example. To detect the lead and gold, a sample is reduced on the charcoal splinter, the beads of the alloy are washed into a curved glass, and the flattened and dried metallic particles treated with pretty strong nitric acid as long as anything dissolves. The acid is then evaporated off, and the soluble portion of the residue dissolved in a drop or two of water. The solution is then brought on to a second curved glass by means of a capillary pipette, and the characteristic precipitate of lead sulphate obtained by addition of a few milligrammes of sulphuric acid. The gold, left undissolved as a brown powder, is completely washed by frequent addition of water and removal of the same with the capillary pipette. A portion of the dried particles of gold fused on a charcoal splinter with soda, yields in the mortar bright golden yellow particles, which may be dissolved in aqua regia and tested with stannous chloride.

ANALYSIS OF GASES. Williamson a. Russell (*Chem. Soc. J.* [2] ii. 238) have described a modification of their apparatus for gas-analysis (i. 274), in which the gases are subjected to the action of reagents in a 'laboratory-vessel' separate from the eudiometer, as in the apparatus devised by Regnault and by Frankland a. Ward (i. 276). This addition permits the use of liquid reagents, which act much more quickly than the solid absorbents used in the former apparatus and in Bunsen's original method. The transference of the gas between the eudiometer and the laboratory-vessel is, however, effected by an arrangement free from the fragility and liability to leakage which constitute the chief inconveniences attending the use of Regnault's and of Frankland a. Ward's apparatus. The eudiometer tube is surrounded by a cylinder of water, as in the apparatus just mentioned. For the detailed description of the apparatus and the mode of using it, we must refer to the original memoir, as it scarcely admits of abbreviation.

Russell (*Chem. Soc. J.* [2] vi. 128) has lately contrived a simpler form of apparatus, which permits the use of liquid reagents in the eudiometer itself, and thus does away with the complication of the laboratory-tube. This apparatus is represented in the following diagrams. The mercury-trough is made of gutta-percha; the form of it is shown in figs. 5 and 6. Fig. 5 is a horizontal section, and fig. 6 a section through Δ n. The larger part of the trough is circular; in this part stands the glass cylinder which contains the water, and in the centre are the eudiometer and pressure-tube. The form of the well in which these tubes are raised or lowered is represented at c; it is $2\frac{1}{2}$ inches long, $1\frac{1}{2}$ broad. The well for the pressure-tube is 14 inches deep measured from the bottom of the trough, and that for the eudiometer 19 inches. These are shown in fig. 6, e and f. The sides of the trough are $3\frac{1}{2}$ inches high. The smaller part of the trough which is without the glass cylinder is shown in fig. 6. Along the bottom of this part there is a channel $\frac{1}{2}$ inch wide, which runs into the well. The depth of this channel starting from the end of the bottom of the trough at n gradually increases till it reaches the well, where it is $1\frac{1}{2}$ inch deep: a n, fig. 6. The circular part of the trough is $3\frac{1}{2}$ inches in diameter, and the total length through Δ n $6\frac{1}{2}$ inches. The above dimensions are all inside measurements. The thickness of the gutta-percha is half an inch.

The pressure-tube is simply a straight piece of tubing of about the same diameter

as the eudiometer. Fig. 7 represents the whole apparatus. The glass cylinder is omitted for the sake of clearness, also the eudiometer, but the clamp intended to hold it is shown in the figure.

The liquid reagent is introduced into the eudiometer, by means of a small syringe, readily made from a piece of tubing about 2 or 3 inches long, and $\frac{1}{8}$ inch internal diameter; one end of it is bent round so as to give it the form of a hook, and drawn out; into the other end a piston fits, made from a piece of stout steel wire, one end of it being roughened or a screw turned on it; and round this cotton wool is tightly wrapped

FIG. 5.

FIG. 6.

FIG. 7.

till it just fits the tube. In order to have a measure of the quantity of liquid to be introduced into the eudiometer, it is convenient to make five or six marks on the straight end of the syringe with a file, a quarter of an inch apart. When the liquid is to be introduced, a dot with a piece of chalk is made on the piston, and it is then pushed down till this chalk dot reaches the mark corresponding to the volume of liquid to be injected.

The next thing to be done is to remove this liquid reagent without altering the bulk

of gas in the eudiometer. For this purpose, it is necessary to find some body which can absorb a certain amount of liquid, but will not carry air with it when introduced into the eudiometer, or abstract gas on being withdrawn. Wet cotton wool is found to have the required properties. It is used in this way: a piece of steel wire, size No. 9 or 10, has one end bent into a loop, and some cotton wool is twisted tightly round it; this mass of wool should be about $\frac{1}{4}$ inch in diameter and $\frac{3}{4}$ inch long. It is placed in a basin of water, and thoroughly kneaded and squeezed for some time; this treatment wets the whole mass of cotton wool and expels all the air adhering to it.

This ball of cotton on the steel wire might of course be introduced into the eudiometer in the same way as Bunsen introduces his solid reagents; but it is found much more convenient, especially where it is important to have the mercury-trough small, to use what may be called a guide-tube. This is merely a piece of fine glass tubing about 8 or 9 inches in length, and bent into a curve at one end. The steel wire is introduced at this end and pulled through till the cotton ball prevents its going further. Held in this way the ball is easily introduced or withdrawn from the eudiometer, and that without dipping the fingers into the mercury. The ball being now held in the tube and thoroughly saturated with water, is lifted from the basin and plunged below the surface of the mercury in the trough; it is then squeezed between the finger and thumb, so as to expel a considerable portion of water, but still to leave it very wet. The guide tube is now introduced into the canal D, fig. 5, of the trough, and pushed down it so that the curved end with the ball comes within the tall glass cylinder. In order to introduce the ball into the eudiometer, the eudiometer is raised so that the open end of it is a little above the well in the trough; a mark on the cylinder, or on one of the supports, will indicate the point to which the top of the eudiometer must be raised in order that the open end of it may be in the right position. When it is thus raised, it is easy to hook the cotton ball projecting from the guide-tube into the eudiometer; then on pushing the wire, the ball rises in the tube and is completely under control. It is well to apply a very little grease to the wire, and if by any chance it should become bent, it must of course be discarded. To withdraw the reagent, the eudiometer is raised and the cotton ball introduced as above described; it is pushed up till the top of it comes in contact with the reagent, which is then quickly taken up by the cotton wool and the meniscus left free from liquid. The ball is now pulled below the surface of the mercury: this should be done with a jerk, to prevent any gas adhering to it, and withdrawn from the trough. The other manipulations with this apparatus are the same as with that of Williamson and Russell, described in vol. i. p. 274.

Russell has also described a method of accurately determining, by means of the apparatus just described, the volume of gas given off in any chemical reaction, and consequently of applying such measurements to various cases of quantitative analysis, such as the analysis of carbonates, the valuation of manganese peroxide and certain other oxides, by treatment with a mixture of sulphuric and oxalic acids, &c.

The measuring tube used in these determinations is about 29 inches long, and rather more than three-quarters of an inch in internal diameter. It is bent at right angles near the upper end, which is left open, and connected by a caoutchouc tube with a small flask, into which the reacting substances are introduced. The connection between the tube and the flask can be closed at pleasure by pressing the flexible tube with a spring clamp. The difference between the volume of air in the tube and flask before and after the reaction, gives, after proper correction, the quantity of gas produced. For details of manipulation we must refer to the original memoir (*Chem. Soc. J.* [2] vi. 310).

Another apparatus for quantitative analysis by measurement of the gases evolved in reactions, 'Gas-volumetrische Analyse,' chiefly in agricultural and techno-chemical investigations, is described by Fr. Schulze (*Zeits. hr. anal. Chem.* ii. 289; *Jahresh.* 1863, p. 661).

Apparatus for measuring the gases absorbed in water, and given off on mixing with alcohol and heating, are described by Bobierre (*Compt. rend.* lvi. 313; and Robinet, *Ann. Ch. Phys.* [3] lxxviii. 177; *Jahresh.* 1863, p. 665).

ANALYSIS, ORGANIC. Cloez (*Ann. Ch. Phys.* [3] lxxviii. 394) describes an apparatus for the analysis of organic bodies, differing from that in general use chiefly by the substitution of iron combustion-tubes for those of glass. The iron tube, 1.15 metre long and 0.020 to 0.222 in diameter, is lined throughout with a layer of oxide by heating it to redness and passing steam through it, and is laid in a furnace of such a length that about 0.2 metre of the tube projects at each end. In the middle part of the tube is placed granulated cupric oxide, kept in its place by

copper foil; and into each end is inserted a semi-cylindrical tray of iron plate, attached to a wire for drawing it out. The tray at the anterior end, which is 0.2 metre long, serves for the reception of various substances, according to the nature of the body to be analysed; thus, for acidified bodies, it is filled with metallic copper; for substances containing chlorine or sulphur, with lead chromate; for difficultly combustible substances, with cupric oxide; in other cases it is dispensed with. The posterior tray, 0.3 metre long, is filled to three-fourths with cupric oxide or lead chromate. The tube thus fitted up is heated to redness; a slow stream of dry air is passed through it so as completely to desiccate its contents; and the cupric oxide in the hinder tray (after cooling, either in the tube itself, or in a separate arrangement) is quickly mixed in an iron capsule with the substance to be analysed. The front end of the tube is next connected by corks with the apparatus for absorbing water and carbonic acid; the tray containing the substance is put into its place, and the combustion is completed as usual, a slow stream of air, previously freed with the utmost care from water and carbonic acid, being passed through the tube during the whole of the combustion. The end of the combustion is ascertained by comparing the numbers of air-bubbles which enter and leave the potash-bulbs. The same apparatus, with a particular arrangement for passing carbonic acid through the tube, may serve also for the estimation of nitrogen.

A method of organic analysis founded on gas-measurements, and resembling that originally employed by Gay-Lussac and Thénard (i. 226), is described by Fr. Schulze (*Zeitschr. anal. Chem.* v. 289; *Bull. Soc. Chim.* [2] viii. 263). The organic substance (weighing at most 0.010 to 0.012 grm.), mixed with a known weight of potassium chlorate, is burnt at a low red heat in a vacuous combustion-tube, and the gaseous products of the combustion are transferred to a eudiometer and analysed, the entire volume being first measured, and the carbon dioxide then determined by absorption. The carbon dioxide occupies the same volume as the oxygen contained in it; consequently after the combustion of carbohydrates ($C^xH^{2x}O^m$) with potassium chlorate the volume of oxygen in the eudiometer corresponds exactly to the oxygen contained in the chlorate; if the measured volume of gas is larger than this, the organic substance must have contained a quantity of oxygen larger than that required to burn the hydrogen contained in it; if smaller, the substance analysed must be richer in hydrogen than a carbohydrate.

Ladenburg (*Ann. Ch. Pharm.* cxxxv. 1) has described a method of organic analysis in which, as in the method of Gay-Lussac and Thénard, the carbon is estimated directly by the quantity of carbon dioxide produced, and the total quantity of oxygen consumed in the combustion is likewise determined, so that the difference between this and the quantity required for the combustion of the carbon gives the quantity which has combined with hydrogen, whence also the amount of the hydrogen itself may be calculated. The oxidising agent is a mixture of silver iodate with strong sulphuric acid. This mixture, when heated alone, even to 300° , does not give off either iodine or oxygen; but when it is heated in contact with an organic substance, carbon dioxide and water are formed by reduction of the iodic acid, whilst the hydriodic acid formed at the same time, together with free iodine, reacts on the iodic acid, necessarily present in large excess as silver salt, in such a manner as to produce iodine and water (without formation of sulphurous acid):

The process is as follows:—The substance to be analysed is weighed in a small glass bulb, which is introduced, together with concentrated sulphuric acid and a known quantity (excess) of silver iodate, into a strong glass tube, which is drawn out and sealed. The bulb having been broken by a slight blow, the tube is heated for an hour or two in an air-bath to 170° – 200° , and weighed after cooling. The tube is then opened by heating its apex to redness, and the carbon dioxide resulting from the reaction is completely removed by warming the tube to 60° at most, then exhausting with a syringe, and passing a stream of dry air through it. On again weighing the tube the loss of weight gives the amount of carbon dioxide. The tube is then cut into small pieces, and the contents, having been carefully rinsed out, are digested with water in a closed flask, till the blackish colour of the precipitate (arising from a little free iodine) has passed into a yellowish-white. The mixture of silver iodide and iodate, having been thoroughly washed by repeated decantation with water, is dissolved in potassium iodide, and the liberated iodine is determined volumetrically in the dilute liquid by means of sulphurous acid, starch, and normal solution of iodine, after the wash-water of the silver salt diluted with sulphurous acid (and containing a little iodic acid) has been added to it. From the quantity of iodine thus determined, the weight of silver iodate still present is calculated, and

thence also the amount which has been reduced; and this finally gives the quantity of oxygen which has been consumed in the oxidation of the substance. Lastly, the equation

$$2h = s + D - A,$$

in which s denotes the weight of substance burned, D the oxygen consumed, and A the carbon dioxide produced, gives the quantity h of the hydrogen.

C. G. Wheeler (*Sill. Am. J.* [2] xli. 33) has described a process for the simultaneous determination of nitrogen, carbon, and hydrogen, consisting essentially of a combination of the process of ultimate analysis in a current of oxygen with Maxwell Simpson's method of estimating nitrogen (i. 243). The combustion-tube, from 2 to 2½ feet long, is filled with the following substances:—1. A mixture of potassium chlorate and cupric oxide.—2. A layer of pure cupric oxide.—3. A mixture of cupric oxide with an exactly weighed quantity (about 0.5 grm.) of pure lead oxalate.—4. Pure cupric oxide.—5. The mixture of the organic substance with cupric oxide.—6. Pure cupric oxide.—7. Metallic copper. The combustion-tube is connected in the usual manner with a calcium chloride tube and a potash apparatus (terminating in a tube which contains solid potash), and the latter with a Bunsen's mercurial gasometer (ii. 808). The process is commenced by heating the potassium chlorate before connecting the apparatus with the gasometer, so as to replace the air by oxygen; the oxygen is then expelled by heating the lead oxalate, which evolves carbon dioxide, and then the metallic copper is heated, the gas-delivery tube being at the same time connected with the gasometer. The combustion is then carried on in the usual way, and when it is completed, oxygen is again evolved by heating the rest of the potassium chlorate. The nitrogen in the gaseous mixture collected in the gasometer is then determined eudiometrically. The quantity of carbon dioxide evolved from the lead oxalate is of course deducted from the weight of the potash apparatus after combustion. A series of experiments made with all sorts of nitrogen compounds for the purpose of testing this process gave very exact results.

Baumhauer (*Archives néerlandaises*, i. 179; *Zeitschr. anal. Chem.* v. 141) has perfected the apparatus formerly described by him (i. 239) for the simultaneous determination of carbon, hydrogen, and oxygen, as follows:—A combustion-tube 70 to 80 centim. long and open at both ends is filled with the following substances, beginning from the anterior extremity: 1. A layer of copper-turnings 20 centim. long.—2. A layer 20 centim. long of fragments of porcelain previously washed with hydrochloric acid and ignited.—3. A layer 25 centim. long of strongly ignited coarse-grained cupric oxide (between plugs of asbestos).—4. The substance to be analysed, contained in a boat of porcelain or platinum, or, in the case of volatile substances, in a glass bulb, which is pushed into the tube by means of a glass rod, to within 5 centim. of the cupric oxide; difficultly combustible substances are previously mixed in the boat with the cupric oxide.—5. At a distance of 6 or 7 centim. behind the substance is placed a second boat, containing a weighed quantity (a few grms.) of silver iodate. The posterior end of the combustion-tube (containing the silver iodate) communicates—by means of a tube containing ignited copper-turnings, a U-tube filled with pumice-stone soaked in sulphuric acid, and a second U-tube containing calcium chloride and soda-lime—with two gasometers, one containing pure nitrogen, the other hydrogen. Before attaching the apparatus for absorbing the water and carbon dioxide, the anterior part of the tube containing the copper-turnings is heated, and a slow stream of hydrogen is passed through it, till the surface of the metal is completely deoxidised. The hydrogen is then displaced by nitrogen, and the part of the tube containing the porcelain boat and the cupric oxide is heated in a continuous slow stream of the gas, the calcium chloride tube and the potash apparatus being at the same time attached. When the whole apparatus is filled with nitrogen, and the potash-ley is also saturated with that gas, the absorption apparatus are detached and weighed, then again attached, and the substance is carefully heated, the stream of gas being continually kept up. As soon as the organic substance is completely burned, or at least completely carbonised, the silver iodate is gradually heated, whereby the still remaining carbon is burned, and the copper reduced from the cupric oxide is reoxidised, the excess of oxygen being retained by the copper-turnings. After the complete decomposition of the silver iodate, the stream of nitrogen is kept up for some time, and then the absorption apparatus are weighed. In the next place, still without interrupting the stream of nitrogen, the copper-turnings alone are heated to redness (the fire being removed from the other parts of the tube), and when the cupric oxide is quite cold, a weighed calcium chloride tube is attached, and a stream of hydrogen is passed through the apparatus. The excess of oxygen of the silver iodate, which

had been taken up by the copper-turnings, is thereby converted into water (*b*), and the weight of this water gives the quantity of oxygen contained in the silver iodate beyond that which was required for the complete combustion of the organic substance. If the boat be now removed from the combustion-tube, the latter is ready for another analysis.

As an example of the calculation and of the degree of exactness attained, we may take an analysis of oxalic acid.

Substances used: Oxalic acid 0.452 grm.; silver iodate 1.256 grm. (yielding on the average 16.92 per cent. oxygen), therefore 1.25 grm. yielding 0.2125 grm.

For the simultaneous determination of nitrogen, there is attached to the potash apparatus a tube *a*, open above and below, and divided into centimetres: this is connected by a strong caoutchouc tube with a second glass tube *b*, of as nearly as possible the same dimensions. On pouring mercury through the latter, it is possible, by raising or depressing *b*, to bring the mercury in the tube into any required position. The whole being prepared for the analysis as in the former case, the tube *a* is connected with the potash apparatus, after it has been raised to such a height that *a* is completely filled with mercury. The supply of nitrogen gas is then cut off, and the tube *b* is depressed so far that the mercury in it stands about 200 mm. lower than in *a*; the whole is then left to cool, and the height of the mercury is observed, as well as the pressure and temperature. The mercury is then brought to the same level in *a* and *b*, and this level is read off. The combustion is now carried on in the manner above described, excepting that no nitrogen is passed through the tube, and, when the evolution of nitrogen from the substance has ceased, the apparatus is left to cool, the height of the mercury is read off, and in this way the amount of nitrogen is ascertained. The gas apparatus are then removed, and the combustion is terminated, as above described, by heating the silver iodate. Baumhauer recommends, however, that the nitrogen shall when possible be determined in a separate portion of the substance.

For Maumené's method of determining the oxygen in organic compounds, see *Zeitschr. anal. Chem.* i. 487.

According to Wanklyn & Frank (*Phil. Mag.* [4] xxvi. 554), organic substances when ignited in a stream of hydrogen give up part (if not the whole) of their oxygen in the form of water, a reaction which affords a means of detecting the presence of oxygen in organic compounds.

A. Mitscherlich (*Pogg. Ann.* cxxx. 536; *Zeitschr. anal. Chem.* vi. 136) has devised a new method of organic analysis, which serves, amongst other purposes, for the direct estimation of oxygen. Two forms of process are employed, the combustion being made in a current of chlorine, or of oxygen, according to the elements to be determined.

1. When any organic substance is heated to redness in an atmosphere of chlorine free from oxygen, the hydrogen is wholly converted into hydrochloric acid, and may be estimated in that form, while the oxygen of the organic body unites with its carbon, or with charcoal added thereto, forming monoxide and dioxide of carbon, from the weight of which the oxygen in the organic substance may be calculated.

The combustion is performed in a porcelain tube 0.6 met. long and 9 mm. in internal diameter, half filled with charcoal. If the substance to be analysed is not volatile below 150°, it is enclosed in a glass tube open at both ends and introduced into the porcelain tube; if volatile below 150°, it is placed in a glass apparatus of peculiar construction. Gaseous substances are enclosed in a graduated jar immersed in water, and are passed into the combustion-tube by a tube attached laterally to that which conveys the chlorine.

Sup.

L

The gases produced by the combustion are passed into absorption-bulbs of peculiar construction, called 'Mitscherlich's bulbs.' The hydrochloric acid resulting from the combustion of the hydrogen is absorbed by a concentrated solution of lead nitrate, which, according to the author, does not absorb free chlorine. The carbon dioxide is absorbed by potash, but it must be previously freed from chlorine by passing the gases through an alcoholic solution of stannous chloride or ferrous sulphate. The carbon monoxide is absorbed by passing it through a series of bulbs filled with a solution of cuprous chloride and hydrochloric acid.

2. For the determination of carbon, sulphur, the halogen elements, and nitrogen, the organic substance is heated in a current of hydrogen, and the mixture of hydrogen with the vaporised body, or its product of decomposition, is burnt in a current of oxygen. The combustion-tube is of hard glass, and is composed of a horizontal branch 200 mm. long, a downward bend of 130 mm., a second horizontal branch 250 mm. long, and a second bend directed upwards and drawn out to a narrow neck, to which the absorption-apparatus are attached. The lower horizontal branch is half filled with sulphuric acid, heated moderately towards the end of the process, to absorb the water generated in the combustion. This lower branch is divided into two parts by a curvature directed upwards. When the organic substance contains sulphur, the part next to the organic body is filled with a mixture of chloride and sulphite of calcium. The sulphuric acid, which is always formed, together with sulphurous acid, eliminates from this mixture an equivalent quantity of sulphurous acid. The oxygen which maintains the combustion is introduced by a lateral branch of the tube.

The carbon dioxide is absorbed by potash. There likewise remains in the tube containing the organic substance a residuum which is regarded as pure carbon and is to be weighed as such. [Is it quite free from hydrogen?] The sulphurous acid is absorbed by a saturated solution of potassium chromate. Hydrochloric acid and bromine are absorbed by lead-nitrate contained in a bulb-apparatus to which is attached a tube, filled half with mercuric oxide and half with calcium chloride. Iodine is weighed in the free state in another tube. Nitrogen is collected at the end of the apparatus after being freed from the excess of oxygen by passing through a tube containing fragments of phosphorus.

Mitscherlich also describes a method of estimating hydrogen in a substance containing sulphur, viz. by volatilising it in a stream of carbon monoxide and burning it with excess of oxygen. The analyses made according to these methods yielded very exact results, but the processes are perhaps too complicated to supersede those in general use.

In a subsequent communication (*Deutsche Chem. Gesellschaft*, i. 45; *Bull. Soc. Chim.* [2] x. 378) Mitscherlich describes a simplified method, by which the carbon, hydrogen, and oxygen may be estimated in a single operation. In this method the chlorine is supplied by *potassium platinochloride*, a substance which gives up its chlorine when heated with organic bodies.

The substance to be analysed is introduced into a porcelain tube filled with a mixture of pumice-stone and potassium platinochloride (containing about 8 grms. of platinum); the air of the apparatus is expelled by a current of nitrogen gas; and the tube is heated to redness. Water is absorbed by phosphoric oxide, hydrochloric acid by lead nitrate, free chlorine by stannous chloride, and carbon dioxide by potash [is not carbon monoxide also sometimes formed?]; the products of the combustion still remaining in the tube are driven into the absorbing apparatus by a current of nitrogen; the whole is left to cool; and the absorption apparatus are weighed.

The porcelain tube is then again heated to redness, and a stream of oxygen is passed through it, whereby the remainder of the carbon is converted into carbon dioxide, which is absorbed in the same apparatus. To avoid any loss of carbon arising from the formation of a solid difficultly oxidable chloride, a glass tube containing cupric oxide is introduced into the porcelain tube, and the vapours of the chlorinated body are passed over this oxide, which burns the carbon completely.

Finally, there remains in the combustion-tube a mixture of pumice-stone, metallic platinum, and potassium chloride; and the tube may be rendered fit for a fresh analysis by passing a current of chlorine through it.

Very volatile substances and gases are introduced into the tube in the manner described in connection with the earlier form of the process, by the aid of a stream of nitrogen.

Estimation of Nitrogen.—Frankland found some years ago (*Phil. Trans.* cxlvii. 63) that in estimating nitrogen by Dumas' method, a certain quantity of the nitrogen sometimes passes off as nitrogen dioxide, even when a considerable quantity of metallic copper is placed in the anterior part of the combustion-tube, so that it

becomes necessary to estimate the volume of the dioxide by means of solution of ferrous sulphate, and to deduct half its volume from the observed amount of the mixed gases. But from experiments recently made by W. Thorp (*Chem. Soc.* [2] iv. 359) in Frankland's laboratory, it appears that when the metallic copper is heated to bright redness, and the gaseous products of combustion are passed over it at a moderate rate, the whole of the nitrogen is evolved in the free state; whereas if the copper is heated only to dull redness, or if the gases pass over it too quickly, part of the nitrogen will escape as dioxide. The presence of a large quantity of aqueous vapour appears to interfere with the complete reduction of the oxides of nitrogen, so that in the analysis of azotised bodies containing much hydrogen, part of the nitrogen may escape reduction, even under conditions otherwise the most favourable; but the proportion of the nitrogen which thus escapes reduction does not exceed 3.76 p. c.; and in an actual analysis, even if the substance burned contained 20 p. c. of nitrogen, the error would be only 0.75 p. c., which would not very materially affect the results.

As the metallic copper used in the analysis of azotised bodies becomes oxidised when the combustion is performed in a stream of oxygen, Stein recommends the use of silver in place of it, that metal having also the advantage of retaining any chlorine that the organic substance may contain. Recent experiments by E. Calberla have shown that the silver completely reduces the nitrogen dioxide to free nitrogen, and does not exert the slightest decomposing action on carbon dioxide (*Bull. Soc. Chim.* [2] x. 382).

J. T. Brown (*Chem. Soc. J.* [2] iii. 211) has given a table to facilitate the calculation of the results of nitrogen determinations by Dumas' method. It gives the values of the fraction $\frac{0.0012562}{(1 + 0.00367T)760}$ for all values of T from 0° to 30°, the numerator being the weight of a cubic centimetre of nitrogen at 0° and 760°. For example, to find the weight of 53 c.c. nitrogen at 15°, and under a pressure of 743.3 mm., we should have

$$0.0000015665 \times 53 \times 743.3 = 0.061718 \text{ grm.}$$

$$\text{Table for the calculation of } \frac{0.0012562}{(1 + 0.00367T)760}$$

For the estimation of nitrogen in substances (manures, for example) of which at least 25 to 30 grms. may be used, Ch. Mène (*Zeitschr. anal. Chem.* vi. 461) uses an earthen retort filled with lumps of potassium hydrate, and provided with a safety-tube. The substance, moistened with strong soda-ley, is introduced into the retort in the form of small pellets, and the retort is heated to low redness, beginning at the upper part. The ammonia must be collected in hydrochloric acid and weighed as ammonium platinochloride, inasmuch as the empyreumatic products would interfere with the volumetric estimation.

Respecting Schloosing's method of determining the nitrogen of organic compounds in the same operation with the carbon and oxygen, see *Zeitschr. anal. Chem.* vii. 269; *Jahresb.* 1867, p. 859.

Analysis of Compounds containing Chlorine or Bromine.—Görup-Besanez (*Zeitschr. anal. Chem.* i. 438) finds that in the combustion of brominated organic compounds by the ordinary method, the quantity of carbon may come out considerably too low (as much as 10 p. c.). This result he attributes to the formation of a fusible copper bromide, which envelopes portions of unburnt carbon and protects them from oxidation. To ensure the perfect combustion of the carbon in such bodies, he recommends the following process. At the posterior end of the combustion-tube, which is drawn out to a long bayonet-point, is placed a layer of cupric oxide 3 inches long; then an asbestos plug; next follows a porcelain boat containing a mixture of the organic substance with ignited lead oxide, and separated by a second asbestos plug from the granulated cupric oxide with which the rest of the tube is nearly filled, the anterior extremity being however occupied as usual by a layer of lead chromate or copper-turnings. The anterior portions of cupric oxide are heated first, then the posterior portions; afterwards heat is applied very gradually and carefully to the boat; and when the dry distillation is finished the combustion is completed in a stream of oxygen, care being taken not to heat the boat too strongly or to continue the stream of oxygen too long, as otherwise bromide of copper (or of lead) may be carried over into the calcium chloride tube.

Kraut (*Zeitschr. anal. Chem.* ii. 242) recommends that, in the analysis of organic compounds containing chlorine, bromine, or iodine, by means of cupric oxide and oxygen, a roll of silver leaf 5 inches long should be placed in front of the metallic copper. The silver will retain the whole of the chlorine, bromine, or iodine, even when oxygen is passed over it, and may be used many times before its surface requires to be renewed by reduction in a stream of hydrogen.

For the detection of iodine, bromine, or chlorine in organic compounds, Erlenmeyer (*Zeitschr. Ch. Pharm.* 1864, p. 638) decomposes a small quantity of the compound in a test-tube, the bottom of which is heated to low redness; the presence of either of these elements may then be recognised by the colour and reaction of its vapour. Liquid compounds may be conveniently examined for these elements by introducing a few drops of the liquid into the long neck of a glass bulb; on gently warming the bulb, and holding it with its neck directed downwards, the liquid is driven out, and may be directed on to the heated portion of the test-tube, where it will be decomposed.

For the estimation of chlorine (simultaneously with carbon and hydrogen), C. M. Warren (*Sill. Am. J.* [2] xlii. 156) places in the anterior part of the combustion-tube a mixture of cupric oxide (precipitated and ignited) with asbestos, to moderate the rapidity of the combustion. To prevent the volatilisation of cupric chloride, the part of the tube where this mixture is placed is heated to only 250° , in an air-bath of iron plate. When the combustion is completed, the cupric oxide is dissolved in dilute nitric acid, and the chlorine precipitated with silver nitrate.

In organic compounds containing a considerable proportion of hydrogen, the amount of chlorine, bromine, or iodine, may, according to Carius (*Ann. Ch. Pharm.* cxxxvi. 129), be very exactly determined by heating the compound with nitric acid and silver nitrate in a sealed tube (i. 247), in the manner described below in the case of sulphur compounds; but the chlorine compounds of the aromatic bodies, chlorobenzene for example, are but slowly and incompletely decomposed by this treatment. An exact estimation of chlorine in such compounds may however be obtained by heating them to about 200° with a mixture of potassium dichromate, silver nitrate, and nitric acid. The silver chromate usually mixed with the resulting silver chloride may be removed by diluting the contents of the tube with a considerable quantity of water and digesting with alcohol. In iodine compounds the resulting iodic acid must be reduced by sulphurous acid.

Estimation of Sulphur and Phosphorus.—Carius (*loc. cit.*) in 1860 described a method of estimating sulphur in organic compounds by heating them in sealed tubes with nitric acid (i. 247). This method he has now modified (*Ann. Ch. Pharm.* cxxxvi. 129) by using, instead of pure nitric acid (which often renders it necessary to evaporate the liquid after neutralisation with sodium carbonate, and fuse the residue), a mixture of nitric acid with potassium dichromate, in such proportion that the chromate—which, in oxidising the organic substance, forms potassium nitrate and chromic nitrate—shall be present only in slight excess. From 3 to 4 pts. nitric acid of sp. gr. 1.4 are sufficient for every 1 pt. of the required potassium chromate. The mode of conducting the process is as follows. From 0.15 to 0.40 grm. of the organic substance is sealed up together with the smallest possible quantity of air in a small glass bulb, the two ends of which are about a millimetre wide, very thin in the glass, and bent sideways. The bulb thus prepared is introduced into

a tube of glass, 10 to 12 millim. wide, roundly sealed at one end, and about half filled with the mixture of nitric acid and potassium chromate. The glass tube is then drawn out at the upper end to a thick-walled capillary tube; the liquid is heated to the boiling point; and when all the air is expelled the capillary tube is sealed. After cooling, it is shaken till the ends of the bulb are so far broken as to form at each end an aperture about a millim. wide, by which the acid liquid can easily enter into the tube. The glass tube is then introduced into an iron tube, which is closed at one end, laid in an inclined position in an iron box serving as an air-bath, and heated therein by a gas-flame to 120°–140°. To open the tube at the end of the operation, it is left to cool completely; the liquid collected near the point is driven back by careful heating; and the extreme point is heated to redness, whereupon the gases escape quietly. The tube is then cut off below the narrow part, and the liquid containing all the non-gaseous products of the reaction is collected.

The resulting blue-green liquid is diluted with 8 or 10 volumes of water, and heated for an hour with 5 to 10 c.c. alcohol to reduce the chromic acid, after which the sulphuric acid is precipitated by barium chloride.

R. Otto (*Zeitschr. f. Chem.* [2] iii. 604) estimates sulphur in organic compounds by combustion with precipitated cupric chromate. The fore part of the tube must not be too strongly heated; the combustion should be made slowly; and the tube must be wide enough to prevent the cupric chromate from being driven out of it by the escaping gases. When the combustion is finished, the contents of the tube are digested with hydrochloric acid mixed with alcohol to reduce the chromic acid; the liquid is filtered; and the sulphuric acid contained in it is precipitated by barium chloride.

For the estimation of phosphorus in compounds which, like oxide of triethyl-phosphine, are not completely oxidised by nitric acid alone, Carius (*loc. cit.*) heats the substance to 180°, with a slight excess (about $\frac{1}{10}$ th more than is required for complete oxidation) of silver iodate and pure hydrogen sulphate (about 2 vol. to 1 vol. of the iodate). The contents of the tube are then diffused through cold water; the filtrate is heated with a little sulphurous acid; and in the liquid, again filtered and evaporated, the phosphoric acid is precipitated in the ordinary way as ammonio-magnesian phosphate.

Salts of Organic Acids.—For the analysis of the potassium, sodium, and barium salts of organic acids, the following process is recommended by Cloez (*Bull. Soc. Chim.* [2] i. 250). A known weight of the salt is mixed with at least 3 pts. of recently ignited tungstic oxide,* and the mixture is burned in a tared porcelain boat, by means of the previously described apparatus of Cloez for organic analysis with cupric oxide and a stream of air (p. 142). In this manner the carbon and hydrogen are determined as usual, and the increase in weight of the porcelain boat after the combustion gives at the same time the quantity of the base (as oxide). Trial experiments made with sodium acetate, potassium tartrate, and barium myristate yielded fairly accurate results.

For the more exact determination of the carbon in the alkaline salts of organic acids, C. Schaller (*Bull. Soc. Chim.* [2] ii. 93) mixes the salt with an equal weight of silica, and then with cupric oxide. Antimonic oxide was long ago recommended for the same purpose by Dumas a. Piria. Schaller estimates the amount of alkali in the salts of organic acids by igniting the salt with half its weight of silica, and weighing the residual alkaline silicate.

Mercury-compounds.—For the analysis of organic mercury-compounds, and of other mercury salts, Frankland a. Duppa recommend the following process. The combustion is made with cupric oxide, air, and oxygen, in a tube which is drawn out in two places near the anterior extremity, bent in a U-shape to receive mercury and water, and then connected with a sulphuric acid tube and a potash-apparatus. When the combustion is finished, and air is being passed through the tube, the mercury collected in the drawn-out part is driven by heat into the U-tube; the latter is then melted off, and connected, instead of the potash-apparatus, with a second sulphuric acid tube; and the water is transferred to the first sulphuric acid tube by means of a vacuum formed by the air-pump. The separation of water from mercury by means of a stream of air at ordinary temperatures is tedious and inexact; and if heat is applied, a portion of the mercury is always driven over into the sulphuric acid tube.

Proximate Analysis of Organic compounds by Limited Oxidation. Chapman a. Thorp (*Chem. Soc. J.* [2] iv. 477) have shown that the products formed

* Cloez prepares the tungstic oxide, (WO₃), by mixing the hot aqueous solutions of 100 pts. commercial crystallised sodium tungstate and 50 pts. sal-ammoniac, washing the separated ammonium tungstate with cold water, and igniting it in an open vessel.

by a regulated oxidation of organic compounds may yield important data for the determination of their molecular structure, and therefore for the investigation and characterisation of cases of isomerism. From experiments on bodies of the fatty series they conclude that complex organic molecules may be separated, by oxidation restrained within determinate limits, into molecules of simpler structure and much more difficult to oxidise, which may be regarded as the proximate constituents of the original more complex molecules.

The oxidising agents used consist of solutions of potassium dichromate mixed with the quantity of sulphuric acid required to produce acid potassium sulphate and chromic sulphate, and containing 3, 5, or 8 p. c. potassium dichromate. The substances to be oxidised are heated with these solutions in sealed tubes; the contents of the tubes are afterwards diluted with water and distilled; and the acid contained in the distillate is either immediately converted into a barium salt (for the saturation of the higher members of the fatty acid series, barium hydrate is better than the carbonate), or (to separate different acids that may be present) it is saturated with potash-ley, and the volatile acid is distilled off fractionally, after the successive addition of a quantity of titrated sulphuric acid sufficient to saturate one-third of the potash present (i. 250).

To remove all doubt as to the applicability of this method, Chapman and Thorp have demonstrated, in the first instance, that acetic acid, propionic acid (prepared from ethyl-cyanide), valeric acid, and caproic acid (whether prepared from amyl cyanide or from the ketone obtained in the distillation of potassium ricinoleate), are not at all attacked, or only in traces (with formation of a small quantity of carbon dioxide), by subjection for twenty-four hours to the action of the 3, 5, or 8 p. c. chromic acid mixture at 100°; and consequently that these acids, when they occur as products of oxidation, remain unaltered in the mixture. At 130°, however, they undergo, more or less easily, a more thorough oxidation, which may be facilitated by the use of a larger excess of strong sulphuric acid, by the presence of free chromic acid, or of a small quantity of manganese dioxide, but never takes place if phosphoric acid is added instead of sulphuric. Dilute solutions of permanganic acid appear to act like the chromic acid mixture, inasmuch as they do not act on acetic or propionic acid even at the boiling heat (and but slowly on formic acid at ordinary temperatures in presence of sulphuric acid); concentrated solutions, however, decompose these acids with facility.

Those oxidation-products which are formed under the influence of a sufficient quantity of the oxidising mixture, and of exhaustive action, are designated as *proximate*; those obtained with an insufficient quantity of the oxidising agent, or when it is not allowed to act for a sufficient time, are called *mediate* products.

The results obtained with certain compounds by the above process, when the oxidation was normal and complete (the mixture of the substance with the chromic acid solution being usually heated to 80° or 90°, never above 100°), may be represented by the following equations:

Alcohols.

Compound Ethers, obtained by the action of an Iodide on the corresponding Potassium-salt.

Iodides.

* The same products were likewise obtained with permanganic acid, both at ordinary and at higher temperatures.

† Formic acid in small quantity was detected in the distillate.

‡ The oxidation takes place slowly, but completely, with a sufficient excess of the dilute (5 p. c.) chromic acid solution; with a very concentrated solution of chromic acid the oxidation goes further.

Amines.

Hydrocarbons, C^nH^{2n} .

From ethyl alcohol there were obtained, as intermediate products, aldehyde and ethyl acetate; from amyl alcohol, valeraldehyde and amyl valerate; from amyl acetate, valeraldehyde.

Mannite and glycerin, when heated with potassium hydrate, yield the same products as the hydrocarbons obtained by acting upon them with hydriodic acid and decomposing the resulting iodides with alcoholic potash. (Mannite yields propionic, acetic, and formic acids; glycerin yields acetic and formic acids.) It therefore appears remarkable that the chromic acid mixture oxidises both these bodies with violent reaction, to acetic and carbonic acids, and that mannite is decomposed by an acidulated solution of potassium permanganate at a gentle heat, according to the equation:

Respecting the products of oxidation of the *diatomic hydrocarbons*, results different from those above detailed have been obtained by Truchot (*Compt. rend.* lxiii. 274). According to this chemist, ethylene and its homologues yield by oxidation with potassium permanganate, the fatty acid immediately lower in the series than the hydrocarbon itself. Thus when a solution of potassium permanganate is poured into a bottle filled with ethylene and standing in cold water (the solution containing 12 to 14 grms. of the crystallised salt to 1 litre of ethylene gas) the liquid is completely decolorised, and yields—after the manganic oxide has been removed by filtration, and the concentrated scarcely alkaline filtrate distilled with tartaric acid—nothing but formic acid with more or less carbon dioxide—no acetic acid. Propylene similarly treated is converted into formic and acetic acids; amylene yields acetic, propionic, and butyric, together with a small quantity of formic acid.

These results have to a certain extent been confirmed by Chapman and Thorp. They find, however, that the higher acids are produced only when an alkaline oxidising agent is employed, and that even in this case they may be resolved by prolonged oxidation into carbonic and acetic acids. Hence they regard Truchot's results as relating only to imperfect oxidation, or perhaps as obtained by operating on mixtures of isomeric hydrocarbons.

The reactions above described are sufficiently exact for the quantitative estimation of the several groups of carbon-compounds into which a complex molecule is thereby resolved. For this application of the process of limited oxidation, which has been worked out by Chapman and Smith (*Chem. Soc. J.* [2] v. 173; *Jahresb.* 1867, p. 338), it is sufficient to know—

1. The quantity of carbon dioxide produced.
2. That of the organic acids or neutral volatile bodies formed.
3. The quantity of oxygen required for the oxidation.

The methods adopted in these determinations are as follows:

1. *Carbon Dioxide*.—The substance to be oxidised (0.2 to 0.5 grm.) is introduced into a flask having a tube soldered laterally to its neck, whereby it is connected with a Will and Varrentrapp's bulb-apparatus (containing strong sulphuric acid for absorbing the vapours), and then with a potash-apparatus and potash-tube. Into the stopper of the flask is fixed a bulb-pipette provided with a stopcock and containing the required quantity of the chromic acid solution (100 grms. potassium dichromate and 126 grms. concentrated sulphuric acid in 1,000 c.c., 150 c.c. of this solution being

* The oxidation succeeded best when the substance was first heated to 70°–80° for half an hour with concentrated chromic acid solution, and this mixture after dilution was heated in the water-bath.

† This compound was oxidised only by a concentrated solution of chromic acid; formic acid was not found among the products.

‡ The rapid evolution of carbon dioxide rendered it necessary to open the tube and close it again during the experiment.

sufficient for the purpose). The weight of the filled potash-apparatus having been determined, the chromic acid solution is allowed to run into the flask; the flask is heated in the water-bath after the pipette has been closed; and the evolution of carbon dioxide and the termination of the experiment are regulated as in a combustion analysis, the vessel, containing the sulphuric acid being at the same time carefully kept cool. The carbon dioxide may also be estimated, though less conveniently, by loss.

2. *Volatile Acids or Neutral Compounds.*—The weighed substance is heated in a closed tube to 100° for about an hour and a half, with a 10 p. c. dichromate solution; the contents of the tube are emptied out into a flask, treated with zinc to reduce the chromic acid still present, and distilled several times to dryness, with repeated addition of water; the united distillates are saturated with barium carbonate; the solution is evaporated; and the weight of the barium salt dried at 150° is determined. The nature of the acid is indicated by the determination of the barium, and, after the separation of that element, by partial saturation and distillation. Neutral volatile substances insoluble in water and in saline solutions may be separated by distillation, receiving the distillate in potash-ley, and saturating it with carbonic acid.

3. To determine the *oxygen consumed*, the oxidised liquid is heated to boiling with excess of potash-ley; the precipitate of chromic oxide (which still retains potash, even after careful washing) is dried, ignited, boiled with strong sulphuric acid and a little alcohol, and again precipitated by ammonia.

As, however, the accuracy of this method is somewhat impaired by the uncertainty relating to the atomic weight of chromium, Chapman, in a subsequent communication (*Chem. Soc. J.* [2] v. 227), recommends the employment of a known weight of potassium dichromate, and the determination of the excess of chromic acid still remaining after the oxidation. Two equal portions of the dichromate solution are taken. One of them is decomposed directly with excess of oxalic acid and dilute sulphuric acid; and the carbon dioxide eliminated is estimated in the manner above described, the liquid being finally heated to the boiling point and kept there for a few seconds. (Percussive ebullition may be prevented by throwing in a few fragments of tobacco-pipe stems.)

A second portion of the solution is made to act upon a known weight of the organic substance, and the mixture is then treated in the same manner with oxalic acid and dilute sulphuric acid. The difference in the quantities of carbon dioxide in the two estimations corresponds to the oxygen consumed by the organic body, which oxygen (since the formation of 88 pts. carbon dioxide from oxalic acid requires 16 pts. oxygen) is calculated therefrom by multiplying by $\frac{1}{5}$.

The following examples may serve to exhibit the utility and scope of this method:

1. *Lactic acid* is oxidised by chromic acid in such a manner that $\frac{1}{3}$ of its carbon is converted into carbon dioxide, and the remaining $\frac{2}{3}$, first into aldehyde (on heating in the water-bath), then into acetic acid (on heating under pressure):

Barium lactate gave 7.76 and 7.69 p. c. carbon as carbon dioxide, and 80.64 p. c. pure barium acetate:

	Found	Calc.
C in form of carboxyl (CHO^2)	7.72	7.62
C in the acetyl compound	15.21	15.24

2. *Diethoxalic acid*, $\text{C}^4\text{H}^{12}\text{O}^5$, is resolved by oxidation into carbon dioxide and propione, $\text{C}^3\text{H}^6\text{O}$:

	Found	Calc.
C in form of carboxyl	9.093	9.091
Propione	65.7	65.15

3. *Propione* heated in a sealed tube with the oxidising liquid yields propionic and acetic acids:

	Found	Calc.
100 pts. propionic consumed of oxygen	57.83	55.8 pts.
and yielded barium acetate and propionate	310.5	312.8 "
The barium in this mixture amounted to	50.94	50.93 p. c.

Diethoxalic acid contains therefore altogether, in accordance with the formula synthetically established by Frankland & Duppa:

				Found	Calc.	
C in form of carboxyl	.	.	.	9.09	9.09	p. a.
C in the propylic form	.	.	.	27.29	27.27	
C in the ethylic form	.	.	.	18.20	18.18	

The determination of the quantity of oxygen consumed in such reactions was found by Chapman, following the second method, to yield the following results:

I. For the conversion of butyric ether into butyric and acetic acids.—II. Of propionic into propionic and acetic acids.—III. Of diethoxallic acid into carbon dioxide, propionic acid, and acetic acid: the organic substance being in each case heated in a sealed tube with a sulphuric acid solution containing 7 p. c. potassium dichromate:

	I.	II.	III.
Oxygen found . . .	27.71	55.90	48.66 p. c.
" calculated . . .	27.58	55.81	48.48 "

Proximate Analysis of Vegetable Tissues (Frémy and Terreil, *Bull. Soc. Chim.* [2] x. 437).—This branch of analysis presents peculiar difficulties, arising partly from the great similarity between the several proximate constituents of vegetable tissue, and secondly from the insolubility of these constituents in all the neutral liquids, such as water, alcohol, ether, &c., which are commonly used in proximate analysis. Frémy and Terreil, however, by the use of more powerful reagents, such as the mineral acids, alkalis, chlorino, &c., have succeeded in obtaining a more complete analysis of several vegetable tissues than any that have hitherto been made.

A complete analysis of several vegetable tissues than any artificial mixture has been made. As an example, they give the analysis of oak-wood. This they find to consist of three parts, viz. (1) The *ligneous cuticle*, which is quite insoluble in hydrated sulphuric acid, $\text{SO}^2_2\text{H}^2\text{O}$ or $\text{SO}^2\text{H}^2\text{H}^2\text{O}$, insoluble also in potash, but is dissolved by chlorine-water and nitric acid, after being first transformed into a yellow acid. This substance, which bears considerable resemblance to the cuticle of leaves, appears to form the cutaneous covering of the fibres and cells of the wood; when separated from the other constituents by means of sulphuric acid, it retains perfectly the structure of the ligneous tissue, so that when examined by the microscope it looks like the wood itself, of which however it forms only about one-fifth.—(2) The *incrusting matter* (Payen) which probably exists in the interior of the fibres and cells. It is soluble in sulphuric acid, which it blackens, but insoluble in chlorine-water. It is not however a definite substance, but a mixture of three others, one of which is soluble in boiling water, a second soluble in alkalis, and a third, which becomes soluble in potash, after being treated with chlorine.—(3) The *cellulosic substance*, which, when pure, dissolves without coloration in strong sulphuric acid, producing a liquid which is not precipitated by water; it is attacked with difficulty by chlorine-water and nitric acid.

Quantitative Analysis.—**A.** To determine the *cellulosic substance*, 1 grm. of sawdust dried at 130° is placed for 36 hours in a vessel filled with chlorine-water, which dissolves the ligneous cuticle and part of the incrusting matter, leaving the cellulosic substance mixed with another part of the incrusting matter, which is converted by the chlorine into an acid soluble in potash. Hence by treating the residue with an alkaline solution, washing it with acid, then with water, and drying at 130°, the cellulosic substance is obtained quite pure. In this manner it is found that oak-wood contains 40 p. c. and ash-wood 39 p. c. of cellulosic substance.—**B.** To determine the *ligneous cuticle*, 1 grm. of sawdust is treated for 36 hours with sulphuric acid of strength corresponding to the formula $\text{SO}^2\text{H}^2.3\text{H}^2\text{O}$ (or in some cases to $\text{SO}^2\text{H}^2.\text{H}^2\text{O}$), which completely dissolves the cellulosic and incrusting substances, while the cuticle remains suspended in the liquid. The residue is washed with pure water, and with alkaline water, and dried. Oak-wood is thus found to contain 40 p. c. of ligneous cuticle, ash-wood only 17 p. c.—**C.** The *incrusting matter* is estimated by difference, and further decomposed as above described.

The total result in the case of oak-wood is as follows:

Ligneous cuticle . . .	20		
Cellulosic substance . . .	40		
Incrusting matter . . .	40	{	
			Matter soluble in water. . . 10
			Body soluble in alkalis . . . 15
			Body transformed into an acid by moist chlorine . . . 15

ANALYSIS, VOLUMETRIC. *Acidimetry and Alkalimetry.*—For the volumetric analysis of acids, Grandeaue (*J. Pharm.* [3] xxxiv. 209) recommends the use of pure calcium carbonate in such a manner as to obviate the necessity of preparing a normal solution of potash or soda. A known volume (about 100 c.c.) of the acid to be tested is diluted to a litre; 2.5 grms. of pure dry calcium carbonate are introduced into a wide-necked flask; dilute acid is added by separate portions of

10 c.c. till the calcium carbonate is quite dissolved; and then a few drops of litmus tincture are added. In another flask, a volume of the same, and equal to that above employed, is also mixed with a few drops of litmus tincture, and the two liquids are saturated with dilute soda or potash-ley, the volumes of the alkaline liquid used for the purpose being noted. The difference of the volumes of the alkaline liquid added in the two cases contains a quantity of alkali equivalent to the calcium carbonate which has saturated a portion of the acid (the volume of which is therefore known), whence also the quantity of acid equivalent to the lime, and the entire quantity of acid, may be calculated.

Mohr (*Lehrbuch der Titrimethode*) recommends the use of *oxalic acid*, $\text{C}^2\text{H}^2\text{O}^4 \cdot 2\text{H}^2\text{O}$, for the preparation of a normal acid solution instead of sulphuric acid, because it is unalterable in the air, being neither deliquescent nor efflorescent; and may be obtained nearly pure in commerce, and completely purified by treating it with a quantity of water insufficient to dissolve it entirely, then filtering, crystallising, and draining the crystals. To prepare the standard solution, take $\frac{12}{1000} = 63$ grms. or 1 equivalent in grams of the crystallised acid; place it in a gauged litre bottle filled two-thirds with distilled water, giving the vessel a rotatory movement to facilitate the dissolution; and fill it up to the gauge-mark with distilled water. If the temperature of the air is 15° , each cubic centimetre will contain 0.063 grms. or $\frac{1}{10000}$ of an equivalent of the crystallised acid.

Pincus (*J. pr. Chem.* lxxvi. 171) recommends normal *nitric acid* titrated by means of calcium carbonate, nearly in the manner described by Grandeaun. Pure dilute nitric acid and potash-ley (free from carbonic acid) are prepared of such strengths that equal volumes of the two saturate one another completely. A weighed quantity (about 1 grm.) of coarsely pulverised Iceland spar is then dissolved at a gentle heat in a measured quantity (in excess) of the acid (which has been made of equal value with the potash), and the excess of acid is then determined by titrating back again with the potash-ley. This gives the volume of acid equivalent to the dissolved limo, and thence it is easy to calculate how much water must be added to the original acid, as also to the potash-ley, in order that 1 cubic centimetre of it may correspond to $\frac{1}{10000}$ of an equivalent of any other acid or base. When the nitric acid has once been thus correctly titrated, and the potash-solution accordingly, it is easy, by means of the latter, to titrate sulphuric, oxalic, or any other acid with perfect accuracy.

Langer and Wawnikiowicz (*Ann. Ch. Pharm.* cxvii. 236) have tested a process, suggested by Bunsen, for applying the standard solutions commonly used for the titration of free acids and alkalis, to the estimation of all acids when in combination with bases which are separable completely and without contamination by caustic or carbonated alkalis. If the salt which is to be examined for its amount of acid be mixed with an excess of titrated alkali-solution till the base is completely precipitated, and the amount of alkali in the liquid filtered from the precipitate be then determined, the quantity of acid which was united with the base in the salt under examination may thence be found. A weighed quantity of the salt is dissolved in water, mixed with the titrated alkali, till a strong alkaline reaction is produced, and, after stirring, a definite volume is filtered off from the known total volume, and the filtrate is titrated for its amount of free alkali. At a proper degree of dilution, the uncertainty arising from the circumstance that the liquids do not occupy exactly the same volume before and after mixture falls within the limits of the other errors of observation. Experiments with various pure nitrates and sulphates gave very exact results. With some salts it was found necessary to heat the alkaline liquid; in the case of bismuth nitrate, exact results are obtained only when sodium carbonate is used, and the liquid supersaturated therewith is boiled for half an hour.

Wolcott Gibbs (*Sill. Am. J.* [2] xlv. 207) has generalised the method proposed by H. Rose for the estimation of nitric acid in certain nitrates, which consists in precipitating the metal by hydrogen sulphide and titrating the acid thus set free. All salts containing non-volatile acids and metals easily precipitable by hydrogen sulphide may be analysed in the same manner. The precipitation should be made at boiling heat, and when it is complete, the precipitate is washed on a filter, and a determinate quantity of the filtrate is titrated by means of a normal alkaline solution.

Titration of Compound Ethers.—Berthelot and Péan de St. Gilles (*Instist.* 1862, p. 110) test the purity of compound ethers by heating them in sealed tubes for 24 hours with a known volume (in excess) of standard baryta-water. The quantity of acid in the ether is then determined by titration of the excess of baryta with standard sulphuric acid.

Wanklyn (*Chem. Soc. J.* [2] v. 170) decomposes compound ethers with a standard solution of alcoholic potash, containing about 6 per cent. potassium hydrate, prepared by dissolving potash in pure alcohol of about 85 per cent. The digestion of the

ether with the alcoholic potash is performed in a long-necked flask, and is for the most part accomplished with great ease and rapidity. The complete disappearance of the smell of the compound ether is in many cases a good criterion of the completion of the reaction. The quantity of acid in the ether is then determined as in Berthelot's method, by titrating the residual potash with standard sulphuric acid. This method gives very exact results, as the following experiments will show:

		100 pts. neutralise of potassium :	
		Exp.	Theory.
Ethyl Benzoate	. . .	25.77	25.78
Ethyl Butyrate	. . .	34.10	33.98
Ethyl Valerate	. . .	30.15	30.77
	$C(C^2H^5)^2OH$		
Ethyl Diethoxalate	$\begin{cases} COOC^2H^5 \\ COOC^2H^5 \end{cases}$	24.20	—
			24.44

Titration of Alkaloids.—F. F. Mayer (*Rép. Chim. app.* v. 102) describes a process for the volumetric estimation of organic bases founded on their precipitability by potassio-mercuric iodide. The standard solution contains in the litre 13.546 grms. ($\frac{1}{10}$ eq.) mercuric chloride and 49.8 grms. potassium iodide; it is to be added to the solution to be tested (not the reverse), and yields distinct precipitates with various bases to the degrees of dilution shown in the following table:

Morphine . . .	2,500	Narcotino . . .	} 50,000	Quinine . . .	125,000
Atropino . . .	7,000	Brucino . . .		Strychnine .	150,000
Conine . . .	800	Quinidino . . .			
Nicotino . . .	25,000	Cinchonino . . .	75,000		

The formation of the precipitates is hindered by the presence of alcohol, ammonin, or acetic acid, but not by extractive matters. For greater accuracy, the excess of the precipitant added should be determined by a normal silver solution.

Volumetric Analysis depending on Absorption of Oxygen.—Mittenzwey (*J. pr. Chem.* xci. 81) describes a process for the volumetric estimation of tannic acid, gallic acid, iron, manganese, and other substances, depending on the measurement of the quantity of oxygen absorbed by these substances in presence of alkalis. The vessel used for the purpose is a half-litre bottle, having a stopper of cork or caoutchouc, through which passes a glass tube bent towards the inner surface of the bottle. With this tube is connected, by a caoutchouc tube which can be closed by a spring clamp, a second glass tube, bent in the same direction as the first, and somewhat narrowed towards the end. In performing an analysis, the bottle, filled with 160 to 200 c.c. of the alkaline liquid and with renewed air, is shaken for a minute or two—avoiding all change of temperature—and the point of the outer tube is then immersed in water (contained in a beaker glass and standing at the same level as the liquid in the bottle), till on opening the spring clamp, no more water passes over into the bottle. The weight of water which thus passes over gives, with due regard to pressure and temperature, the volume of oxygen absorbed: 1 grm. of tannic acid or 0.7 grm. of gallic acid dissolved in 200 c.c. of 3 to 5 per cent. potash-ley (or of 2 to 3 per cent. soda-ley) absorbs 175 c.c. oxygen; with more concentrated solutions the absorption is less complete. Gallic acid absorbs oxygen much more rapidly than tannic acid. Iron and manganese compounds (for which latter, however, the particular oxide formed has not been determined) are introduced into the vessel in the forms of dissolved ferrous or manganous salt, together with a little solid caustic potash.

Volumetric Analysis without Weighing.—The problem proposed by Mohr (*Ann. Ch. Pharm.* cxvi. 128), 'To carry out analytical weight-determination, without the use of weights, with solutions of unknown strength, and the strength of which is moreover not to be determined,' has been solved by Pauli, Hillier, and Dietrich (*ibid.* cxvii. 386; *Jahresb.* 1860, p. 612). The general principle of the solution is as follows:

Equal quantities of the pure and impure substance to be titrated are weighed out, and measured volumetrically with the same liquid, any given number of cubic centimetres of which will of course give 100 per cent. for the pure substance, and a proportionally smaller quantity for the impure substance. The pure substance may also be replaced by another of similar chemical activity (e.g. manganese dioxide by potassium dichromate or iodine, sodium carbonate by calcium carbonate, &c.). It then only remains to compare by calculation the (known) quantitative difference of action exerted by the two substances to be titrated on the measuring liquid.

ANAMESITE. A variety of dolerite occurring at Steinheim, near Hanau, intermediate in character between crystalline dolerite and compact basalt. For analyses see *Jahresb.* 1865, p. 921; 1866, p. 973.

ANAMIDES. This name is applied by Baeyer (*Ann. Ch. Pharm. Suppl.* v. 79) to compounds derived from amides by abstraction of ammonia, just as anhydrides are formed from acids by abstraction of water; thus:

ANATASE. This form of titanic oxide has been found to occur in an oolitic iron ore from the coal-beds of Cleveland (Wöhler, *Jahresb.* 1867, p. 980).

ANCHETINE. A substance obtained from the root-bark of *Ancheta salutaris*, and supposed to be the medicinal principle of that bark. It is extracted by leaving the crushed bark in contact with the air till it is completely fermented, then exhausting with hydrochloric acid, and precipitating with ammonia from the filtered solution. It crystallises in straw-yellow needles without odour, having a nauseous taste, insoluble in ether and in cold water, slightly soluble in boiling water, easily in alcohol, forming a slightly alkaline liquid. Dilute acids neutralise it, forming salts, some of which are crystallisable (Pockolt, *Arch. Pharm.* [2] xcvii. 271).

ANDESIN. This mineral is found accompanying the emeries of Chester County, Pennsylvania. Structure fine-grained. Fracture conchoidal. Hardness = 7.5. Sp. gr. = 2.586. Colour, greenish-white. Contains 62.00 p. c. SiO_2 , 24.40 Al_2O_3 , 3.50 CaO, 0.70 MgO, 8.07 Na $_2$ O, and 1.00 water (= 99.67) (F. Jackson, *Sill. Am. J.* [2] xlii. 107; *Bull. Soc. Chim.* [2] viii. 420).

ANDROPOGON. A genus of grasses, the leaves of which yield several fragrant volatile oils. Citronella oil, from the leaves of *A. Schenanthus*, consists almost wholly of an oxygenated oil boiling at 200°, and having a sp. gr. of 0.8741 at 20°. Lemon-grass oil, from *A. Nardus*, has very nearly the same properties. Indian geranium oil (probably identical with East Indian grass oil, from *A. Iwarancusa*, ii. 942) contains several bodies scarcely separable by distillation. Respecting the optical properties of these oils, see OILS, VOLATILE, iv. 186.

ANEMONIN and **ANEMONIC ACID** are produced, according to O. L. Erdmann (*Jahresb.* 1858, p. 512), from the acid liquid obtained by distillation of *Ranunculus scleratus*. S. Dobraschinsky (*Jr. Pharm.* [4] i. 310) prepares anemonin by distilling the fresh flowering herb of *Anemone pratensis* with water, agitating the distillate with $\frac{1}{10}$ th pt. of chloroform, and dissolving the residue of the chloroform extract in hot alcohol; the anemonin then separates in crystals.

ANETHOIN. See the next article.

ANETHOL or **ANISE-CAMPHOR.** $C^{10}H^{12}O$.—Kraut and Schlun (*Zeitschr. Ch. Pharm.* 1863, p. 359; *Jahresb.* 1863, p. 551) have examined the liquid and solid modifications of anethol from oil of anise and oil of fennel, and have found that this body is optically inactive in both modifications, from whichever source it may be obtained; further, that anise and fennel oils are mixtures of liquid and solid anethol in various proportions, but that fennel oil likewise contains a hydrocarbon, $C^{10}H^{14}$, which turns the plane of polarisation to the right; anise-oil, which does not contain this hydrocarbon, is optically inactive. Solid anethol melts at 21.1°, boils at 232°, and has a sp. gr. of 0.989 at 28°. Anisoïn (i. 298), better called anethoin, may be obtained by the action of stannic chloride or of strong sulphuric acid, either on solid or on liquid anethol, also from metanethol (most conveniently by distilling anise-oil with strong sulphuric acid). Anisoïn is resolved by dry distillation into liquid metanethol, which passes over, and a solid modification, *isanethol*, which remains behind.

Metanethol boils at 232.5°, has a sp. gr. of 0.9708 at 18°, may be converted, as above mentioned, into anethoin, and by heating for several hours to 320°, partially into isanethol.

Isanethol is a light-yellow, viscid mass, resembling Venice turpentine; it does not alter at 380°, dissolves easily in ether, less easily in alcohol, and in contact with oil of vitriol is converted into anethoin.

Anethol heated with 2 pts. of strong hydriodic acid in a flask with upright condensing tube, gives off methyl-iodide amounting to about 50 p. c. of the anethol used. Hence it is probable that anethol is the methylic ether of an allyl-phenol, and that its rational formula is $C^8H^4 \begin{cases} OCH^3 \\ C^2H^2 \end{cases}$ (Ladenburg a. Leverkus, *Ann. Ch. Pharm.* cxli. 260). This phenol, C^8H^4O , has lately been obtained by Ladenburg by prolonged heating of purified anise-oil with potassium hydrate. (See AXOL.)

When oil of anise, or the compound $C^{10}H^{10}O.HCl$, formed by direct addition of hydrochloric acid to anethol (i. 298), is treated with sodium amalgam, and the product is subjected to fractional distillation, a liquid is obtained which boils between 220° and 224° , and is intermediate in composition between anethol and the compound $C^{10}H^{10}O$, containing 2 at. hydrogen more (Ladenburg, *Deut. Chem. Gesellsch.* 1869, p. 371; *Zeitschr. f. Chem.* [2] v. 576).

Anethol Bromide, $C^{10}H^{12}Br_2O$, is produced by adding bromine to anethol dissolved in ether, and remains, on evaporating the ether, as a crystalline very deliquescent mass, which gives off hydrobromic acid. By recrystallisation it is obtained in needles melting at about 15° (Ladenburg, *loc. cit.*).

Compound of Anethol with Quinine, $C^{10}H^{12}O.2C^{20}H^{24}N_2O_2.2H_2O$.—Crystallises from a hot alcoholic solution of 5 pts. quinine and 1 pt. anise-oil, and may be rendered colourless by recrystallisation, with addition of animal charcoal. The dry compound, which scarcely smells of anise-oil, gives off the whole of its water and alcohol at 100° – 110° without fusion; it is decomposed by hydrochloric acid, but not by cold water; crystallises from ether in monoclinic prisms and tables, from alcohol mostly in acute four-sided double pyramids, having all their summits truncated (O. Hesse, *Ann. Ch. Pharm.* cxxiii. 382).

Chloranethol, $C^{10}H^{11}ClO$, is produced by leaving anethol in contact for some hours with phosphorus pentachloride, and treating the resulting granular mass with water (Kraut a. Schlun, *loc. cit.*); also by the action of the pentachloride on oil of anise (Ladenburg). It is a somewhat yellowish liquid, which solidifies at low temperatures, melts at -6° , and boils at 257° , giving off a small quantity of hydrochloric acid. Sp. gr. 1.154 at 0° . Heated with potash it gives off HCl , and is converted into a liquid, $C^{10}H^{10}O$, which, however, is difficult to obtain quite free from chlorine. This liquid has an unpleasant odour, is insoluble in water, boils at 240° – 242° , and gives no precipitate with an ammoniacal solution of silver or copper. Chloranethol is not attacked by potassium acetate even at high temperatures, but when heated to 250° with silver acetate, it yields a distillate partly consisting of anisic acid (Ladenburg, *Zeitschr. f. Chem.* [2] v. 575).

ANGELIC ACID. $C^8H^8O^2 = \begin{matrix} CH(C^8H^7) \\ | \\ COOH \end{matrix}$ (p. 41).—This acid occurs as a

glyceride in croton oil, and may be obtained from that oil, together with crotonic acid, by saponification (ii. 112). It is produced, together with an alcoholic substance called laserol, by heating laserpitin (v. 1091) with strong potash-ley, especially in presence of alcohol:

The angelic acid may be distilled off from the acidulated product with water (Feldmann, *Ann. Ch. Pharm.* cxxv. 236).

Angelic acid heated to 180° – 200° for eight hours with hydriodic acid and red phosphorus is completely converted into valeric acid (Ascher, *Zeitschr. f. Chem.* [2] vi. 217).

Bromangelic Acid, $C^8H^6Br_2O^2$ (Jaffé, *Ann. Ch. Pharm.* cxxv. 291).—This acid is formed on gradually mixing 1 pt. of angelic acid, well cooled under water, with 2 pts. of bromine, as a viscid mass which crystallises after a while, and may be purified by conversion into a potassium salt and separation with hydrochloric acid. It then forms a white crystalline mass, which melts with partial decomposition at 76° , and dissolves sparingly in water, easily in alcohol and ether. It is inodorous, has an acid taste and reaction, decomposes carbonates, and forms with the alkalis and alkaline earths easily soluble salts, with the heavy metallic oxides easily decomposable precipitates. The *potassium-salt*, $C^8H^5KBrO^2$, forms sweet-tasting crystalline laminae, and decomposes in aqueous solution even at ordinary temperatures, more quickly at the boiling heat. The *lead and silver salts* form white precipitates which decompose readily, with formation of metallic bromide. The *ethylic ether*, $C^8H^6(C^2H^5)Br_2O^2$, obtained by distilling an alcoholic solution of the potassium-salt with sulphuric acid, is a yellowish liquid having an odour of peppermint, and decomposing partially at about 185° .

Bromangelic acid is an addition-product, not a substitution-product, and is isomeric with dibromovaleric acid; in fact, angelic acid behaves to bromine just in the same manner as fumaric, maleic, and the pyrocitric acids (p. 48). On the other hand, angelic acid shows little or no tendency to pass into a saturated acid by taking up nascent hydrogen. Its lower isomeride, acrylic acid, $C^3H^4O^2$, is converted by sodium amalgam into propionic acid, $C^3H^6O^2$; but angelic acid when thus treated does not

yield valeric acid; and bromangelic acid treated with sodium amalgam is merely resolved into sodium bromine and angelic acid; when heated with hydriodic acid in sealed tubes, it yields merely traces of valeric acid, recognisable by its odour. Potassium bromangelate heated with water gives off carbon dioxide, and yields a brominated oil, C^4H^7Br , which boils with partial decomposition at 97° :

This oil has a pungent tear-exciting odour, and (like bromangelic acid itself) yields, when treated with excess of potash, a gas, probably quartine or crotonylene, C^4H^8 , which smells like allylene, burns with a bright flame, is absorbed by water and by bromine, and is not precipitated by ammoniacal silver solution. The oil C^4H^7Br is decomposed by silver acetate, yielding silver bromide, and probably also crotyl acetate; it unites with bromine, producing rise of temperature, and forming a viscid non-distillable oil, $C^4H^7Br^2$. Hence the brominated compound C^4H^7Br behaves on the one hand like bromobutylene, and on the other like crotyl bromide, the homologue of allyl bromide (Jaffé).

ANILINE. This name is applied sometimes to pure phenylamine, C^6H^5N or $C^6H^5.H^2.N$, sometimes to the mixture of phenylamine and toluidine, which is obtained by reduction of commercial nitrobenzol, and used for the manufacture of aniline-red. We shall here use it in the latter sense, designating the pure base C^6H^5N , as phenylamine or amidobenzene.

Manufacture of Aniline.—The preparation of aniline by the reducing action of ferrous acetate on nitrobenzol is shortly described at p. 421, vol. iv. The chief alterations that have been made in it consist in the reduction of the proportion of acetic acid, and the application of high pressure or superheated steam for the distillation. The apparatus used consists of a cast-iron cylinder (fig. 8), having a capacity of about 1,000 litres. In the axis of this cylinder there is a hollow shaft or spindle *a*

Fig. 8.

carrying a stirrer *d*, and worked by bevelled wheels, to which motion is given by a steam engine. The shaft *a* is ground to an elbow *b*, connected with the steam-main *c*, and held down by a screw, so that when the steam is turned on, it passes through the hollow elbow down the shaft, and then blows out at the bottom *d* among the products. In this manner the aniline is volatilised and passes with the steam through the neck *e* into a worm not shown in the figure, by which it is condensed.

To start the operation, 10 kilograms of acetic acid of 8° Bm. (sp. gr. 1.060), diluted with six times its weight of water—or rather with the acid liquid obtained in a previous distillation of aniline—are poured into the vessel through an aperture at the top; 30 kilogs. of pulverised cast iron and 125 kilogs. of nitrobenzol are added; and the stirrer is set in motion. The temperature quickly rises, and a brisk reaction takes place, accompanied by disengagement of vapour and the commencement of distillation.

From this time fresh quantities of the finely divided iron are added till the total quantity amounts to 180 kilograms. The stirrer is kept in motion during the whole operation, and should not be stopped till an hour or two after the last additions of iron. The heat produced by the reaction gives rise to a copious distillation of acid water and nitrobenzol, together with traces of benzol. These products collect in a receiver placed below the worm, and are returned to the cylinder from time to time. In some manufactories, the nitrobenzol, instead of being introduced all at once, is made to flow into the cylinder in a continuous fine stream; in this case the whole of the iron is introduced at the commencement of the operation.

At the end of the reaction, the cylinder contains a brown-red mass composed essentially of ferric hydrate, aniline, acetic acid, and unaltered iron. To extract the aniline, the stirrer having been kept in motion for an hour or two longer, and the mass then left at rest for some hours, steam is blown through the shaft, in small quantities at first, till the whole mass is raised to the boiling point. The aniline and other volatile products are then carried forward by the steam, and, passing out by the neck *c*, are condensed by the worm and collected in a receiver below.

Some manufacturers, however, prefer distillation over the open fire. In this case, the cylinder having been left to cool after the termination of the reaction, the brown semifluid mass is removed by the large aperture *b* at the bottom, and distilled without previous neutralisation, either in iron cylinders like gas-retorts, or in small cast-iron alembics. This mode of distillation is said by some authorities to be more economical than that in which steam is used; also to give for the most part a more abundant product, better adapted for the manufacture of rosaniline. Aniline distilled in this manner generally contains acetanilide.

By the processes above described, 125 kilograms of nitrobenzol may be converted into aniline in 12 hours in each cylinder of 1,000 litres.

The crude product of the distillation contains water, acetic acid, acetone, benzol, and aniline. To get rid of the adventitious substances, it is strongly supersaturated with alkali, whereby the water is completely separated, and the oily mixture is decanted and rectified. Acetone then passes over first, then benzol (always a sign of bad preparation), and lastly, from 180° to 230°, the aniline. A second rectification, generally between 180° and 210°, yields it in the state in which it is found in commerce. Some manufacturers mix the aniline before rectification with quicklime, which retains all the acetic acid and the water.

The residues left after the second distillation are called 'queues d'aniline;' they have been examined by Hofmann, who has obtained from them the bases paraniline, tolylene-diamine, and xenylamine or martylamine (iv. 352; v. 872, 1054).

ANILINE COLOURS. The manufacture and applications of these colours have received considerable extensions since the account of them in vol. iv. pp. 465-473, was written. We proceed to notice the more important of these extensions.

Aniline Black. Lauth's method of obtaining this colour (iv. 466) has been modified by Camille Koechlin, the alteration consisting in replacing the hydrochloride of aniline by the tartrate, a salt which does not injure even the most delicate tissues, and has also the advantage of not attacking the mordants with which it is mixed for printing. The tartrate of aniline by itself would not be capable of producing aniline black; but in presence of sal-ammoniac, the proportion of which is considerably increased in this modified process, double decomposition, resulting in the formation of aniline hydrochloride, gradually takes place upon the tissue.

The improved process consists in boiling together 10 litres of water, 2 kilograms of starch, 2 kilograms of roasted starch, 2 kilograms of aniline, 1 kilogram of sal-ammoniac, and 1 kilogram of potassium chlorate; then when the mixture has cooled, and immediately before printing, adding 1 kilogram of cupric sulphide and 2 kilograms of tartaric acid. The cupric sulphide may be advantageously prepared by dissolving 1 kilogram of flowers of sulphur without the aid of heat in 4 litres of caustic soda of 38° Bm., and adding this liquid to a solution of 5 kilograms of cupric sulphate in 120 litres of water, the solution being heated to 120°.

Various other processes have been recently published for the preparation of aniline black, but hitherto they have not practically replaced the process with cupric sulphide. Higgin of Manchester recommends the use of the arsenate, tungstate, or oxide of chromium, together with chlorate of potassium and hydrochloride of aniline (*Bull. Soc. Chim.* [2] vii. 93). There is also an aniline black called 'Lucas black,' the composition of which is kept secret; it is sold in the form of a paste containing all the elements necessary for the production of the black, and requiring only to be thickened and printed in order to develop the colour. Dullo (*Illustr. Geverbeet.*, 1866, p. 161) prepares an aniline black in the form of paste, by mixing 100 grms. of light aniline (heavy aniline gives brown instead of black) with 80 grms. of hydrochloric

acid, 10 grms. of manganese dioxide, and 1,000 grms. of water. The precipitate is washed by decantation, and then mixed with ammonia, whereupon its colour changes from green to black, and if the absorption of oxygen from the air be assisted by due agitation, the colour becomes developed throughout the entire mass.

The composition of aniline black is not known, neither is its mode of formation thoroughly understood; but it appears to depend upon oxidation of the aniline by the potassium chlorate and the cupric sulphide, which being successively reduced by the aniline and reoxidised by contact with the air, act as carriers between the oxygen of the air and the aniline. The sal-ammoniac, the presence of which is very useful, if not indispensable, appears to act by dissolving the cuprous compounds as they are formed, and thereby facilitating their reoxidation.

Aniline black is much valued for printing on calico, on account of its brilliancy and permanence. It acquires a greenish hue by long exposure to light and air, but may be brought back to its normal colour by treatment with alkaline solutions. It has not hitherto been successfully applied in practice to the dyeing of silk and wool, but the difficulties which this application of it presents will perhaps be overcome. Lightfoot, the discoverer of aniline black, has shown that it may be fixed on wool if the wool has been previously oxidised with chloride of lime (*Chem. News*, 1866, p. 59); and, still more recently, Jules Persoz has succeeded in dyeing wool with aniline black by mordanting it with a mixture of potassium bichromate and cupric sulphate, and then passing it through a solution of aniline. The difficulty of fixing the black on animal fibres appears to be due to the fact that it is precipitated in flocks too large to penetrate into their pores (*Dictionnaire de Chimie*, i, 326).

Aniline Blue. Of all the blue compounds produced by the reaction of the different reagents upon aniline, the only one that has come into practical use as a dye is the 'bleu de Lyon,' or triphenyl-rozaniline, obtained by heating a salt of rozaniline with aniline (iv. 472). To obtain it of fine quality, it is found necessary to use a salt of rozaniline containing an organic acid. The mixture which is found to answer best consists of 10 kilogs. of crystallised rozaniline acetate, 30 kilogs. of aniline (containing but little toluidine, and therefore boiling at a low temperature), 1.5 kilog. of benzoic acid, and 2.2 litres of caustic soda solution of 38° Bm. (sp. gr. 1.333). This mixture is heated in an enamelled cast-iron pot, which is placed over an oil-bath set in brickwork and closed with a lid, through which passes an escape-tube connected with a condensing worm. The bath is heated for about three hours, the temperature being gradually raised from 180° to 210°. At first the red colour of the mixture changes slowly, but afterwards rapidly; the change is complete when a drop of the mixture spread out on a glass plate with a little hydrochloric acid appears of a pure blue colour without mixture of violet by candle or gas light.

The following process, communicated by M. Bardy to Wurtz's *Dictionnaire de Chimie*, affords the means of preparing at the same time a fine blue and a fine violet dye (*violet impérial*).

Rosaniline hydrochloride is mixed with 30 p. c. of its weight of sodium acetate; the mixture is evaporated to dryness; free aniline is then added, together with a quantity of crystallised potassium acetate equal to 10 p. c. of the rozaniline salt; and the mixture is heated to 175° till the whole assumes a pure blue colour. The product is then removed from the boiler and dissolved, with aid of heat, in one and a half times its weight of strong hydrochloric acid. The blue compound, insoluble under these circumstances, floats on the surface; it is collected, washed with water, and treated with five times its weight of caustic soda at 32°; and the mixture, after boiling for twenty minutes, is diluted with 15 parts of boiling water and filtered. The base thus obtained is purified from traces of mono- and diphenyl-rozaniline by washing with tepid alcohol, then dissolved in its own weight of sulphuric acid diluted with 10 pts. of water; the liquid is boiled for ten minutes and filtered; and the blue deposit left on the filter is washed.

The hydrochloric acid solution is diluted with a quantity of water equal to 1.5 p. of the weight of the crude blue, whereby a precipitate is formed consisting of diphenyl-rozaniline; then again with 23 pts. of water, which throws down mono-phenyl-rozaniline. The mother-liquors of this second precipitate, saturated with lime and mixed with acetate and chloride of sodium, yield a considerable quantity of very pure hydrochloride of rozaniline.

Aniline blue is insoluble in water, and this circumstance forms a great drawback to its use, inasmuch as when employed for dyeing, it is thrown out of solution in the dye-bath, and then mechanically adheres to the goods, so that it afterwards rubs off. It may indeed be kept in solution by the use of large quantities of alcohol, but this treatment greatly adds to its cost.

Mr. Nicholson has, however, discovered an economical method of rendering this blue perfectly soluble in water, namely by the use of strong sulphuric acid, with which it appears to form a sulphoconjugated acid, analogous to sulphindigotic acid. The blue is first boiled with dilute sulphuric acid, to remove all substances soluble therein, and the residue, after thorough drying, is treated with strong sulphuric acid of 86° Bm. (sp. gr. 1.842), which dissolves it. The solution is heated to 150° for half an hour, then diluted with 4 volumes of water and filtered. That which remains on the filter is the blue in its soluble modification, but rendered insoluble for the time by the presence of the sulphuric acid. It is washed several times with water, cautiously when the acidity of the water becomes considerably reduced, as the modified blue, though insoluble in the dilute acid, is easily soluble in pure water.

An improvement on the mode of preparing the soluble blue has been made by Max Vogel (*Bull. Soc. Chim.* 1866, ii. 253), who heats 1 pt. of the insoluble blue to 130° for six hours with 8 pts. of fuming sulphuric acid. Leonhardt obtains a peculiar modification of aniline blue by dissolving it in alcohol and precipitating with water. The product thus formed easily diffuses through water, and remains suspended in a state of very minute division which greatly facilitates the dyeing. It is in fact identical in every respect with that which is produced by the dyer himself in the boiler, but its preparation in a chemical manufactory affords the means of recovering the alcohol, which would otherwise be completely lost. A similar result is obtained by dissolving ordinary aniline blue, without the aid of heat, in strong sulphuric acid and precipitating with water. Under these circumstances no sulpho-acid is formed, but merely a solution analogous to that of alizarin in sulphuric acid (Monnet & Drury, *Dictionnaire de Chimie*, i. 323).

Soluble aniline blue is much used for silk-dyeing, but it is thought not to be so fast as the normal compound. A modification of it, known commercially as 'Nicholson's blue,' is now very extensively used in Great Britain for wool-dyeing, but its application does not appear to be understood in France and Germany.

Another soluble aniline blue, called 'bleu de Paris,' was discovered by Persoz de Luynes and Salvétat. It is prepared by heating aniline with stannic chloride to 180° for thirty hours. It is generally described as probably identical with the 'bleu de Lyon,' but is in reality quite different, being easily soluble in water, and crystallising freely in blue needles with a copper reflex. It consists of the hydrochloride of an organic base, which is precipitated from its solution by alkalis as a purplish-blue powder. It dyes silk readily and retains its blue colour by artificial light; but it is difficult to prepare in large quantities, and has never been introduced commercially.

Toluidine blue has been already described (iv. 472).

Diphenylamine blue.—The formation of compounds having a fine blue colour, by the action of various reagents on diphenylamine, was first pointed out by Hofmann (iv. 463); but the discovery of a diphenylamine blue adapted for use in dyeing is due to Girard & De Laire (*Bull. Soc. Chim.* [2] vii. 360). They prepare it by heating to about 230°, under pressure or in an open vessel with continual recondensation of the vapour, a mixture of 1 mol. of pure aniline and 1½ mol. of aniline hydrochloride.

The transformation of diphenylamine into a blue dye may be effected by heating 2 pts. of the base with 3 pts. of carbon trichloride to about 160° for several hours. Hydrochloric acid and carbon dichloride are then evolved, and the mass is converted into a bronze-coloured product, which must be washed with benzol and petroleum, and then dissolved in alcohol or wood-spirit; the filtered solutions, precipitated with twice their volume of hydrochloric acid, yield the blue almost pure and amounting to 40 p. a. of the diphenylamine employed. Another process consists in heating diphenylamine to 110°–120° for three to five hours with an equal weight of oxalic acid; but the product thus obtained is not very abundant (Brimmeyr, *Dingl. pol. J.* clxxxv. 49).

Diphenylamine blue yields very pure colours in dyeing. Its composition is probably the same as that of triphenyl-rosaniline:

It can be produced only with a mixture of diphenylamine and ditolylamine. Pure diphenylamine similarly treated yields a blackish blue, ditolylamine a maroon-brown, and phenyl-toluidine a bluish-violet.

Another very important of these colouring matters, specially known as aldehyde green, was discovered in a remarkable manner. Towards the year 1861 Leuch obtained a blue colour by the action of aldehyde on a substance which he called 'aniline acid.' This product had a magnificent

blue colour, but was found to be utterly unstable, and therefore useless as a dye. It was however experimented upon by Chérpin, a chemist in the dye-works of M. Usèbe, near St. Ouen; and he, finding himself unable to fix it, mentioned his difficulties to a photographic friend, who recommended him to try hyposulphite of sodium, as that salt was always used for 'fixing' photographs! Chérpin followed this counsel, but instead of fixing his blue, he found that it was changed into a splendid green dye, now known as 'aldehyde green.'

To prepare this colouring matter, about $1\frac{1}{2}$ pt. of aldehyde is gradually added to a cold solution of magenta, prepared by dissolving 1 pt. of the latter in 3 pts. of strong sulphuric acid and 1 pt. of water. The mixture is then heated in a water-bath till a drop of the product diffused in water produces a fine blue coloration, and then poured into a large quantity of boiling water containing three or four times as much sodium hyposulphite as the magenta employed. After boiling for a short time, the liquid is filtered off from a greyish insoluble residue which forms. The filtrate contains the green. This process being a very simple one, many dyers now prepare the green colouring matter as they require it. It may, however, be precipitated by means of tannin or sodium acetate, collected on filters, and drained to a paste, or, if necessary, dried. It is found in the market in both these forms. Hirzel (*Deutsche Industrie Zeitung*, 1864, No. 31, p. 307) prepares this colour by treating a solution of the aldehyde blue with ammonium sulphhydrate instead of the hyposulphite, heating the mixture till it turns green, then filtering and treating the green solution as above.

The composition of aldehyde green is not exactly known; but, according to Lauth, it contains sulphur as an essential constituent, and is produced whenever a solution of aldehyde blue is brought in contact with nascent sulphur. This view is in accordance with results recently obtained by Hofmann. According to E. Lucius, on the contrary, the aldehyde green exists ready formed in an acid solution of a rosaniline salt mixed with aldehyde; and the sodium hyposulphite acts merely by removing the blue or violet substances which are always formed at the same time; the same separating action is indeed exerted, not only by hydrogen sulphide and sulphurous acid, but by animal charcoal, silica, flowers of sulphur, &c. (*Patents*, 1864, Nos. 200 and 301).

Aldehyde green is undoubtedly the salt of an organic base, and this base may be separated from it by decomposing an aqueous or alcoholic solution with soda or ammonia, most readily by operating on the product precipitated with sodium acetate. The base is of a pale green colour, like chromic hydrate; it is slightly soluble in alcohol, and the solution is completely altered by boiling. It dissolves in acids, forming bright green but very unstable salts, and is changed to the normal colour of aldehyde green by absorbing carbonic acid from the air.

Aniline green is principally employed in silk dyeing. It is a splendid colour, and very brilliant both by day and by artificial light.

2. *Green produced by the ethylation or methylation of Rosaniline or of Methylaniline violet.*—This green, known commercially as 'iodine green,' appears to have been discovered by several chemists at nearly the same time. Its preparation, which has been described successively by Tillemans of Crefeld, by Lucius (*Jahresb.* 1864, p. 818), by Poirrier & Chappat (*Bull. Soc. Chim.* [2] vi. 504), and by Wanklyn & Paraf (*ibid.* vii. 269), consists in subjecting the violets of triethyl- or trimethyl-rosaniline (Hofmann's violet), or the violets of methylaniline to the action of an excess of alcoholic iodide. The process given by the last-mentioned chemists is as follows: A mixture of equal parts of rosaniline, methyl alcohol, and an alcoholic iodide is heated for three hours to 110° ; and the product of the reaction is washed with sodium carbonate, which dissolves a small quantity of green colouring matter, leaving the greater part of the product in the form of an insoluble salt, which is in fact Hofmann's violet. This latter is decomposed by a caustic alkali, so as to set the base at liberty; and this base, after being dried and pulverised, is again subjected to the action of the alcoholic iodide; a third operation carried out in the same manner converting nearly all the violet into green. The product, being soluble in water rendered slightly alkaline with sodium carbonate, may thus be easily separated from the foreign matters which accompany it, as well as from the violet salt which remains unaltered.

The green thus obtained with methyl iodide has a very fine colour, and, like the aldehyde green, preserves its character by artificial light. It is much used for cotton and silk dyeing; its colour is bluer than that of aldehyde green, and it is therefore more useful, as it yields with picric acid a greater variety of green shades.

Important observations on the manufacture and constitution of 'iodine green' have lately been published by Hofmann & Girard (*Deut. Chem. Gesellsch. Ber.* 1865, p. 440; *Zeitschr. f. Chem.* [2] 7, 652). The following proportions gave a satisfactory result: 1 pt. rosaniline acetate, 2 pts. methyl iodide, and 2 pts. methyl alcohol. The methyl iodide might be replaced by bromide (13 pt.), but in the manufacturing

process the iodide is preferred.* The reaction takes place in large closed boilers (autoclaves) of enamelled wrought or cast iron, capable of sustaining a pressure of 25 atmospheres, and surrounded by jackets in which a stream of boiling water circulates for eight or ten hours. The operation is then completed and the boiler is left to cool. It then contains a mixture of violet and green colouring matter dissolved in methyl alcohol, together with considerable quantities of methyl acetate and methyl oxide, which latter escapes with violence on opening the boiler. The volatile products having been removed by distillation, the residual pasty mass of colouring matters is poured into a large quantity of boiling water, whereby the green is completely dissolved, while the violet remains undissolved, with the exception of a small quantity held in solution by the acid set free during the reaction. The insoluble violet is separated by filtration, and the small quantity dissolved is precipitated by addition of common salt, after the free acid has been neutralised by sodium carbonate. To hit the exact point of saturation in the deep-coloured liquid, a sample is filtered from time to time, and, instead of litmus-paper, a thin skein of silk is introduced into the filtered liquid: as soon as the silk acquires a pure green colour without any admixture of violet, the addition of sodium carbonate may be discontinued, the precipitation of the violet colour being then complete. The liquid when quite cold is finally passed through a sand filter to remove the precipitated violet; and the green is precipitated by a cold-saturated solution of picric acid. The picrate of iodine green thus obtained, being but slightly soluble in water, is rapidly washed therewith, and, after evaporation, sold to the dyers in the form of paste. The violet colouring matters obtained in the preceding process in the form of iodides are converted into the corresponding bases by means of sodium hydrate, and from these bases further quantities of iodine green may be obtained by treatment with methyl iodide.

To obtain crystallised iodine green, the coloured product of the reaction is poured into a quantity of water, much smaller than that used in the process above described, and after addition of common salt, the liquid is mixed with a larger quantity of sodium carbonate, in order to ensure the complete precipitation of the violet. The filtrate on cooling deposits a considerable quantity of iodine green in crystals, which may be washed once or twice with cold water to remove adhering common salt, and then dried at the temperature of the air. To obtain the compound quite pure and in a state fit for analysis, the crystals are dissolved in warm absolute alcohol, and the filtered solution is poured into a large excess of absolutely anhydrous ether, whereby a shining crystalline precipitate is formed, which is washed on a filter with cold ether, and, after evaporation of the ether, dried over sulphuric acid. Lastly, the crystalline precipitate is dissolved in warm alcohol, which on cooling deposits chemically pure iodine green in splendid prisms, having the peculiar metallic lustre of the wing-cases of cantharides. When dried over sulphuric acid they consist of

If left in a vacuum for forty-eight hours they give off 1 mol. water, and if left still longer, the compound undergoes further decomposition.

The corresponding chloride, obtained by decomposing the iodide with silver chloride, dries up to a green transparent brittle vitreous mass. The solution yields with platonic chloride a brown amorphous precipitate consisting of the *platinochloride*:

The *picrate*, $\text{C}^{\text{H}}_3\text{H}^{10}(\text{CH}^3)_3\text{N}^3 \left\{ \begin{array}{l} (\text{CH}^3)_2\text{C}^{\text{H}}\text{I}^2(\text{NO}^2)_2\text{O} \\ (\text{CH}^3)_2\text{C}^{\text{H}}\text{I}^2(\text{NO}^2)_2\text{O} \end{array} \right.$ separates on adding picric acid to the aqueous solution of the iodide, as a dark green precipitate, which, by recrystallisation from boiling alcohol, yields the salt in well-defined prisms, yellowish by transmitted light, and shining like etched copper in reflected light.

The *nitrate* crystallises in slender needles, the *nitrate* in prisms. These salts are

* Considering the comparatively small equivalent of bromine, and the low price at which it may now be obtained from the Stassfurt salt-works, it is remarkable that so few attempts should hitherto have been made to substitute it for iodine in manufacturing processes. So far as the preparation of aniline colours is concerned, the chief difficulty in the use of the bromides of methyl and ethyl arises from their low boiling points (13° and 14°), in consequence of which large quantities of the compounds are lost. This difficulty may, however, be surmounted by using, instead of these bromides, a mixture of methyl or ethyl alcohol with amyl bromide, a compound easily and readily prepared, and boiling at 130° . In the first stage of the reaction which then takes place, amyl alcohol, together with methyl or ethyl bromide, thus

and the bromide of methyl or ethyl thus obtained brings about the methylation or ethylation of the aniline base, as well as the bromination (Hofmann & Gieseler).

obtained by treating the free base with acetic and nitric acid. A compound of the iodide with zinc iodide, obtained by precipitating the iodide with acetate or sulphate of zinc, crystallises from hot water in prisms not altered at 100°. A solution of tannin precipitates a compound which has not been analysed.

Transformations of iodine green.—The green crystals of the iodide, as already observed, undergo a gradual change when left in a vacuum. If crystals which have been thus left for some months are drenched with water, they partly dissolve, forming a green solution, and if this be poured off, the remaining crystals dissolve in alcohol with a fine violet colour. This transformation into a violet compound takes place in a few hours at the temperature of boiling water, and instantly at 130°–150°; thus the green iodide dissolves with splendid violet colour in boiling aniline. The violet compound consists of methyl iodide of trimethyl-rosaniline, and is formed from the hydrated dimethyl iodide by loss of water and methyl iodide:

The formation of the violet colouring matter from the green iodide likewise takes place when a solution of the latter in methyl alcohol enclosed in a sealed tube is heated for two or three hours in the water-bath. The liquid then assumes a deep violet-blue colour, and deposits long cantharides-green needles of the compound

which are but sparingly soluble in alcohol even at the boiling heat. These are best recrystallised from methylic alcohol, in which they are somewhat more soluble. The same compound is occasionally formed in the action of methyl iodide on trimethyl-rosaniline. Together with these sparingly soluble crystals, whose solution is violet with a decided tinge of blue, there is also formed another blue-violet salt, but less decidedly inclining to blue. This salt is extremely soluble in alcohol, but may be crystallised by slow evaporation of the alcoholic solution. It is identical with the violet salt above mentioned as obtained by the simple action of heat on the green iodide, namely $\text{C}^{20}\text{H}^{16}(\text{CH}^3)_3\text{N}^2 \cdot \text{CH}^3\text{I}$.

A molecule of the green iodide heated in methyl-alcoholic solution under pressure undergoes the same transformation as when heated in an open vessel; but the separated molecule of methyl iodide, which would escape into the air if it were not confined, fixes itself upon a second molecule of the green compound, converting it into the sparingly soluble violet compound with 3 mol. methyl iodide.

The green and violet iodides treated with alkalis are converted into the corresponding bases (hydrates), which are colourless. The base corresponding to the iodine green may also be obtained by decomposing a solution of the picrate in ammoniacal alcohol with soda-ley.

If in the preparation of iodine green, either the proportions of the materials, or the temperature, or the time of heating, differ considerably from those above described (p. 162), a colourless product is likewise obtained, which may be separated from the coloured products formed at the same time by means of hot alcohol, in which it is nearly insoluble. On dissolving it in water, evaporating, and recrystallising several times from dilute alcohol, this compound is obtained in prismatic crystals, having the composition of trimethyl iodide of pentamethylated leucaniline: $\text{C}^{20}\text{H}^{16}(\text{CH}^3)_5\text{N}^2 \cdot (\text{CH}^3\text{I})^2 + \text{H}_2\text{O}$. (See LEUCANILINE.)

3. A third kind of green, known commercially as 'Perkin's green,' resembles the iodine green more closely than the aldehyde green, but differs from it in solubility and in being precipitated by sodium carbonate. It contains an organic base, which is nearly colourless, and is by no means a chemically powerful body. Like the iodine green, it is precipitated by picric acid, forming a picrate which crystallises from alcohol in small prisms having a golden reflex.

This colour is now much used, chiefly for calico-printing.

Aniline Maroons and Browns. These colours, like the aniline yellows, possess only a second-rate industrial importance. Girard & De Laire obtain a maroon by melting 4 pts. of aniline hydrochloride, projecting into the fused mass 1 pt. of rosaniline hydrochloride, and heating the mixture to 240°; it then quickly changes from red to maroon. The colouring matter thus obtained is soluble in water, and is precipitated therefrom by alkalis and alkaline salts.

A. Schultz prepares a fine garnet colour by passing a current of nitrous vapours into a solution of soda or ammonia holding rosaniline in suspension. The dye thus obtained produces on wool, silk, and cotton, fine shades varying from puce to garnet.

Horace Koechlin utilises the brown substances noticed by Hofmann in the oxida-

tion of **rosaniline**; he fixes these browns on tissues by printing on wool a mixture of fuchsin, oxalic acid, and potassium chlorate; and on cotton the same, with addition of cupric sulphide. This brown may also be fixed upon cotton by means of albumin. It may be prepared in a state fit for this application by acting on fuchsin with potassium chlorate and hydrochloric acid. The product thus obtained is insoluble in water, soluble in alcohol and in strong sulphuric acid, and is precipitated from these solutions by water (*Moniteur scientifique*, 1866, p. 262).

Jacobson (*Dingl. pol. J.* clxxvii. 405) describes two processes for obtaining aniline brown, viz. (1) Heating 1 pt. of picric acid to 140° with 2 pts. of aniline as long as ammoniacal vapours are disengaged; dissolving the product in dilute hydrochloric acid, and precipitating with caustic soda. (2) Heating a strong solution of ammonium chromate to 100° , together with aniline formate.

Wise heats to 140° a mixture of 1 pt. rosaniline, 1 pt. formic acid, and $\frac{1}{2}$ pt. sodium acetate, and thereby obtains a substance which dissolves in alcohol with a fine scarlet colour. On heating this substance with three times its weight of aniline, it is transformed into a product having a rich brown colour (*Bull. Soc. Chim.* 1866 [2] vi. 431; *Dictionnaire de Chimie*, i. 329).

Aniline Pink, also known commercially as 'safranin,' is a colouring matter much redder than magenta, produced by oxidation of aniline. It was discovered some years ago by Perkin, and is now employed to a limited extent in the arts. It appears to be an organic base composed of $C^{18}H^{15}N^1$. It gives crimson solutions with acids, forms crystallisable salts, and its reactions show that it is closely related to mauveine (Perkin, *Proceedings of the Royal Institution*, 1869).

Aniline Red. Fuchsin, Magenta, &c.—The use of arsenic acid for the preparation of this colour has nearly superseded all others. In the description of this process given in vol. iv. p. 468, it is stated that 12 pts. of the dry acid of commerce are to be heated with 10 pts. of aniline, *with or without addition of water*. Experience has shown, however, that the addition of water is absolutely necessary to the success of the process.

The manufacture of magenta is now conducted in an apparatus similar to that represented in fig. 9. This apparatus consists of a large iron pot, *a*, about 4 ft. in diameter, set in a furnace of brickwork, and provided with a stirrer worked by hand. All the gearing for this stirrer is fixed to the lid, so that stirrer, lid, and all may be

FIG. 9.

lifted away by means of a crane, or other suitable apparatus. There is also a bent tube fixed into the lid, and connected with a condensing worm, *d*, by means of a joint, which can be made or broken at pleasure. In preparing magenta, a quantity of aniline containing about 25 per cent. of toluidine, and a nearly saturated solution of arsenic acid, are introduced into this apparatus, and well mixed by working the stirrer; the proportion of the materials is in about the ratio of 1 of aniline to 1.5 of a 75 per cent. solution of arsenic acid. When these are well mixed, the fire is

lighted. After the product has been heated for some time, water begins to distil over, then aniline and water, and, lastly, nearly pure aniline.

This operation requires some hours for completion, and this is determined by inserting an iron rod from time to time, and drawing out a portion of the product for examination, as well as by the amount of aniline which distils over. When the heating has been completed, a steam-pipe is introduced into the apparatus, and steam blown through the fused mass; by this means an additional quantity of aniline is separated. The lid is then liberated and lifted, with the stirrer, from the apparatus, and the product left to cool before it is removed. A more elaborate and larger apparatus is sometimes used, which possesses considerable advantages over the smaller one. The iron pot is larger, and is provided with an outlet at the side, which is closed during the operation, and the shaft of the stirrer is hollow (as in the aniline apparatus, fig. 8), and worked by steam. When the operation of heating is concluded, steam is blown down the shaft, and, after the addition of water, the product is boiled and run out of the outlet in the side of the pot; by this arrangement it is unnecessary to disconnect the lid of the apparatus, and the product does not require to be removed by mechanical means, as with the apparatus previously described.

The crude product obtained by heating aniline and arsenic acid is next transferred to vats, boiled with water and filtered. Common salt is then added, which precipitates the crude magenta: this is collected and dissolved in boiling water, again filtered, and the solution on cooling deposits the colouring matter in the crystalline state. This, when recrystallised, constitutes commercial magenta (Perkin's *Lectures on Coal-tar Colours*).

The several varieties of commercial aniline red have been shown by Hofmann to be salts of a colourless base, rosaniline, $C^{20}H^{19}N^3$, derived from 1 mol. of phenylamine and 2 mols. of toluidine, by elimination of 3 mols. of hydrogen:

For its rational constitution, Hofmann gives the formula $2\left(\begin{smallmatrix} C^6H^7N \\ H^2 \end{smallmatrix}\right)^N$. Crystal

lised rosaniline is $C^{20}H^{19}N^3.H^2O$.

Rosenstiehl has shown (*Bull. Soc. industr. de Mulhouse*, 1868, p. 931; *Bull. Soc. Chim.* [2] xi. 267) that commercial fuchsine or magenta always contains, in addition to rosaniline, another red colouring matter, isomeric therewith. The formation of this new colouring matter is due to the presence of pseudotoluidine or paratoluidine in commercial aniline, a fact previously demonstrated by Rosenstiehl (*Bull. Soc. Chim.* [2] x. 192). Rosaniline prepared from a mixture of pure aniline and pure normal toluidine, and pararosaniline prepared in like manner from aniline and paratoluidine, resemble each other in tinctorial quality and power, and indeed in all their physical and chemical properties, excepting that pararosaniline, when precipitated by an alkali from a hot solution, remains amorphous, whereas rosaniline under the same circumstances is soon converted into crystalline scales; and that rosaniline when subjected to the reducing action of hydriodic acid yields aniline and toluidine, whereas pararosaniline similarly treated yields aniline and paratoluidine.

Moreover, it appears from recent experiments by Coupier, that red colouring matters, very closely resembling the rosaniline salts, may be prepared without the simultaneous action of aniline and toluidine, in fact, from nearly pure toluidine or xylylidine without the aid of aniline at all; e.g. by heating a mixture of 100 pts. of Coupier's toluidine (which is liquid), 160 pts. of solution of arsenic acid (of 75 p. c.), and 35 pts. hydrochloric acid to 150° – 160° for three or four hours; or 67 pts. crystallised toluidine, 95 pts. nitrotoluene, 65 pts. hydrochloric acid, and 7 pts. of ferrous chloride to 190° for three hours. Xylylidine also yields red colouring matter when subjected to similar treatment.

Toluidine red possesses properties analogous to those of aniline red, but is distinguished from the latter by the bluer tint which it communicates to vegetable or animal fibres; by its more regular transformation into derivatives of other colours, especially green; by its greater depth of colour; and by its much greater solubility in water. It is, moreover, obtained in greater abundance from a given quantity of material, the yield amounting to 40 p. c. of the material employed, whereas that of aniline red seldom exceeds 30 p. c. The addition of aniline to the toluidine actually diminishes the quantity obtained, the diminution being directly proportionate to the quantity of aniline added. Xylylidine red yields in dyeing more violet tints than toluidine red (*Bull. Soc. industr. de Mulhouse, avril et mai 1866*; *Bull. Soc. Chim.* [2] vi. 500; *Moniteur scient.* 1866, p. 599; *Dictionnaire de Chimie*, i. 319).

Coupier has also devised a process for the manufacture of aniline red in which the

use of arsenic acid is avoided. It consists in heating to about 200° a mixture of pure aniline, nitrotoluene, hydrochloric acid, and a small quantity of metallic iron. The product is pasty and quickly solidifies to a friable mass resembling crude fuchsine (*Bull. Soc. Chim.* [2] xi. 269).

Aniline Violets. Of these dyes there are several varieties.

1. **Mauve or Aniline purple**, the first discovered of the aniline dyes. It consists of the sulphate or other salt of mauveine, $C^{10}H^{14}N^4$, a base which in the free state has a violet colour, and forms violet solutions. The rational formula of this base has not been determined; but it differs from rosaniline in not requiring for its formation the presence of toluidine; in fact, Perkin finds that it may be prepared by the oxidation of pure aniline (phenylamine) obtained from indigo. The same result has been obtained by Schützenberger.

Aniline purple is almost always prepared by oxidising aniline with potassium bichromate and sulphuric acid, the process originally given by Perkin. A patent has, however, been taken out by Dale and Caro for obtaining it by treating a salt of aniline with cupric chloride. Another mode of producing it is to heat a solution of aniline in hydrochloric acid with chloride of lime. When aniline hydrochloride is treated with a very dilute solution of chloride of lime, not in excess, a blue compound is produced, called Runge's blue; this indeed is the well-known reaction which gave rise to the name *Kyanol*, formerly applied to aniline. This blue is very unstable, but Perkin has lately succeeded in obtaining it in the solid state by treating a solution of aniline with dilute chloride of lime and adding common salt. The colouring matter is thereby precipitated in an impure state; but by treating it with cold ether or benzol, a large quantity of brown impurities is separated, and the Runge's blue is left in the solid state. It dissolves in alcohol, forming a blue or nearly blue solution, which, however, changes spontaneously into mauve in a day or two, and quickly on boiling. Silk dyed with the blue likewise assumes a mauve colour when steamed.

In France, aniline purple is sometimes manufactured by the action of chloride of lime on a solution of aniline in hydrochloric acid, the crude product being purified in the same manner as that obtained with bichromate. The product thus obtained is said to be more abundant than that yielded by Perkin's process; but the colour is more reddish and is not so highly valued.

2. **Methylaniline Violets.**—These dyes, produced by the oxidation of methylaniline and dimethylaniline, were discovered by C. Lauth (*Rép. Chim. app.* 1861, p. 345), and the methods of preparing them have recently been improved by Poirrier and Chappat (*Bull. Soc. Chim.* [2] vi. 502).

The preparation of methylaniline on the large scale is effected: α . By heating a mixture of aniline hydrochloride (100 pts.) and methyl alcohol (50 to 80 pts.) to 250° or 300° in enamelled iron vessels, for three or four hours. The product, consisting for the most part of methylaniline hydrochloride, is decomposed by an alkali and purified by distillation.— β . By heating to 300° for several hours a mixture of 100 pts. aniline, 50 to 80 pts. methyl alcohol, and 100 pts. sal-ammoniac; the product is methylaniline itself.— γ . By treating aniline with methyl nitrate, either in the cold or at 100° ; in the latter case the reaction is very quick.— δ . By heating aniline with methyl chloride, either in an open vessel or under pressure. The product of either of these reactions is usually a mixture of methylaniline and dimethylaniline, the latter, of course, increasing with the quantity of methyl alcohol employed.

The methylated derivatives of aniline may be transformed into violet or blue-violet compounds, by the action of various reagents, e.g. by stannic chloride, mercuric iodide, iodine chloride, &c. The reaction usually takes place at about 100° , producing colouring matters which incline to blue in proportion as the aniline is more methylated; and in any case a violet once obtained may be rendered bluer by treating it after purification with an alcoholic iodide. The following are some of the processes recommended:—

α . Adding 5 to 6 pts. of stannic chloride by small successive portions to 1 pt. of methylaniline; heating the mixture to 100° till it becomes very thick; treating the product several times with a caustic alkali to remove tin; and purifying the resulting violet by the methods adopted for most aniline colours.— β . The stannic chloride may be replaced by iodine chloride diluted with 5 or 6 times its weight of water, or by a mixture capable of producing it: 100 pts. of methylaniline, for example, being treated with 20 pts. of iodine and 20 pts. of potassium chlorate.— γ . 1 pt. of methylaniline, $1\frac{1}{2}$ pt. mercuric chloride, and 1 pt. potassium chlorate.— δ . 1 pt. of methylaniline, 3 pts. of mercuric iodide, and 1 pt. of potassium chlorate.— ϵ . 1 pt.

of methylaniline, and 3 to 4 pts. of benzene hexchloride, the mixture in this last case being heated to 150°–160°.

The violets obtained by these several reactions are soluble in water, alcohol, and acetic acid. They are fixed upon tissues by methods similar to those adopted for other aniline colours. Nothing is known respecting their composition.

3. *Mauvaniline* and *Violaniline*. These compounds are formed, together with a yellow body, *chrysotoluidine*, in the preparation of *rosaniline* by the oxidation of aniline with arsenic acid. It is well known indeed that the quantity of *rosaniline* obtained by this process does not amount to more than half of that which is indicated by theory, the second half of the aniline being converted into a black matter insoluble in water. These residues were for some time regarded as useless for the purposes of the dyer; but the recent experiments of Paraf (*Bull. Soc. Chim.* [2] vii. 92) have shown that they may be made to yield colouring matters available in dyeing and calico-printing; and these researches have been completed by Girard and De Laire (*ibid.* p. 366), who have obtained from these residues the bases above mentioned.

100 pts. of commercial aniline boiling at 183° to 188° (containing 2 pts. aniline to 1 pt. toluidine) are heated to 170° for five hours with 164 pts. of a solution of arsenic acid of the strength of 70 p. c. The product is exhausted with water, which dissolves arsenate of *rosaniline*, and the residue contains the arsenates of *mauvaniline*, *violaniline*, and *chrysotoluidine*, together with various impurities. The mixture of these salts is decomposed by boiling with caustic soda; and the precipitated bases are treated with dilute hydrochloric acid, which dissolves the *mauvaniline* and *chrysotoluidine*, leaving the *violaniline* undissolved. The hydrochloric acid solution is mixed with common salt, which precipitates hydrochloride of *mauvaniline*, while the *chrysotoluidine* salt remains in solution. The *mauvaniline* is precipitated from the solution of the hydrochloride by the addition of an alkali.

Violaniline, *mauvaniline*, *rosaniline*, and *chrysotoluidine* form a homologous series, as shown by the following formulæ:

Mauvaniline is insoluble in water, soluble in alcohol, ether, and benzol, and forms crystals containing $\text{C}^{19}\text{H}^{17}\text{N}^3 \cdot \text{H}^2\text{O}$. Its salts are soluble in water, forming solutions of a fine reddish-violet tint, which they likewise impart to fabrics in dyeing.

Violaniline exhibits similar properties, but is insoluble in ether and in benzol. Its salts are not of much value for dyeing, as they produce merely dull bluish violet colours.

Mauvaniline treated with aniline yields phenylated derivatives analogous to the phenyl-rosanilines; with the iodides of ethyl and methyl it also forms ethylated and methylated derivatives similar to those obtained in like manner from *rosaniline*.

4. *Violets derived from Rosaniline.*—a. *Violet impérial*. The colouring matters known by this name are produced by heating a *rosaniline* salt with a quantity of aniline less than sufficient to form aniline blue. They were at first regarded as mixtures of aniline blue (triphenyl-*rosaniline*) with magenta, but Hofmann has shown that they are definite compounds, viz. monophenyl-*rosaniline*, $\text{C}^{20}\text{H}^{19}(\text{C}^6\text{H}^5)\text{N}^3$, and diphenyl-*rosaniline*, $\text{C}^{20}\text{H}^{17}(\text{C}^6\text{H}^5)_2\text{N}^3$, the former producing reddish-violet, the latter bluish-violet dyes. A method of obtaining these violet compounds simultaneously with aniline blue has already been described (p. 160).

b. *Hofmann's Violets.*—These compounds, consisting of triethyl- and trimethyl-*rosaniline*, are described in vol. iv. p. 471. They may be rendered soluble in water by liberating the base by means of a boiling solution of soda, and redissolving it in an acid (Duprey, *Bull. Soc. Chim.* [2] vii. 95).

Picrate of triethyl-*rosaniline* yields in dyeing very beautiful green tints (Keisser, *Moniteur scientifique*, 1867, p. 536).

γ. *Violets obtained by substitution of other radicles for the hydrogen of rosaniline.*—By heating 6 pts. of magenta dissolved in 30 pts. of alcohol of 90 p. c. with 4 pts. of brominated oil of turpentine to 150° in a closed vessel for eight hours, Perkin has

obtained a fine violet dye known as the *Britannia violet*. It possesses the golden-green lustre so common to all the aniline colours; is easily fusible, amorphous, and very soluble in water. It is very extensively employed for dyeing and printing, and can be produced of any shade from purple to a blue violet.

Wanklyn, by heating equal parts of rosaniline, alcohol, and isopropyl iodide to 100° in a closed vessel, obtains a violet compound, the base of which may be isolated by boiling with an alkali.

Smith and Sieberg (*Deutsche Industrie-Zeitung*, 1865, p. 488) employ for the same purpose the iodated and brominated derivatives of acetone.

Lastly, there is a dye called *Dahlia impérial*, of a very pure violet colour and soluble in water; but its preparation is kept secret.

Aniline Yellows. These colours have not yet attained any considerable importance in dyeing or printing. Chrysaniline, $C^{12}H^{11}N^3$, is described in vol. iv. p. 473.

Chrysotoluidine, $C^{12}H^{11}N^3.H^2O$.—The formation and preparation of this substance have been described in connection with mauvaniline (p. 168). It may also be obtained by heating crystallised toluidine, or the crude anilines distilling between 195° and 205°, with carbon trichloride. It is separated in the manner already indicated; the process may however be simplified by repeated treatment with zinc and hydrochloric acid, whereby the rosaniline is separated in the form of leucaniline.

Chrysotoluidine treated with alcoholic iodides yields fine roseate shades; with aniline it forms maroon-coloured products.

Diazo-amidobenzene and Amido-diphenylimide, $C^{12}H^{11}N^3$.—These isomeric compounds are both produced by the action of nitrous acid on an alcoholic solution of aniline, the former at ordinary, the latter at higher temperatures:

Diazo-amidobenzene or azodiphenyldiamine is described at p. 460, vol. iv. Amidodiphenylimide is identical with a yellow substance which Schiff obtained (*Compt. rend.* lvi. 1234) by the action of stannate or antimonate of sodium on a salt of aniline. It may be prepared by heating to 100°, 10 pts. of water, 1 part of aniline nitrate, and 3 pts. of sodium stannate, then gradually adding caustic soda. A brisk reaction is thereby set up, and the operation may be regarded as terminated when the liquid assumes a red colour on being mixed with an acid. It is then left to cool, the stannic oxide is removed by means of hydrochloric acid, and the residue is purified by repeated solution in dilute boiling hydrochloric acid and precipitation with ammonia.

Amidodiphenylimide is a yellow crystalline powder. All its solutions when slightly acidulated dye silk and wool of a deep lemon-yellow colour. The picroa dies wool with a colour approaching to cochineal-red. Heated with aniline it yields a blue dye. A very remarkable circumstance connected with these isomeric aniline yellows is that they are volatile and may be removed from tissues by the mere application of heat (Martius & Griess, *Bull. Soc. Chim.* 1866 [2] vi. 168).

Toluidine treated with nitrous acid or with sodium stannate yields a compound homologous with amidodiphenylimide (Martius & Griess).

Jacobsen (*Deutsche Industrie-Zeitung*, 1866, p. 458) produces a yellow colouring matter by mixing 100 pts. of aniline hydrochloride with 400 pts. of water and 40 pts. of mercurous nitrate. After 24 hours, the mass is redissolved in boiling water, which on cooling deposits the product in a state of purity.

Zinaline.—This name is given by Vogel (*J. pr. Chem.* xciv. 453) to a yellow colouring matter which he obtains by the action of nitrous acid on aniline, or on any of the colouring matters derived from it. It is described as a substance having a fine yellow colour, insoluble in water, soluble in alcohol, ether, chloroform, acids, and alkalis. The alkaline solution has a splendid red colour, and on addition of acid deposits the zinaline with its original yellow tint. Zinaline is moderately stable, not being altered by oxidising agents or by sulphurous acid. It melts below 100°, and at a higher temperature gives off thick yellow vapours, then suddenly takes fire with a slight detonation. Vogel assigns to it the formula $C^{12}H^{11}N^3O^2$.

USES OF ANILINE COLOURS.—1. *In Dyeing and Calico-printing.*—The aniline colours are mostly organic bases or salts, and thereby differ essentially from most of the vegetable colouring matters, which are weak acids. Hence considerable difficulty was at first found in their application to dyeing and printing, because they would not combine with the ordinary mordants used for the colouring matter of dye-woods, such as alumina and oxide of tin. These observations refer to the dyeing and printing of

vegetable fibres, and not to silk or wool, as these materials absorb the aniline colours without the intervention of a mordant.

In silk-dyeing the principal difficulty experienced in applying these colours was owing to their great affinity for the fibre, which interferes with the production of an even colour, especially in dyeing light shades. After a time, however, it was found that this obstacle could be overcome by dyeing the silk in a weak soap-lather to which the colour had been added. This not only caused the dyeing to proceed with less rapidity, but also kept the face of the silk in good condition. Silk dyed by this process is left soft, but may afterwards be rendered hard or 'scroop' by rinsing in a bath of slightly acidulated water. This process was first used for dyeing silk with the mauve or aniline purple. It has, however, been since found suitable for nearly all the aniline colours, as magenta, Hofmann and Britannia violets, &c.

The process of *printing* silk with aniline colours is comparatively simple. An aqueous or alcoholic solution of the colouring matter is thickened with gum senegal, printed on with blocks, and when dry, exposed to the action of steam for about half an hour. The gum is then washed off, and the goods are finished.

A *discharge style* may be produced on silk dyed with magenta by printing on it with powdered zinc mixed with gum. The rosaniline, $C^{20}H^{10}N^3$, is thereby converted into leucaniline, $C^{20}H^{12}N^3$, the compounds of which are white. The same process may be applied to any of the coloured derivatives of magenta. Two colours may in like manner be produced on silk (for example, a green ground with purple spots) by taking silk dyed with any of the derivatives of magenta, and printing it with the discharge previously mixed with the colour it is desired to introduce, of course employing a colouring matter which is not affected by the discharge, as aniline purple, aniline pink, &c.

The dyeing of wool with aniline colours is a very simple process, the wool being merely worked in a hot aqueous solution of the desired colouring matter, no mordant being required. Acids are generally found to be injurious, and therefore a neutral bath is preferred, the operation being finished by bringing the temperature nearly up to that of boiling water. With *Nicholson's blue*, the process of dyeing is different, and consists of two distinct operations, the wool being first worked in an alkaline solution of the colour, which gives it a kind of grey or slate shade, and then in an acid bath, which develops the colour.

The *printing* of wool is similar to that of silk, the colouring matter being simply thickened with gum, printed on the goods, steamed, and then washed.

For dyeing cotton, mordants are required. The ordinary mordants, such as alum, are of no use, for the reason above mentioned. The method devised by Perkin and Pullar, depending upon the insolubility of the compounds which these colours form with tannin, is described, with reference to aniline purple, in the article *DYEING* (ii. 357). The cotton is first soaked in a decoction of sumach or other tanning agent, then in a solution of sodium stannate, and lastly in water acidulated with sulphuric acid. The cotton thus prepared contains an insoluble compound of tin and tannin, which possesses a great affinity for aniline purple and nearly all the other aniline colours.

For *printing* calico with aniline colours, the method now almost universally employed is that of Perkin and Schultz, which consists in printing the colouring matter with a mordant composed of a solution of aluminium arsenite in aluminium acetate. On steaming the cloth printed with this mixture for about half an hour, the colour is firmly fixed in the fibre. After steaming, the goods are generally soaped and then finished. One of the great advantages of this process is that it can be worked in patterns with a great variety of colours; it is also suitable for nearly all the aniline colours as well as the mauve, yielding shades of great brilliancy.

The application of *aniline black* to calico-printing has been already noticed (p. 160 also *iv.* 456).

Other uses of Aniline Colours.—Although the chief use of these colours is for dyeing and calico-printing, they are, nevertheless, employed in the form of lakes in several other branches of industry, as in lithography, type-printing, paper-staining, &c. These lakes are usually prepared by adding to the solution of the colouring matter mixed with alum, a certain quantity of tannin or benzoic acid, which forms therewith an insoluble compound; some manufacturers likewise add soap.

The lakes thus prepared are now used to a large extent for paper-staining. They are likewise employed in lithography and type-printing; but for these latter purposes special preparations are more frequently used. Sometimes the lithographic ink or varnish is mixed with starch-powder stained with an alcoholic solution of the required aniline colour; sometimes the varnish is mixed with the dried precipitate obtained by adding water to a mixture of an aniline colour with an alcoholic solution of resin sometimes again the base of the colouring matter is dissolved in oleic acid, whereby

which dissolves in ether, and separates therefrom in the crystalline form. This ether boiled for a long time with strong potash-ley, dissolves and forms potassium anisate, from which anisic acid (melting at 175°) may be separated by hydrochloric acid. By using ethyl iodide instead of methyl iodide in the above reaction, and proceeding in the same way, ethylparaoxybenzoic acid, $C^6H^4(C^2H^5O)^2$, the next higher homologue of anisic acid, may be obtained (Ladenburg, *Ann. Ch. Pharm.* cxli. 241; *Jahresb.* 1866, p. 388). See PARAOXYBENZOIC ACID in this volume.

γ. Anisic acid is also produced by the oxidation of the methylic ether of cresol, $C^6H^4(OCH^3).CH^3$. This ether is prepared by treating cresol with methylic iodide and a little methyl alcohol in an apparatus so arranged that the condensed vapours may flow back again, the vessel being plunged into cold water if the action becomes too violent, afterwards gently heated, and the product washed with water and caustic potash, then purified by distillation. The colourless liquid thus obtained, boiling at 174° , is converted into anisic acid by heating it with potassium dichromate and sulphuric acid in a flask with upright condensing tube (Körner, *Bull. Soc. Chim.* [2] x. 468.)

Anisates. (Engelhardt, *J. pr. Chem.* xxiv. 417.)—Anisic acid is monobasic, the formulae of its salts being $M^+C^6H^4O^3$ for univalent and $M^{++}(C^6H^4O^3)^2$ for bivalent metals. Anisates corresponding to the bimetallic or so-called basic salicylates (v. 154) have not been obtained, excepting in the case of the lead-salt. The potassium salt $K^+C^6H^4O^3$ crystallises from alcohol of 70 p. c. in thin nacreous laminae. The similarly prepared sodium salt forms shining transparent rhombic laminae, $2Na^+C^6H^4O^3.H^2O$, which, by prolonged contact with the mother-liquor, are converted into efflorescent, apparently monoclinic crystals, containing $Na^+C^6H^4O^3.5H^2O$. The barium salt $Ba^{++}(C^6H^4O^3)^2$ crystallises in thick, colourless, shining rhombic plates; the strontium salt $Sr^{++}(C^6H^4O^3)^2.H^2O$, and the calcium salt $Ca^{++}(C^6H^4O^3)^2.H^2O$, in laminae which give off their water at 140° – 170° . The magnesium salt $Mg^{++}(C^6H^4O^3)^2.4H^2O$ dissolves easily in water and in alcohol, and crystallises from the latter in stellate groups of flexible needles. The normal lead salt $Pb^{++}(C^6H^4O^3)^2.H^2O$ is obtained by precipitating ammonium anisate with lead-acetate, as a heavy white powder, which crystallises from hot water in shining laminae, fusing, with loss of water, between 80° and 90° . A boiling solution of this salt yields with basic lead acetate, a salt containing $2Pb^{++}C^6H^4O^3.H^2O$, which becomes anhydrous at 140° . The greenish blue precipitate thrown down by anisate of sodium or ammonium from a cupric salt is a mixture of anisic acid with a basic salt (Zervas). According to Schiff (*Jahresb.* 1862, p. 204), a blackish-green diammoecupriconium anisate, $(N^2Cu^+Am^2H^+)(C^6H^4O^3)^2.2H^2O$, is obtained by dissolving cupric anisate in ammonia and leaving the solution to evaporate in an atmosphere of ammonia.

NITRANISATES.—The potassium salt $K^+C^6H^4(NO^2O^2).H^2O$ crystallises from alcohol in shining elongated tables; the sodium salt $Na^+C^6H^4(NO^2O^2).H^2O$, from water and alcohol, in yellow needles; the barium salt $Ba^{++}[C^6H^4(NO^2O^2)]^2.4H^2O$, and the strontium salt $Sr^{++}[C^6H^4(NO^2O^2)]^2.H^2O$, are white flocculent precipitates; the calcium salt $Ca^{++}[C^6H^4(NO^2O^2)]^2.4H^2O$ when re-crystallised from water forms microscopic flexible needles. The lead salt $Pb^{++}[C^6H^4(NO^2O^2)]^2$ crystallises in needles which explode violently at a red heat (Engelhardt, *loc. cit.*).

Amidanisic Acid, $C^6H^4(NH^2O^2) = C^6H^4(NH^2) \left\{ \begin{array}{l} OCH^3 \\ CO^2H \end{array} \right.$ or *Oxyanisic acid*,

$\left\{ \begin{array}{l} H^+ \\ (C^6H^4O^2)^- \\ H^+ \end{array} \right\} N$ $\left\{ \begin{array}{l} N \\ O^+ \end{array} \right.$, improperly called *Anisamic acid* (i. 296).—This acid, like other

amidated acids, forms crystalline compounds with mineral acids. With hydrochloric acid it forms the compound $C^6H^4NO^2.HCl$, which crystallises in slender white needles moderately soluble in water and in boiling alcohol, sparingly soluble in dilute aqueous hydrochloric acid. This hydrochloride forms with platinum chloride a double salt, $2(C^6H^4NO^2.HCl).PtCl^4$, which crystallises in golden-yellow needles easily soluble in warm alcohol and water. With nitric acid, amidanisic acid forms the compound $C^6H^4NO^2.HNO^3$, easily soluble in hot water and alcohol, sparingly soluble in nitric acid, and crystallising therefrom in tufts of prisms. With sulphuric acid it forms the compound $2C^6H^4NO^2.H^2SO^4$, which has a saccharine taste, dissolves easily in water, and crystallises from alcohol in silky needles (Cahours, *Ann. Ch. Phys.* [3] liii. 322).

Amidanisic acid distilled with excess of caustic baryta or potash is decomposed, with formation of anisidine, $C^6H^4NO^2$ (Cahours). Dissolved in excess of nitric acid and subjected to the action of nitrogen dioxide, it is converted, with evolution of nitrogen, into a crystalline non-azotised acid (Cahours). By the action of nitrous

acid or a nitrous ether, not in excess, on its cold alcoholic solution, it is converted into diazoanis-amidanisic acid. $C^6H^5N^2O = C^6H^5N^2O \cdot C^6H^5NO^2$ (Griess; see iv. 289):

AMIDANISIC ETHERS.—The *ethylic ether* $C^6H^5(C^2H^5)NO^2$ is produced by the action of ammonium sulphide on an alcoholic solution of ethyl nitranisate (i. 302). The solution, concentrated by gentle heat, and filtered from separated sulphur, yields ethyl amidanisate, on further evaporation, as an oil which crystallises after some time, and may be obtained by repeated crystallisation in colourless prisms easily soluble in warm alcohol, less soluble in ether. It dissolves easily in aqueous alkalis and forms crystalline compounds with acids. The *hydrochloride* $C^6H^5(C^2H^5)NO^2.HCl$ forms crystals soluble in alcohol and ether, colourless after recrystallisation; the *platino-chloride* $2[C^6H^5(C^2H^5)NO^2.HCl].PtCl^4$ separates from alcoholic solution in brownish-red prisms, which become dull on exposure to the air, and are insoluble in ether.

Methyl Amidanisate, $C^6H^5(CH^3)NO^2$, is prepared like the ethyl compound, which it resembles. Its *hydrochloride* crystallises in small shining prisms, and unites with platonic chloride, forming the compound $2[C^6H^5(CH^3)NO^2.HCl].PtCl^4$, which crystallises from alcohol in reddish prisms (Cahours, *loc. cit.*).

Azo-anisic acid, $C^6H^5N^2O^2$, is produced by the action of sodium-amalgam on an alkaline solution of nitranisic acid, acidulated towards the end of the reaction. A coloured substance is thereby produced, the ammoniacal solution of which deposits, on addition of barium chloride, a small quantity of a red barium salt, and afterwards, in a closed vessel, yellow crystals of *barium azoanisate*, $C^6H^5N^2O^2.BaN^2O^2$. The acid separated from this barium salt is yellowish, insoluble in water, alcohol, and ether, and does not reduce silver solutions (Alexejeff, *Compt. rend.* lv. 473; Strecker, *Jahresb.* 1863, p. 347).

Chloranisic and Bromanisic Acids (Reinecke, *Bull. Soc. Chim.* [2] vii. 177).—The monochlorinated and monobrominated acids, produced by the action of aqueous chlorine and bromine on anisic acid, are described in vol. i. 301, 302.

Dichloranisic acid, $C^6H^5Cl^2O$, is produced, together with tetrachloroquinone, by treating anisic acid with hydrochloric acid and potassium chlorate in presence of a large quantity of water. It crystallises from alcohol in large shining needles, insoluble in water, melting at 196° .

Dibromanisic acid, $C^6H^5Br^2O$, is produced by heating anisic acid with bromine and water to 120° . It resembles the dichlorinated acid, melts at 207° – 208° , and sublimes in long beautiful needles.

Both these acids dissolve without decomposition in hot nitric acid, and are deposited therefrom on cooling; the monochlorinated and monobrominated acids are easily decomposed under the same circumstances, with loss of CO^2 ; a similar decomposition of the dichlorinated and dibrominated acids takes place only after long boiling.

Dibromanisic acid subjected to the prolonged action of bromine and water, is converted into tribromanisol, according to the equation:

Tribromanisol crystallises from boiling alcohol in colourless needles, which melt at 87° , and may be sublimed. Bromine converts it into tetrabromoquinone, $C^6Br^4O^2$, doubtless with simultaneous formation of methyl bromide.

Iodanisic Acid, $C^6H^5IO^2$.—Griess obtained this acid, together with the hydriodate of amidanisic acid, by the action of hydriodic acid on diazo-amidanisic acid (*Ann. Ch. Pharm.* cxvii. 1). It is also produced (probably in a different modification) by the action of iodine and iodic acid on anisic acid (Peltzer, *Bull. Soc. Chim.* [2] ix. 148):

The materials, in the proportions indicated by the equation, are heated together for about six hours to 115° – 150° . The acid is nearly insoluble in water, whether hot or cold; dissolves in 165 pts. of cold ether, and is somewhat more soluble in boiling ether and alcohol. The solutions deposit the acid in needle-shaped crystals having a vitreous lustre. It melts at 234.5° , and sublimes at a somewhat lower temperature in small nacreous laminae. Nascent hydrogen converts it into anisic acid.

Ammonium iodanisate forms small groups of hard, white, needle-shaped crystals which give off ammonia at 100° . The *barium salt* $Ba(C^6H^5IO^2).3H^2O$ forms vitreous prisms several lines long. The *calcium salt* $Ca(C^6H^5IO^2).3H^2O$ is more soluble than the barium salt, and crystallises in small nacreous needles. The *lead salt* is a

water, agitating with ether, and evaporating the ethereal solution (*Chem. Zentr.*, *Ann. Ch. Pharm.* cxvii. 243).

ANISIC PINACONE. See HYDRANISOÏN, under ANISOÏN.

ANISIDINE. See AMIDO-METHYLPHENOL, under PHENOL-DERIVATIVES.

ANISOÏN. This name was originally applied to a crystalline isomeride of anethol, better called anethoïn (p. 156). It has lately been given by Rosell to a polymeride of anisaldehyde, $C^{12}H^{10}O^4$, related to that compound in the same manner as benzoïn to bitter almond oil. This body is obtained by adding to dilute alcohol containing a very small quantity of potassium cyanide, as much anisic aldehyde as it can take up without turbidity, leaving the solution to itself for three months, then adding water, and agitating. Anisoïn then crystallises out, and may be purified by recrystallisation from hot alcohol. It forms colourless and inodorous needles, six-sided prisms with perpendicular end-faces, or six-sided pyramids; melts at 109° – 110° ; is nearly insoluble in water; dissolves with difficulty in cold alcohol and ether, more easily on heating, and especially in boiling alcohol. Strong sulphuric acid dissolves it, with red colour, rapidly changing to pale green, and on heating to yellow, then at a much higher temperature to a splendid purple-red. Dissolves in alcoholic potash, with violet colour, which disappears on boiling with a sufficient excess of potash (Rosell, *Zeitschr. f. Chem.* [2] v. 562).

Hydranisoïn and Iso-hydranisoïn. $C^{12}H^{10}O^4$ (C. Saytzeff, *Zeitschr. f. Chem.* [2] iii. 678; Samosadsky, *ibid.* iv. 641; Rosell, *ibid.* v. 562).—These isomeric bodies, included by Samosadsky under the name of anisic pinacones, are produced by the action of sodium amalgam (containing 3 p. c. sodium) on anisic aldehyde in alcoholic solution. The liquid after three days deposits colourless tabular crystals of hydranisoïn, apparently consisting of rhombic pyramids with predominant pinaconoidal faces. This substance is insoluble in cold water, very slightly soluble in warm water, somewhat more in ether, easily in hot alcohol. It melts at 172° , and resolidsifies at 140° . When distilled in a stream of carbon dioxide, it partly sublimes undecomposed, and is partly converted into anisic aldehyde. By distillation in the air, anisic acid is likewise produced. Hydranisoïn is strongly attacked by concentrated nitric acid, with evolution of nitrous fumes, turning red and separating as an oil, which gradually dissolves, the solution yielding crystals of nitranisic aldehyde. Hydranisoïn treated with potassium dichromate and sulphuric acid, emits a strong odour of anisic aldehyde, and forms a solution which deposits anisic acid. It is not acted upon by potash either in aqueous or in alcoholic solution. With phosphorus pentachloride it yields anisyl chloride.

Iso-hydranisoïn separates from the alcoholic solution of anisic aldehyde treated with sodium amalgam, only after addition of water. It crystallises in slender interlaced needles, and when boiled with water, partly dissolves, partly separates in oily drops which solidify in the crystalline form on cooling. It is extremely soluble in alcohol and ether, and reacts with nitric acid, sulphuric acid, and chromic acid, in the same manner as hydranisoïn.

Desoxyanisoïn, $C^{12}H^{10}O^3$, is produced by boiling hydranisoïn or iso-hydranisoïn with dilute sulphuric acid; separates from the solution in oily drops, which solidify on cooling; and may be obtained by recrystallisation in tufts of needles. It dissolves easily in alcohol and ether, melts at 95° , and solidifies again in the crystalline form, but very slowly, often not till cooled to 20° ; reacts neutral; is converted by oxidation with chromic acid mixture into anisic aldehyde and anisic acid (Rosell).

A compound isomeric or polymeric with desoxyanisoïn is obtained by the action of tin or zinc and hydrochloric acid on anisic aldehyde or hydranisoïn, and may be separated from the resinous product of the reaction by ether, in which it is insoluble. It is a colourless crystalline body melting at 215° , not coloured by nitric acid, dissolving with difficulty in alcohol, and only after long boiling (Samosadsky).

ANISOSALICYLOL. $C^{12}H^{12}O^4$.—See SALICYLOL, v. 170.

ANISURIC ACID. Found in the urine after anisic acid has been swallowed (Græbe a. Schultzen, *Ann. Ch. Pharm.* cxlii. 345).

ANKERITE (i. 307).—This variety of dolomite occurs in rhombohedrons and twin crystals (R : R terminal = $106^{\circ}1'$), accompanied by rock-crystal, samsonite, and calcite, in cavities in a decomposed siderite, on the Erzberg, near Vordernberg, in Styria (Zepharovich, *Jahresb.* 1867, p. 1007). An analysis by Reichenbach (*Wien. Akad. Ber.* lv. [2] 648) gave 43.69 p. c. $CaCO_3$, 12.77 $MgCO_3$, 2.75 $MnCO_3$, and 41.00 $FeCO_3$ (= 100.11).

ANOL or ALLYLIC PHENOL. $CH^3HO = CH^2CH_2OH$.—Formed by

prolonged heating of purified anise-oil with potassium hydrate. On adding water to the product, a small quantity of unaltered anethol separates as an oil, while potassium anolate remains in solution; and on decomposing this solution with an acid, carefully avoiding rise of temperature, anol separates in yellow flocks, which crystallise from hot water in white shining laminae. Anol melts at 92.5° , boils at about 250° , and dissolves in alcohol, ether, and chloroform; it does not, however, always crystallise from these solutions, but sometimes passes, especially on exposure to the air, into a brown liquid insoluble in hot water (Ladenburg, *Deut. Chem. Gesellsch.* 1869, p. 371; *Zeitschr. f. Chem.* [2] v. 575).

ANTHRACENE. $C^{14}H^{10}$ (Berthelot, *Bull. Soc. Chim.* [2] vii. 223; viii. 238; ix. 295.—Graebe a. Liebermann, *Zeitschr. f. Chem.* [2] iv. 279, 503, 724; v. 602; vi. 257; *Ann. Ch. Pharm. Suppl.* vii. 257.—Fritzsche, *N. Petersb. Acad. Bull.* xi. 385; xiii. 531; *Jahresb.* 1867, p. 600; 1868, p. 433).—The name anthracene has been applied to two different hydrocarbons, viz. the compound $C^{14}H^{10}$, examined by Fritzsche and Anderson, described in vol. iv. pp. 850–852 (as paranaphthalene), and the compound $C^{14}H^{12}$, examined by Dumas a. Laurent (*Ann. Ch. Phys.* [2] i. 187), first called paranaphthalene, and afterwards by Laurent, anthracene. Berthelot regards this last compound as methyl-anthracene. Graebe a. Liebermann have, however, shown that the analyses which Dumas a. Laurent gave of their hydrocarbon are not sufficiently exact to decide between the formulæ $C^{14}H^{12}$ and $C^{14}H^{10}$; that, on the other hand, the analyses of Laurent's *anthracenuse* agree very well with the formula $C^{14}H^{10}$, and not at all with Laurent's own formula, $C^{14}H^{12}O_2$. The so-called anthracenuse is therefore identical with the compound called by Anderson *oxanthracene*, by Graebe a. Liebermann *anthraquinone*, and appears to have been obtained from a mixture of hydrocarbons consisting mainly of $C^{14}H^{10}$. It may be concluded therefore that the hydrocarbon $C^{14}H^{12}$ has no existence, at least as a constituent of coal-tar. Fritzsche's *photene* is identical with pure anthracene, $C^{14}H^{10}$.

The preparation of anthracene from coal-tar, according to Anderson and Fritzsche, is given in vol. iv. p. 350. Fritzsche's latest method is as follows: Crude anthracene is dissolved in hot coal-tar naphtha, and the less fusible portion which separates out each time is repeatedly crystallised till it exhibits the crystalline characters to be presently described. The yellow colour, arising from chrysogen, which obstinately adheres to it, may be removed by exposure to sunshine. Lastly, the hydrocarbon must be boiled with alcoholic picric acid, to remove any possible trace of a more soluble hydrocarbon of higher boiling point. Berthelot rectifies the solid product of the distillation of coal-tar, collecting apart that which passes over from 340° to a little above the boiling point of mercury; distils again, arresting the operation at 350° ; dissolves the residue in boiling coal-oil (B. P. 120° – 150°); presses the crystals which are deposited from the solution on cooling; and repeats this operation four or five times. The product is then recrystallised from alcohol, and the purification is finally completed by cautious sublimation in an ordinary retort.

Anthracene may be formed artificially: 1. By heating benzyl chloride, C^7H^7Cl , with water to 200° , dibenzyl, $C^{14}H^{14}$, being probably formed at the same time according to the equation,

(Limpricht, *Ann. Ch. Pharm.* cxxxix. 303; *Jahresb.* 1866, p. 592).—2. By passing the vapour of toluene or xylene through a red-hot tube:

3. By passing a mixture of benzene and ethylene gas or cinnamene vapour, or of diphenyl or chrysene vapour with ethylene gas, through a red-hot tube; also by exposing a mixture of benzene and naphthalene to a white heat (Berthelot):

4. By heating alizarin with zinc-dust—a mixture of metallic zinc, zinc-oxide, and zinc hydrate—the hydrogen required for the transformation being supplied by the hydrate:

A mixture of 1 pt. alizarin and 30 to 50 pts. of good zinc-dust is placed at the closed end of a combustion-tube, a layer of zinc-dust several inches long being placed in front of it and about 6 inches of the tube being left empty; the unmixed zinc-dust is then heated, and afterwards the mixture is gradually heated to low redness. The quantity of anthracene thus obtained is about 30 per cent. of the alizarin used, the calculated quantity being 74 per cent. The loss arises from the formation of secondary products. Anthracene may be obtained in like manner from purpurin, $\text{C}^{14}\text{H}^8\text{O}^3$; chrysophanic acid, $\text{C}^{14}\text{H}^8\text{O}^4$ or $\text{C}^{14}\text{H}^{10}\text{O}^4$; and aloin (Graebe a. Liebermann).

Anthracene crystallises in well-defined four- or six-sided tables having a dazzling white lustre and a beautiful violet fluorescence, which however is exhibited only when the crystals are quite pure and white (Fritzsche; see also Perkin, *Chem. Soc. J.* [2] ix. 22). From large quantities of the alcoholic solution, still coloured yellow by chrysogen, it separates in monoclinic crystals exhibiting the combination $\infty\text{P}.$ $\infty\text{P}.$ $+ 2\text{P}.$ ∞ , and having their axes a (clinod.): $b : c$ (principal) = $1:422 : 1 : 1:878$ (Fritzsche). It melts at 210° – 212° (Fritzsche), at 213° and distils at about 360° (Graebe a. Liebermann). By prolonged exposure to light it is converted into an isomeric body, paranthracene (paraphotene), which forms microscopic flat crystals, or four-sided tables, melting at 244° , nearly insoluble in all solvents, not attacked by strong sulphuric acid, by ordinary nitric acid even at the boiling heat, by bromine at 100° , or by a solution of bromine in carbon bisulphide; reconverted into anthracene by fusion.

Anthracene heated to 280° with 100 times its weight of strong hydriodic acid is transformed into several hydrocarbons of the paraffin series $\text{C}^{2n}\text{H}^{2n+2}$, viz. tetradecane, $\text{C}^{14}\text{H}^{30}$, as principal product; heptane, C^7H^{16} , in considerable quantity; sextane, C^6H^{14} , and ethane, C^2H^6 , in smaller quantity; also a somewhat considerable quantity of an oily, nearly solid paraffin, probably $\text{C}^{22}\text{H}^{46}$, which does not distil over at 300° . The formation of the first two and the last of these products is represented by the equations

while the sextane and ethane are formed thus:

With a smaller quantity of hydriodic acid (20 times the weight of the anthracene), the principal product is toluene:

with traces of benzene and ethane:

and a small quantity of a liquid hydrocarbon volatilising above 260° , apparently a hydride of anthracene:

Anthracene is converted by oxidising agents, as by a mixture of potassium dichromate and sulphuric acid, into anthraquinone, $\text{C}^{14}\text{H}^8\text{O}^2$, identical with Anderson's oxanthracene (iv. 362).

Respecting the conversion of anthracene into alizarin, $\text{C}^{14}\text{H}^8\text{O}^4$, see ALIZARIN (p. 83).

Anthracene Hydrides. The dihydride $\text{C}^{14}\text{H}^{12}$ is formed by heating anthracene to 150° – 160° with hydriodic acid and red phosphorus; also by gradually adding sodium amalgam to anthracene gently warmed with alcohol of 95 per cent. in a flask with upright condenser, and neutralising the product from time to time with an acid till a sample of the product melts at 106° , or no longer turns red when heated with picric acid and benzol. It melts at 106° , sublimes at about the same temperature, boils without decomposition at 305° , crystallises in tabular monoclinic combinations $\infty\text{P}.$ $\infty\text{P}.$ $- \text{P}.$ ∞ ; has a peculiar odour, especially strong when the substance is heated; is insoluble in water, but dissolves very abundantly in alcohol, ether, and benzol; distils with vapour of water or alcohol; does not fluoresce in the solid state, but its solutions exhibit a blue fluorescence. Strong sulphuric acid at 100° converts it into anthracene:

Sup.

N

sulpho-acids of anthracene being formed as secondary products. Bromine added to a solution of the dihydride in carbon bisulphide produces dibromanthracene:

With less than 3 mol. bromine to 1 mol. of the dihydride, part of the latter remains unaltered, no reproduction of anthracene taking place. The dihydride heated with dilute *nitric acid* yields a number of nitro-products, amongst which is dinitro-anthraquinone (Fritzsche's reagent, p. 180). It is not altered by boiling with iodine in alcoholic solution, and not perceptibly altered by sodium amalgam (Graebe a. Liebermann).

The *hexhydride*, $C^{10}H^{16}$, is obtained by heating the dihydride to 200° – 220° for ten or twelve hours with hydriodic acid and $\frac{1}{4}$ to $\frac{1}{2}$ pts. by weight of amorphous phosphorus, washing the product with water, separating it from unaltered phosphorus by solution in alcohol, pressing the residue between bibulous paper, and distilling: the portion which boils at 290° is the hexhydride. It melts at 63° , dissolves easily in alcohol, ether, and benzol; crystallises therefrom in laminae; is resolved at a red heat into hydrogen and anthracene; and is much less acted upon by nitric acid than the dihydride.

A *tetrahydride* of anthracene does not appear to exist; the dihydride treated with hydriodic acid alone is partly converted into hexhydride (Graebe a. Liebermann).*

Bromanthracenes. *Dibromanthracene*, $C^{10}H^8Br^2$, was first obtained by Anderson (iv. 351). Graebe a. Liebermann prepare it by treating anthracene under carbon bisulphide with 1 mol. bromine. It forms long yellow needles which melt at 221° (according to Anderson at 182°), dissolve easily in benzol, sparingly in alcohol and ether. With *picric acid* it forms a red crystalline compound; with sulphuric acid, a sulpho-acid. By nitric acid it is easily converted into anthraquinone. It is not altered by boiling with *potash*, either in alcoholic or in aqueous solution; but when heated with alcoholic potash to 160° – 170° , it yields anthracene, together with aldehyde and acetic acid; probably thus:

Monobromanthracene does not appear to exist.

Dibromanthracene-tetrabromide, $C^{10}H^8Br^4$, is produced by spreading dibromanthracene (1 mol.) on a glass plate, and placing it under a bell-jar, together with a capsule containing the requisite quantity of bromine (2 mols.); washing the product, after complete absorption of the bromine, with ether; and recrystallising it from benzol: $C^{10}H^{10} + 4Br^2 = 2HBr + C^{10}H^8Br^2.Br^2$. Anderson obtained the same compound (iv. 352), but regarded it as anthracene-hexbromide, $C^{10}H^8Br^6$. It melts between 170° and 180° (at 182° , Anderson), and is at the same time resolved into tribromanthracene, bromine, and hydrobromic acid:

Tribromanthracene, $C^{10}H^8Br^3$, obtained by heating the preceding compound to 200° as long as vapours of bromine and hydrobromic acid are given off, and crystallising the residue from benzol, forms yellow needles sparingly soluble in alcohol, easily in benzol, melts at 169° , and sublimes in needles. By *nitric acid* of sp. gr. 1.4, or, better, by *chromic acid* and glacial acetic acid, it is converted into dibromanthraquinone:

It unites directly with dry bromine, forming $C^{10}H^8Br^3.Br^2$ (Graebe a. Liebermann).

Tetra-bromanthracene. $C^{10}H^8Br^4$ (obtained by Anderson, who regarded it as dibromanthracene dibromide, $C^{10}H^8Br^2.Br^2$).—Prepared by adding a strong aqueous solution of $\frac{1}{4}$ to $\frac{1}{2}$ pt. potassium hydrate to 1 pt. dibromanthracene-tetrabromide heated with alcohol in the water-bath, and recrystallising the yellow product from commercial benzol of high boiling point. Melts at 254° (at 238° , Anderson), and is converted by oxidising agents, especially by nitric acid of sp. gr. 1.4 and potassium dichromate, into dibromanthraquinone (Graebe a. Liebermann).

Chloranthracenes. Anderson obtained the compounds $C^{10}H^{10}Cl^2$ and $C^{10}H^8Cl^4$ (iv. 353). *Dichloranthracene*, $C^{10}H^{10}Cl^2$, is formed by treating anthracene with chlorine at 100° , or by exposing it for some time to an atmosphere of chlorine at ordinary temperatures. It was obtained in the latter way by Laurent, who, however, assigned to it the incorrect formula $C^{10}H^8Cl^2$. Perkin (*Chem. Soc. J.* [2] ix. 14) prepares it by passing chlorine gas over benzol holding in suspension about one-fifth of its weight of purified commercial anthracene, until the whole becomes a crystalline

* Graebe a. Liebermann formerly stated that a tetrahydride was produced in this manner, but their more recent experiments show that the product was only a mixture.

pasty mass. The product is then thrown on a linen filter, drained, well washed with cold benzol, then dried, and further purified, first by distillation, then by two or three crystallisations from benzol. It then separates in golden-yellow needles. It dissolves easily in benzol, sparingly in alcohol and ether, melts at 205°, and sublimates in yellow needles. Its solutions, especially the alcoholic solution, exhibit a splendid blue fluorescence. It is not attacked by potash-ley. Oxidising agents convert it into anthraquinone. A mixture of the boiling solutions of dichloranthracene and picric acid in benzol yields on cooling, small bright red needles of dichloranthracene picrate, $C^{14}H^8Cl^2.C^6H^3(NO_2)^3O$ (Perkin).

Tetrachloranthracene, $C^{14}H^8Cl^4$, is prepared by passing chlorine over anthracene at 170°–180°, treating the product (probably dichloranthracene tetrachloride) with alcoholic potash, and crystallising the resulting yellow compound from benzol. Stellate groups of golden-yellow needles, slightly soluble in alcohol, somewhat more freely in hot benzol, nearly insoluble in cold benzol. Melts at 220°. Converted by nitric acid into dichloranthraquinone (Graebe a. Liebermann).

Sulpho-acids of Dichlor- and Dibrom-anthracene.

Disulpho-dichloranthracenic Acid. $C^{14}H^8Cl^2SO^4 = C^{14}H^8Cl^2 \begin{Bmatrix} SO^2H \\ SO^2H \end{Bmatrix}$

(Perkins, *Chem. Soc. J.* [2] ix. 15).—Prepared by adding 1 pt. of dichloranthracene to about 5 pts. of fuming sulphuric acid, heating the mixture for a short time on the water-bath, then gradually pouring it into several times its bulk of water, neutralising with barium carbonate, and evaporating the filtrate to a small bulk. The sulpho-acid then remains as a slimy mass of minute orange-yellow needles, which may be drained on a porous tile. It is easily soluble in water; is precipitated therefrom by strong sulphuric or hydrochloric acid; has a strong acid taste and reaction. Its dilute solutions and those of its salts exhibit a strong blue fluorescence, less powerful, however, than that of a solution of aesculin. The composition of the acid is inferred from that of its salts.

The *sodium salt* $C^{14}H^8Cl^2(SO^2Na)^2$ crystallises in small orange-red needles easily soluble in water. The *barium salt* $C^{14}H^8Cl^2Ba(SO^2)^2$ is thrown down from the solution of the sodium salt by barium chloride, as a canary-yellow precipitate nearly insoluble in water. The *strontium salt* $C^{14}H^8Cl^2Sr(SO^2)^2$ separates on mixing the hot solutions of sodium disulphodichloranthracenate and strontium chloride, and evaporating, in yellow crusts, sparingly soluble in water. The *calcium salt* obtained by neutralisation is yellow and easily soluble in water.

Disulphodichloranthracenic acid subjected to the action of oxidising agents rapidly exchanges its chlorine for oxygen (O^2), and is converted into disulphanthraquinonic acid:

A similar result is obtained by heating the chlorinated acid with strong sulphuric acid; thus:

Disulphodibromanthracenic Acid. $C^{14}H^8Br^2 \begin{Bmatrix} SO^2H \\ SO^2H \end{Bmatrix}$ (Perkin, *Chem. Soc. J.*

[2] ix. 19).—Prepared, like the preceding, by the action of fuming sulphuric acid on dibromanthracene. It is crystalline, and its dilute solutions are fluorescent, as also are those of its salts, but much less strongly than those of the dichlorinated acid. The *sodium salt*, obtained by adding sodium sulphate to the crude solution of the acid neutralised with barium carbonate, crystallises in easily soluble microscopic needles, containing $C^{14}H^8Br^2(SO^2Na)^2$. The *barium salt* $C^{14}H^8Br^2Ba(SO^2)^2$ obtained by precipitation is insoluble in water and in hydrochloric acid, even at the boiling heat.

Disulphodibromanthracenic acid is converted into disulphanthraquinonic acid by the action of oxidising agents, in the same manner as the dichlorinated acid. With strong sulphuric acid the reaction is

ANTHRACENE-CARBONIC ACID. $C^{14}H^8.CO^2H$ (Graebe a. Liebermann, *Deut. Chem. Ges. in Berlin*. 1869, 678; *Zeitschr. f. Chem.* [2] vi. 213).—Produced by melting anthracene with liquid carbonyl chloride (phosgene) in a sealed tube to 200° for twelve hours. On digesting the contents with dilute sodium carbonate, which leaves a resin undissolved, and acidulating the filtrate, anthracene-carbonic acid separates in light yellow flocks, consisting of interlaced needles. It is nearly insoluble in cold water, and but slightly soluble in boiling water, from which,

however, it may be recrystallised. From alcohol, in which it dissolves easily at ordinary temperatures, it separates in long light-yellow needles having a silky lustre. In capillary tubes it melts at 206° , with evolution of carbon dioxide; but when a somewhat larger quantity is slowly heated in an oil-bath, it begins to decompose even at 150° , yielding a sublimate of anthracene. When heated with soda-lime, or more strongly by itself, it is completely resolved into anthracene and carbon dioxide. Its salts are decomposed by heat in a similar manner. They are mostly soluble in water and in alcohol. The *barium salt* is white; the *silver salt* $C^{14}H^8.CO^2Ag$ exhibits under the microscope the appearance of golden-yellow compressed prisms. The acid dissolved in glacial acetic acid is converted by oxidation with chromic acid into anthraquinone:

ANTHRAQUINONE. $C^{14}H^8(O^2)^2$. Laurent's *Paranaphthalose* or *Anthracenuse*; Anderson's *Oxanthracene* (iv. 352); Fritzsche's *Oxyphotene*.—This compound, related to anthracene in the same manner as quinone, $C^6H^4O^2$, to benzene, is produced by oxidation of anthracene, and of its dichloro- and dibromo-derivatives. It is most easily prepared by dissolving anthracene in warm glacial acetic acid, adding 2 pts. by weight of potassium dichromate, and assisting the action, as soon as it slackens, by heating the liquid on the water-bath till the solution has acquired a deep green colour. On diluting with water, and distilling the separated well-washed and dried mass, anthraquinone passes over, while a cinder rich in chromium remains behind. For preparation on the small scale it is better to use as the oxidising agent a mixture of glacial acetic acid and chromic acid; there is then a less abundant formation of the products which carbonise during distillation (Graebe & Liebermann; Fritzsche).

Anthraquinone melts at 273° and sublimes in yellow needles, sometimes in thick dark golden-yellow prisms. The yellow colour belongs essentially to it, but varies greatly in depth, according to the size of the crystals; finely divided anthraquinone, such as is obtained by precipitating a solution in sulphuric acid with water, appears nearly colourless. Anthraquinone is a very stable substance; it withstands the action of extremely energetic oxidising agents, and is not attacked by alcoholic potash at 200° , or even by fusion with potassium hydrate. Bromine does not act in the cold on anthraquinone either in the dry state or dissolved in carbon bisulphide; at 100° it forms dibromanthraquinone. When anthraquinone is heated to 150° for some hours with *hydriodic acid* (boiling at 127°) and a little yellow phosphorus, anthracene is produced, together with a small quantity of anthracene dihydride. Heated with excess of *zinc-dust*, it yields anthracene, the hydrogen necessary for the formation of that body being supplied by the zinc hydrate present:

Dibromanthraquinone, $C^{14}H^8Br^2O^2$, is obtained by heating an intimate mixture of anthraquinone and bromine to 100° for a considerable time. A better mode of preparation is to heat 1 pt. of tetrabromanthracene with 2 pts. potassium dichromate and 5 or 6 pts. colourless nitric acid of sp. gr. 1.4 in a capacious flask as long as bromine continues to escape; then dilute with water, and recrystallise the washed product from benzol. The oxidation succeeds well also with chromic acid and glacial acetic acid. Dibromanthraquinone crystallises in light-yellow needles, sublimes without decomposition, dissolves very slightly in alcohol, more easily in benzol and chloroform. By heating with potash it is converted into alizarin (p. 84).

Monobromanthraquinone, $C^{14}H^7BrO^2$, is obtained from tribromanthracene in the same manner as dibromanthraquinone from tetrabromanthracene. It crystallises in yellow needles, melts at 187° , sublimes without alteration, dissolves sparingly in alcohol, scarcely at all in cold benzol, with moderate facility in hot benzol. Heated with potassium hydrate it yields alizarin, according to the equation

Dichloranthraquinone, $C^{14}H^8Cl^2O^2$, is obtained, though not quite pure, by oxidation of tetrachloranthracene. It forms yellow needles, sparingly soluble in alcohol and ether, somewhat more soluble in benzol than the corresponding bromine compound.

Dinitroanthraquinone, $C^{14}H^8(NO^2)^2O^2$. Anderson's *Dinitroxanthracene*, Fritzsche's *Oxydinitrophotene*, is obtained, together with anthraquinone, by heating anthracene to 90° with dilute nitric acid. The two bodies are separated by solution in boiling alcohol of 95 p. c., which on cooling deposits the nitro-compound in laminae (Fritzsche, *N. Petersb. Acad. Bull.* xxii. 43; see also Anderson, iv. 352).*

* Fritzsche's memoir contains voluminous directions for the preparation of this compound in the pure state; see also *Jahresb. f. Chem.* 1868, p. 394.

This compound, called 'Fritzsche's reagent,' unites directly with all the solid hydrocarbons of coal-tar, and is very useful for effecting their separation. By means of it Fritzsche has detected six different hydrocarbons in the mother-liquor of the preparation of anthracene. (See PHOSPHOR.) The compound of dinitro-anthraquinone with anthracene, $C^{14}H^{10}.C^{14}H^6(NO_2)_2O_2$, is obtained in violet laminae belonging to the monoclinic system, by dissolving 9 pts. of the nitro-compound and 10 pts. of anthracene in 100 pts. of coal-naphtha, and leaving the filtered liquid to cool.

On *Disulphanthraquinonic* and *Sulphoxanthraquinonic acids*, see p. 84.

ANTIMONY. Native antimony occurs in veins in Silurian clay-slate in the Russel mine, about 70 miles from Quebec (Weisbach, *Jahrb. Min.* 1867, p. 609).

Respecting the amorphous or explosive antimony deposited from solutions of the metal under certain circumstances by electrolysis (i. 315), the following additional details have been published by Gore (*Chem. Soc. J.* [2] i. 365). This explosive antimony may be obtained from solutions of the bromide or iodide, as well as from the chloride of antimony; but its properties differ to a certain extent according to the nature of the solution used and the mode of deposition.

For the preparation of the explosive antimony it is necessary to use weak currents of constant strength (three elements of Smee's or Grove's battery) and concentrated acid solutions. In electrolysing a solution of antimonious chloride (prepared with 1 pt. antimonious oxide and 5 or 6 pts. hydrochloric acid of sp. gr. 1.12), the current must be of such a strength that the quantity of metal deposited in an hour upon a square inch of the negative electrode (which may consist of copper, silver, or platinum) shall not be less than half a grain; for as soon as this lower limit is reached, the character of the deposit changes suddenly from that of the black amorphous explosive metal to that of pure grey crystalline antimony. In the electrolysis of antimonious bromide (obtained by dissolving 1 pt. antimonious oxide in 10 pts. hydrobromic acid of sp. gr. 1.3) the current must be strong enough to deposit from 3 to 5 grains of antimony per square inch in an hour; for that of antimonious iodide (1 pt. of the oxide dissolved in 15 pts. of aqueous hydriodic acid of sp. gr. 1.25) the current should deposit not more than a grain of antimony per square inch in an hour.

The amorphous antimony deposited from the *chloride* has a density of 5.8. The temperature at which sudden evolution of heat takes place from it varies according to external circumstances: it begins at 77°, but does not attain its full intensity till the entire mass of metal has been heated to 93°–99°; contact with a red-hot wire or scratching with a metallic point sets up the sudden decomposition even at ordinary temperatures. If the metal is surrounded by a good conductor of heat, hot water for example, the evolution of heat takes place gradually.

The metal precipitated from solution of antimonious *bromide* is lighter in colour, duller, and less compact than that obtained from the chloride; its sp. gr. is 5.44. When heated to 121°, and then touched with a red-hot wire, it gives off a considerable quantity of heat with explosive violence; if the metal has not been previously heated to that temperature, the evolution of heat is confined to the part touched by the wire. Scratching the heated substance with a steel point does not give rise to any evolution of heat (when heated to 160°, however, it explodes spontaneously). When fused in a glass tube, it leaves metallic antimony and gives off a volatile substance of buttery consistence, the quantity of which varies in the different layers of one and the same precipitate from 18.4 to 20.5 p. c.: this substance is, according to Gore, a mixture of antimonious bromide with hydrobromic acid.

The third variety of the explosive metal, obtained from the *iodide*, is grey, scaly, of only slightly metallic aspect, and more friable than either of the other two; its sp. gr. is 5.25. It gives out much less heat than the other varieties; the evolution of heat takes place when the metal is heated throughout its mass to 176°; contact with a red-hot wire gives rise to it only when the metal has been previously heated to at least 170°. On the other hand, it is more easily decomposable than the varieties obtained from the bromide and chloride, and often falls to powder even in the electrolytic liquid, giving off hydrogen at the same time. When heated in a tube, it yielded 22.2 p. c. of a solid red fusible sublimate saturated with moisture (antimonious iodide with aqueous hydriodic acid).

All three varieties of amorphous antimony, when moderately and continuously heated to a temperature short of that at which sudden decomposition takes place, give off their heat gradually. They cannot long be preserved without alteration, but after a year or more they exhibit an acid reaction and sourish smell not belonging to them in their original state, and if then digested with dilute hydrochloric and tartaric acid, yield a much larger quantity of soluble substance than they do when recently prepared. Hence Gore regards the explosive metal as a chemical compound—though unstable and in varying proportions—of metallic antimony with a salt of antimony.

Antimonious fluoride when subjected to electrolysis yields nothing but the ordinary crystalline metal.

Reactions of Antimony.—1. The characteristic flame-reactions of antimony are described in the article ANALYSIS (p. 133).

2. *Distinction of Antimony from Tin and Arsenic.*—When a few drops of a solution of antimony acidulated with hydrochloric acid, but free from nitric acid, are placed in contact in a platinum capsule with a piece of metallic zinc, there is formed, immediately in concentrated, more slowly in dilute solutions, a precipitate of metallic antimony, which is brown or black according to the thickness, adheres closely to the platinum, is insoluble in hydrochloric acid either cold or hot, and is easily oxidised by boiling nitric acid. Both the trioxide and the higher oxides of antimony give this reaction, which becomes perceptible, at all events after an half an hour, even in solutions containing only $\frac{1}{30,000}$ pt. of antimony; in still more dilute solutions it becomes doubtful. Tin-solutions (stannous and stannic) yield under the same circumstances an easily loosened deposit of tin, resembling the platinum in colour, and easily soluble in hot hydrochloric acid. The same reaction is exhibited by meta-stannic acid, when drenched with dilute hydrochloric acid in a platinum capsule, and placed in contact with metallic zinc. Acidulated solutions of arsenious acid treated in like manner with zinc give off arsenetted hydrogen, and yield a deposit of arsenic which partly adheres to the zinc (never to the platinum), partly floats like flocks in the liquid; solutions of arsenic acid behave in a similar manner, but yield a much smaller deposit of arsenic. Tin and arsenic cannot be mistaken for antimony in this reaction; moreover, even when present in considerable quantity, they do not interfere with the characteristic reaction of antimony; indeed when tin is present, the antimony may be distinctly recognised in still more dilute solutions, and identified by its insolubility in hydrochloric acid (Fresenius, *Zeitschr. anal. Chem.* i. 444).

Another method of distinguishing these three metals one from the other, founded on the different behaviour of the sulphides with hydrochloric acid, is given by W. Stein (*Arch. Pharm.* [2] ci. 317). When the mixed sulphides are treated with fuming hydrochloric acid, arsenious sulphide alone remains undissolved. On mixing the acid solution with an equal volume of saturated aqueous hydrogen sulphide, the antimony sulphide is precipitated, and the filtrate, mixed with a larger quantity of the same solution, yields a precipitate of stannic sulphide.

On the different behaviour of arsenetted and antimonetted hydrogen with iodine, see ARSENIC.

Quantitative Separation of Antimony from Tin.—Antimonious sulphide, Sb_2S_3 , and stannous sulphide, SnS_2 , are converted into the corresponding chlorides by dry hydrochloric acid gas, even at ordinary temperatures; the antimonious chloride thus formed volatilises easily in the stream of gas, while the stannous chloride may be heated to incipient fusion without volatilising therein. To render this mode of separation available, however, the tin must be wholly present as stannous salt. If it is in the form of stannic chloride, the separation may be effected by digestion with iron (thin iron plate), in presence of free hydrochloric acid, till the iron is completely dissolved; the antimony is thereby separated in the metallic state, while the tetrachloride of tin is converted into the dichloride. About 3 pts. of iron are required to 1 pt. of antimony (Tookey, *Chem. Soc. J.* xv. 462).

According to Clasen (*J. pr. Chem.* xcii. 477), the separation of tin from antimony by means of iron succeeds particularly well when the quantity of tin is large in proportion to that of the antimony, whereas in the contrary case part of the precipitated antimony redissolves in the acid. In such a case, therefore, it is necessary, before dissolving the alloy [or other mixture or compound of the metals], to add a weighed quantity of tin (from 8 to 10 times the weight of the antimony), which has afterwards to be deducted in estimating the tin. Thin harpsichord wire may be used for the precipitation, and the washing of the antimony (which must be dried at 100° before weighing) is best effected with hot water acidulated at the beginning with a few drops of hydrochloric acid, and finally with absolute alcohol containing a few drops of ether. Moreover, as the pulverised antimony appears not to be quite insoluble in dilute hydrochloric acid, it is best to add iron wire to the solution heated to the boiling point as long as it dissolves. After the precipitation of the antimony, and complete dissolution of the iron, the decanted liquid, acidulated with a little hydrochloric acid, should be further tested with metallic iron, to see if any further separation of antimony will take place (Clasen).

When an alloy of antimony, tin, lead, and a little copper is oxidised with nitric acid, either strong or dilute, the resulting oxides of tin and antimony always retain a little lead, which cannot be washed out, and the quantity of which is greater if the

oxidation has been assisted by heat. The complete separation of lead may, however, be easily effected by heating a weighed quantity of the oxides dried at 110° to 120° in a slow stream of dry hydrochloric acid gas, till the tin and antimony are completely volatilised. The solution of the residual lead chloride is added to the nitric acid solution containing the copper and the principal part of the lead, and the tin and antimony in the distilled chlorides are separated by digestion with pure metallic iron, as above described. The antimony after washing with cold water is dried at 110° (Tookey, *loc. cit.*).

Other methods of separating antimony from arsenic, tin, &c., are described in the Dictionary under the several metals.

Volumetric Estimation of Antimony.—Antimonious oxide in alkaline solution reacts with solution of iodine in the same manner as arsenious oxide (i. 265), and may therefore be estimated like the latter. If the antimony is in the form of tartar-emetic, the solution is previously mixed with excess of sodium carbonate, which does not form any precipitate. Free antimonious oxide is dissolved in tartaric acid, and then saturated with sodium carbonate. A commercial sample of tartar-emetic may be valued by comparing it, by means of sodium carbonate and a normal iodine-solution, with a pure sample of the salt.

R. Schneider (*Pogg. Ann.* ex. 634) effects the volumetric estimation of antimony by treating antimonious sulphide with boiling hydrochloric acid, absorbing the evolved hydrogen sulphide in dilute ammonia, and titrating with solution of iodine. One molecule of antimonious sulphide, Sb_2S_3 , thus treated gives off $3\text{H}_2\text{S}$. To perform the estimation, the antimonious sulphide precipitated from a solution containing tartaric acid is well washed on a filter, and decomposed by heating with hydrochloric acid in a small glass flask fitted with a delivery-tube, for conveying the vapours into an inverted retort containing the aqueous ammonia, as in Bunsen's apparatus represented in figs. 48, 49, vol. i. p. 266. This retort is filled with deaerated water containing from 30 to 50 c.c. of strong aqueous ammonia; its contents after cooling are diluted with from half a litre to a litre of deaerated water, according to the quantity of antimonious sulphide used; and a measured volume of this liquid, still in the dilute state, is slightly acidulated with sulphuric acid, and titrated with iodine-solution and starch-solution. Denoting by a the quantity of hydrogen sulphide corresponding to a cub. cent. of iodine-solution, and by t the number of cub. cent. of iodine-solution used, the quantity of antimony is given by the formula:

$$x = \frac{2\text{Sb}}{3\text{H}_2\text{S}} \cdot a t = \frac{2 \cdot 122}{3 \cdot 34} a t = 2.431 a t.$$

The determination of the hydrogen sulphide may be made more exact by receiving the gas evolved in the same apparatus in a neutral or slightly alkaline solution of sodium arsenite, and titrating the remaining portion of arsenious acid with solution of iodine. The solution of the sodium arsenite contains in the cubic centimetre about 0.005 or 0.006 grm. of arsenious acid, and is most easily compared with an iodine-solution of known strength, by adding to a known quantity of the arsenic solution, first a few drops of hydrochloric acid sufficient to produce an acid reaction, then an excess of sodium bicarbonate, a small quantity of starch-solution, and finally the iodine-solution. The hydrochloric acid gas which passes over into the receiver together with the hydrogen sulphide soon renders the liquid acid, and throws down arsenious sulphide. The contents of the retort when cold are mixed with a little tartaric acid and diluted to a known volume, and in a measured portion of the filtered liquid, after supersaturation with sodium bicarbonate, the amount of arsenious acid is determined by solution of iodine. Denoting the volume of iodine-solution corresponding to the arsenic-solution used by V , that of the iodine-solution corresponding to the arsenic-solution after the distillation has been performed, by v , and the quantity of iodine in a cub. cent. of the iodine-solution by a , the quantity of antimony sought is:

$$x = \frac{\text{Sb}}{\text{I}} (V - v) a = 0.96 (V - v) a.$$

Guyard (*Bull. Soc. Chim.* 1863, p. 89) gives the following method, founded on the fact that antimonious oxide in dilute very acid solution, when freed from all foreign metals, is converted by potassium permanganate into antimonic acid. A solution of 1 to 1½ grm. of the antimony-compound to be tested is supersaturated with ammonia and yellow ammonium sulphide, and the antimonious sulphide separated from the filtrate by dilute hydrochloric acid is dissolved in strong hydrochloric acid. The solution mixed with a little tartaric acid is filtered, freed from hydrogen sulphide, diluted to about a litre, and then titrated with a solution of potassium permanganate till a red coloration is produced. The value of this solution must be

previously fixed by titration with antimonious sulphide, or, better, with tartar-emetic, so that 30 c.c. may correspond to 1 gm. of antimony.

ANTIMONY BROMIDE. SbBr_3 .—Nicklès (*Compt. rend.* xlviii. 837) prepares this compound by treating pulverised antimony with bromine dissolved in carbon bisulphide. The bromide dissolves in the liquid, and crystallises therefrom in rhombic pyramids, often assuming the form of flattened prisms from development of the end-faces (according to Nicklès, prisms of 69° , with acuminations of 80° ; angle of the contiguous pyramidal faces = 181°).

ANTIMONY CHLORIDES. When a solution of antimonious oxide or antimonious sulphide is distilled with hydrochloric acid, a portion of that acid passes over first, together with the aqueous vapour, and then *antimonious chloride*, which ultimately passes over quite anhydrous. In the distillation of a hydrochloric acid solution of antimony containing nitric acid, this acid and hydrochloric acid are volatilised, but no antimony, till finally, after all the nitric acid has escaped, a small quantity of antimony pentachloride is volatilised (H. Rose, *J. pr. Chem.* lxxvi. 137).

Antimonious chloride unites with *aniline hydrochloride*, forming the crystalline compound $3\text{C}_6\text{H}_5\text{N} \cdot \text{SbCl}_3$ or $[(\text{C}_6\text{H}_5)_3\text{Sb}^+\text{H}^+]\text{N}^-\text{Cl}^3$ (Schiff; see PHENYL-AMMONIUMS, iv. 474).

When 1 mol. antimonious chloride and 3 mol. alcohol are heated to 150° in a sealed tube, ethyl chloride and hydrogen chloride are formed, together with crystals of an oxychloride, $\text{Sb}_2\text{O}_3\text{Cl}_2 = 2\text{SbOCl} \cdot \text{Sb}_2\text{O}_3$ (algaroth powder). These crystals are monoclinic but nearly right-angled rhombic prisms, having their acute edges bevelled. When 1 mol. antimonious chloride is heated with 1 mol. alcohol to 160° for several hours, ethyl chloride and hydrogen chloride are also formed, together with crystals of antimonious oxychloride, SbOCl . These crystals are soluble in alcohol and ether, and are partly decomposed by water into hydrochloric acid and algaroth powder, $\text{Sb}_2\text{O}_3\text{Cl}_2$ (Schäffer, *Zeitschr. f. Chem.* [2] iv. 606; further, *Ann. Ch. Pharm.* clii. 314).

A compound of *antimonic chloride* with *nitrous oxychloride*, $\text{SbCl}_5 \cdot \text{NOCl}$, is obtained by passing the vapour of nitrogen tetroxide into antimonic chloride. It forms a dry sulphur-yellow, very hygroscopic powder, which, when heated, volatilises without previous fusion, leaving a small quantity of antimonious oxide. The distillate solidifies in the crystalline form after complete cooling. It is decomposed by water, but dissolves without turbidity in aqueous tartaric acid (R. Weber, *Pogg. Ann.* cxxiii. 347).

Antimonic chloride likewise forms definite compounds with the higher chlorides of phosphorus, selenium, and sulphur. The compound $\text{SbCl}_5 \cdot \text{PCl}_3$ is produced by heating antimonious or antimonic chloride with phosphorus pentachloride, and remains, after distilling off the excess of the more volatile chlorides, as a slightly volatile, infusible, spongy yellow mass, which quickly absorbs water from the air. The compound with *phosphoric oxychloride*, $\text{SbCl}_5 \cdot \text{PCl}_3\text{O}$, separates on mixing antimonic chloride with an excess of phosphoric oxychloride, as a white, deliquescent, crystalline substance, which must be dried on a brick over sulphuric acid and lime. The *selenium compound*, $\text{SbCl}_5 \cdot \text{SeCl}_4$, is prepared by treating a mixture of 1 at. selenium and 1 at. antimony fused and cooled again, with chlorine, out of contact with air, and freeing the resulting whitish mass from excess of antimonic chloride by draining on a brick. Antimonious selenide treated with chlorine forms a pulverulent mass, which appears to be a mixture of the preceding compound with selenium chloride. The *sulphur compound*, $\text{SbCl}_5 \cdot \text{SCl}_2$, is formed, together with free sulphur, by the action of dry chlorine on antimonious sulphide, and remains, on warming the product, as a dry powder which dissolves in dilute nitric acid, without separation of sulphur (R. Weber, *Pogg. Ann.* cxxv. 78). H. Rose assigns to this last compound the formula $2\text{SbCl}_5 \cdot 3\text{SCl}_2$ (v. 636).

A *hydrate of antimonic chloride*, $\text{SbCl}_5 \cdot 4\text{H}_2\text{O}$, separates, when a solution of the chloride in the smallest possible quantity of water is left to stand over oil of vitriol, in deliquescent crystals, which may be recrystallised without decomposition from a small quantity of water. The trichloride does not form a hydrate under similar circumstances. A small quantity of water mixes with it, without turbidity, and a mixture of it with a somewhat larger quantity of water left to evaporate over oil of vitriol ultimately yields anhydrous crystals of antimonious chloride.

ANTIMONY FLUORIDES. *Antimonious fluoride*, SbF_3 , is obtained by dissolving antimonious oxide in hydrofluoric acid. The solution slowly evaporated between 70° and 90° deposits the compound in rhombic octohedrons; by more rapid evaporation it is obtained in prisms, and by still more rapid evaporation in presence of an excess of acid, in small scales. Antimonious fluoride is deliquescent, and has a sharply acid taste, with styptic after-taste; dissolves easily in water, forming a solution which does not become turbid on dilution. The solution, if evaporated

without addition of acid, deposits at a certain degree of concentration an insoluble powder, probably an oxyfluoride, which immediately redissolves on addition of hydrofluoric or hydrochloric acid; the same compound separates when the crystals deliquesce in the air, and when thus formed exhibits nearly the composition $2\text{SbF}_3 \cdot \text{Sb}_2\text{O}_3$ or $\text{Sb}_2\text{F}_3\text{O}_3$; it appears also to be produced by the action of hydrofluoric acid on an excess of antimonious oxide. Antimonious fluoride heated in a retort containing air yields a sublimate consisting of hard, very deliquescent crusts interspersed with slender needles, and leaves a copious residue of antimonious oxide (Flückiger, *Ann. Ch. Pharm.* lxxxiv. 248).

Antimonious fluoride unites with the fluorides of the alkali-metals, forming double salts containing 1, 2, and 3 mols. of alkaline fluoride to 1 mol. of antimonious fluoride; but the last-mentioned proportion is known only in the case of the sodium salt. These double fluorides decompose when heated in contact with the air, with formation of antimonious oxide. When wrapped up in a thin plate of sodium, and sharply struck, they decompose suddenly, with detonation and deflagration. The *ammonium-salt* $2\text{NH}_4\text{F} \cdot \text{SbF}_3$ is obtained by dissolving antimonious oxide and ammonium carbonate in excess of hydrofluoric acid and evaporating. It crystallises in anhydrous rhombic tables ($\infty\text{P} \cdot \infty\text{P} \cdot \text{I}'$) and prisms ($\infty\text{P} \cdot \bar{\text{P}} \infty \cdot \infty\text{P} \infty$, with the angle $\infty\text{P} : \bar{\text{P}} =$ about 88°). It absorbs water from moist air, and dissolves in 0.9 pt. water at ordinary temperatures, with production of cold. The solution is acid, attacks glass strongly, and is precipitated by alcohol and ether. The dry salt is infusible; does not give off ammonia at 140° , volatilises completely when quickly heated in an open platinum crucible, but is partly decomposed by slow heating, giving off ammonium fluoride, and leaving antimonious oxide. The *lithium salt* $2\text{LiF} \cdot \text{SbF}_3$ crystallises with difficulty in large ill-defined prisms requiring more than 20 pts. of water for solution. The *dipotassic salt* $2\text{KF} \cdot \text{SbF}_3$ is formed by dissolving 1 mol. of antimonious oxide and about 3 mol. of potassium carbonate in excess of hydrofluoric acid, and separates from the concentrated solution in small laminae, or by slow cooling, and especially when a saturated solution is evaporated at 60° – 70° , in large thin transparent rectangular laminae or tables. Sometimes also acute octohedrons or rhombic laminae are formed, which become opaque if left in the liquid for some days, but by solution or evaporation are converted into the ordinary crystals. Potassio-antimonious fluoride is acid, has a sour taste with astringent after-taste, dissolves in 9 pts. of water at 13° , and in less than 2 pts. at the boiling heat; insoluble in alcohol and ether. The dry salt does not lose weight at 120° ; it melts at a red heat, and solidifies on cooling to a radio-crystalline mass. It etches glass in the moist, but not in the dry state. The *monopotassic salt* $\text{KF} \cdot \text{SbF}_3$ is formed by dissolving 1 mol. of antimonious oxide and 1 mol. of potassium carbonate in hydrofluoric acid; the solution saturated while warm yields large hard rhombic crystals, which become turbid on exposure to the air, or by slower cooling in soft slender silky needles; it dissolves in $2\frac{1}{2}$ pts. water. The *sodium salt* $3\text{NaF} \cdot \text{SbF}_3$ is formed by mixing a solution of 1 mol. of antimonious oxide (Sb_2O_3) in excess of hydrofluoric acid, with 6 mol. of sodium fluoride (NaF), and separates on cooling in small shining transparent prisms. It melts when strongly heated, dissolves in 14 pts. of water at ordinary temperatures, and in 4 pts. at the boiling heat, forming an acid solution (Flückiger, *loc. cit.*).

Antimonic Fluoride. SbF_5 (Marignac, *Ann. Ch. Pharm.* cxlv. 237).—This compound is easily formed by dissolving antimonie hydrate in hydrofluoric acid, and remains on evaporation in a vacuum as a gummy mass; the solution, when evaporated by heat, leaves a white insoluble residue, apparently an oxyfluoride. By adding potash, soda, or ammonia to the solution acidulated with hydrofluoric acid, double fluorides are produced, which are very soluble, and crystallise with difficulty; they are permanent in the air in the solid state, but alterable in solution, and are partly converted by repeated evaporation into oxyfluorides. Their aqueous solutions are not precipitated by acids, alkalis, or hydrogen sulphide. They are not isomorphous with the corresponding double fluorides of tantalum and niobium.

Ammonio-antimonic fluoride, $\text{NH}_4\text{F} \cdot \text{SbF}_3$, forms needle-shaped hexagonal prisms acuminated with a rhombohedron, whose terminal edges form an angle of about 96° . The solution mixed with excess of ammonium fluoride and left to evaporate deposits the *diammonio salt* $2(2\text{NH}_4\text{F} \cdot \text{SbF}_3) \cdot \text{H}_2\text{O}$ in rectangular flattened prisms, exhibiting the combination $\infty\text{P} \cdot \infty\bar{\text{P}} \infty \cdot \infty\text{P}$, with P and several undeterminable faces subordinate. Angle $\infty\text{P} : \infty\text{P} = 9^\circ \cdot \infty\bar{\text{P}} : \infty\bar{\text{P}} = 134^\circ 25'$; $\infty\text{P} : \text{P} = 148^\circ 25'$.

The *monopotassic salt* $\text{KF} \cdot \text{SbF}_3$ crystallises in thin tablets from a solution of gummy potassium antimonate in aqueous hydrofluoric concentrated by evaporation. The solution mixed with excess of potassium fluoride and evaporated, yields the *dipotassic salt* $2\text{KF} \cdot \text{SbF}_3 \cdot 2\text{H}_2\text{O}$ in beautiful shining monoclinic prisms exhibiting the

combination $\infty P . \infty P \infty . [P \infty] . + P . - P . + 2P \infty . - 2P \infty$, the hemi-pyramids however occurring but rarely and subordinately. Angle $\infty P : \infty P = 58^\circ$; $\infty P : \infty P \infty = 119^\circ$; $\infty P \infty : [P \infty] = 91^\circ$; $[P \infty] : [P \infty]$ over the principal axis = $83^\circ 16'$; $-P : -P = 92^\circ 50'$; acute angle of the axes = $89^\circ 16'$. The salt melts at about 90° in its water of crystallisation, and dries up, with evolution of hydrofluoric acid, to a gummy mass no longer soluble in water.

Sodio-antimonie oxyfluoride, $NaF.SbOF^3.H_2O$, is obtained by adding sodium carbonate to a solution of antimonious fluoride containing free hydrofluoric acid, and crystallises by spontaneous evaporation in small deliquescent hexagonal prisms with rhombohedral or six-sided pyramidal summits. By adding hydrofluoric acid to a solution of this salt, and leaving the liquid to evaporate, *sodio-antimonie fluoride*, $NaF.SbF^3$, is obtained in cube-like forms, which however are double-refracting. It decomposes readily in solution, and on evaporation the oxyfluoride is again obtained.

ANTIMONY HYDRIDE. SbH^3 . *Stibine. Antimonetted Hydrogen.*—This gas has not yet been obtained pure, but only mixed with hydrogen. According to Th. Humpert (*Chem. Centr.* 1865, p. 86), a gas containing a rather large proportion of stibine is obtained by decomposing a concentrated solution of antimonious chloride with sodium amalgam, part of the stibine thus evolved being however immediately decomposed and coating the sides of the flask with a thick layer of antimony. Rieckher (*Jahresb.* 1867, p. 255) finds that when antimonious solutions are decomposed by zinc and dilute acid, the quantity of antimony precipitated as metal is to that evolved as stibine, in proportions varying from 95 : 8 to 96 : 4, so that only a small fraction passes off as stibine.

Stibine is decomposed by strong sulphuric acid (but more slowly than arsine, with evolution of hydrogen sulphide, and separation of a velvet-black powder containing antimony and hydrogen; also antimonious sulphide, if the passage of the gas into the acid be continued for a long time (Humpert, *loc. cit.*). According to Dragenlorff (*Zeitschr. anal. Chem.* v. 200), stibine, whether dry or moist, is decomposed by solid potassium hydrate, which thereby becomes covered with a metallically lustrous film, probably consisting of potassium antimonide, which quickly disappears in contact with water or moist air. Arsine, on the contrary, is not decomposed by potash. On passing a mixture of the two gases through a tube three or four inches long, containing lumps of potassium hydrate about as large as peas, the stibine is completely absorbed, while the arsine passes on unaltered. Drying tubes containing potash must therefore be avoided in the preparation of stibine, whereas the detection of arsenic as arsine in presence of antimony is simplified by their use. Potash-ley of sp. gr. 1.25 acts upon stibine in the same manner as the solid hydrate, though not so quickly.

Respecting the action of iodine on stibine, and the method founded thereon of distinguishing antimony from arsenic, see ARSENIC.

ANTIMONY IODIDES. Nicklès obtains *antimonious iodide*, SbI^3 , in the same manner as the bromide (p. 184). It forms red tabular crystals, permanent in the air, and consisting of the hexagonal combination of $P . P .$ &c.; basal angle of the double pyramid, 133° ; terminal, 120° . Schneider (*Pogg. Ann.* cix. 609) obtains this compound in crystals of considerable size by heating a mixture of 1 mol. antimonious sulphide and 6 at. iodine. An orange-red sulphidiode then sublimates at first, and condenses on the upper part of the flask in small laminae and needles, while the tri-iodide SbI^3 condenses on the lower and hotter parts of the flask in large, thin, poppy-red, hexagonal plates similar to those obtained by Nicklès; the compound is isomorphous with the tri-iodides of arsenic and bismuth. It dissolves slowly but completely in carbon bisulphide, and separates on cooling in small, sharply defined, shining laminae, of somewhat lighter colour than that obtained by sublimation. It is quickly decomposed by alkaline hydrates and carbonates, yielding pure antimonious oxide (Schneider).

Antimonious iodide forms double salts with the iodides of the more positive metals. They are prepared by adding pulverised antimonious iodide to warm saturated solutions of the several iodides, and evaporating the filtered solutions at mean temperatures. The *potassium salt* $3KI.2SbI^3.3H^2O$ forms dark black-brown rectangular laminae, ruby-red by transmitted light, becoming anhydrous at 100° , and then assuming a cinnamon-red colour. The *sodium salt* $3NaI.2SbI^3.12H^2O$ forms light orange-red rectangular prisms acuminate by four faces resting on the prismatic edges; it becomes anhydrous and orange-coloured at 100° . There are three *ammonium salts*. A warm saturated solution of 1 mol. of antimonious iodide in 3 mols. of ammonium iodide first deposits the salt $3NH^4I.4SbI^3.9H^2O$ in scarlet rectangular prisms, becoming crimson when anhydrous; then successively the following

salts: $3\text{NH}_4\text{I} \cdot 2\text{SbI}_3 \cdot 3\text{H}_2\text{O}$ in dark black-brown rectangular laminæ, ruby-red by transmitted light, resembling the potassium salt, becoming carmine-red when anhydrous; and $4\text{NH}_4\text{I} \cdot \text{SbI}_3 \cdot 3\text{H}_2\text{O}$, in large almost black rectangular prisms, acuminate with four faces resting on the prismatic edges, translucent with ruby-red colour in thin layers, carmine-red when anhydrous. The barium salt $\text{BaI}_2 \cdot \text{SbI}_3 \cdot 9\text{H}_2\text{O}$ forms translucent rhombic prisms of $105^\circ 32'$ with perpendicular end-faces, having a vitreous lustre, and translucent, with deep orange-red colour. All these salts are decomposed by water, with separation of antimonious oxy-iodide; they dissolve in hydrochloric and in acetic acids with yellow colour, in tartaric acid without colour, give up antimonious iodide to carbon bisulphide, and are decomposed by strong sulphuric acid, with separation of iodine and evolution of hydriodic acid. The compounds containing fixed metallic iodides are decomposed when heated in a tube, yielding a sublimate of antimonious iodide and a residuo of the fixed iodide; the ammonium salts sublime completely, with partial decomposition and separation of iodine-vapours (J. Schæffer, *Pogg. Ann.* cix. 611).

Nicklès (*Compt. rend.* li. 1097; *Jahresh.* 1860, p. 176) has described several groups of double salts of antimonious iodide, which he finds to be isomorphous with the corresponding bismuth-compounds. Among these he especially particularises two groups, viz. $\text{mI} \cdot \text{MI}_3 \cdot 2\text{H}_2\text{O}$ and $\text{mI} \cdot \text{MI}_3 \cdot \text{H}_2\text{O}$; also the corresponding bromides $\text{mBr} \cdot \text{MBr}_3 \cdot \text{H}_2\text{O}$ [where $\text{m} = \text{K}, \text{Na}, \text{or } \text{NH}_4$, and $\text{M} = \text{Sb or Bi}$]. The compounds containing $2\text{H}_2\text{O}$ crystallise in right rhombic prisms of 97° ; those with H_2O in right rhombic prisms of $135^\circ 35'$, with a dome and many secondary faces. The compounds prepared by Nicklès, some of which contain bismuth and antimony replacing one another isomorphously, are:

- | | |
|---|---|
| a. $\text{NH}_4\text{I} \cdot \text{SbI}_3 \cdot 2\text{H}_2\text{O}$ | ζ. $\text{NH}_4\text{Br} \cdot \text{BiBr}_3 \cdot \text{H}_2\text{O}$ |
| β. $\text{NH}_4\text{I} \cdot (\text{Bi}, \text{Sb})\text{I}_3 \cdot 2\text{H}_2\text{O}$ | η. $\text{NH}_4\text{Br} \cdot \text{Bi}(\text{Br}, \text{I})_3 \cdot \text{H}_2\text{O}$ |
| γ. $\text{NH}_4\text{I} \cdot \text{BiI}_3 \cdot \text{H}_2\text{O}$ | θ. $\text{KI} \cdot \text{SbI}_3 \cdot \text{H}_2\text{O}$ |
| δ. $\text{NaI} \cdot \text{BiI}_3 \cdot \text{H}_2\text{O}$ | ι. $\text{NaI} \cdot (\text{Bi}, \text{Sb})\text{I}_3 \cdot \text{H}_2\text{O}$ |
| ε. $\text{KI} \cdot \text{BiI}_3 \cdot \text{H}_2\text{O}$ | |

The compounds α, γ, δ, and ι were obtained by the action of iodine or bromine on antimony or bismuth, in presence of a saturated solution of ammonium, potassium, or sodium chloride; a double iodide or bromide then crystallises out, while a double chloride remains in solution. β crystallises from the mixed alcoholic solution of potassio antimonious iodide and ammonio-bismuthous bromide. θ crystallises, together with other compounds, from a solution of antimony in alcohol containing iodide or chloride of potassium; ζ from a solution of bismuth in alcohol or ether containing bromine and a little ammonium bromide. The crystals of α are red, of β black (red when pulverised); ζ forms yellow needles. These double salts are decomposed by water, and even by unsaturated solutions of alkaline chlorides, bromides, or iodides. Most of them are rendered turbid by alcohol, but ζ is soluble in that liquid. They give up the whole of their water over oil of vitriol, as well as when heated to 100° ; some, especially α and ζ, appear to undergo decomposition at that temperature. In violet light these double salts acquire a reddish colour, especially the bismuth-compounds, which are for the most part yellow, brown, or black; the black iodide of bismuth likewise turns red in violet light (Nicklès).

The isomorphism of corresponding bismuth and antimony compounds is also confirmed by Linnaus's investigations of certain double salts of bismuth iodide, which appear to have the same crystalline form as the analogous antimony-compounds examined by Schüffer. See BISMUTH.

Antimonic Iodide, SbI_5 , is formed, according to Van der Espt (*Arch. Pharm.* [2] cxvii. 115), by heating 1 pt. of antimony with 5 pts. of iodine; it then sublimes in red transparent laminæ, decomposable by water into hydriodic and antimonic acids. It is also said to be produced by passing antimonetted hydrogen into an alcoholic solution of iodine. But, as the crystals obtained by these processes have the same form as those of the triiodide (p. 186), these statements must be regarded as somewhat doubtful.

ANTIMONY OXIDES. *Antimonious oxide*, Sb_2O_3 , occurs in Borneo in the form of a yellowish or reddish-white compact mass, having a crystalline structure, and yielding a yellowish-white powder. Here and there it occurs in rhombic prismatic crystals, half an inch long, with dihedral summits, horizontally striated, and having a nacreous lustre. Sp. gr. 4.64 to 4.68. It appears to have been formed by oxidation of the trisulphide (antimony-glance), which is found imbedded in it (Phipson, *Compt. rend.* lii. 752). Hallett and Stenhouse have proposed the use of antimony tetroxide, Sb_2O_4 , prepared by roasting this native oxide, as a white

pigment. It has the advantage of not being blackened by hydrogen sulphide, but is inferior to zinc-white, barium sulphate, and white lead in whiteness and opacity (*Repertory of Patent Inventions*, 1861, Nov. p. 374; *Dingl. pol. J.* cxlii. 373; *Hofmann's Report*, 1862, p. 79).

W. Lindner (*Zeitschr. f. Chem.* [2] v. 442) prepares antimonious oxide by dissolving the native sulphide in a rather strong solution of ferric chloride containing a slight excess of hydrochloric acid. The antimony then dissolves in a very short time, without evolution of noxious gases, and the whole of the sulphur is precipitated. By diluting with water, and washing the resulting precipitate, a very pure algaroth powder is obtained, which when treated with soda yields pure antimonious oxide.

Antimonious oxide is obtained in the prismatic form by the action of water at 150° on the oxychloride (Debray, *Compt. rend.* lviii. 1209). According to Terreil (*ibid.* lxii. 302), the prismatic oxide is always produced in the combustion of the metal and in the roasting of antimonious sulphide; the octohedral form, on the other hand, when the prismatic oxide is sublimed at a dull red heat in non-oxidising gases; by rapid sublimation the octohedral crystals are reconverted into the prismatic. The two forms may be produced simultaneously by passing a slow stream of dry air through a porcelain tube containing a boat filled with metallic antimony, the tube being at first heated only where the metal is placed, but after a few hours likewise at the point where the prismatic oxide might condense. After the operation has been continued for 12 hours, prisms alone are found in the neighbourhood of the metal, prisms with implanted octohedrons at some distance further, and pure octohedrons at the end of the tube. These artificial oxides agree perfectly in their properties with the native varieties of the oxide (i. 323). The sp. gr. of the artificial prismatic oxide is 3.72, that of the native 3.70. The prismatic oxide is more easily attacked by reagents, and especially more readily dissolved by acids and alkalis than the octohedral oxide; ammonium sulphide colours it brown-red and finally dissolves it. The artificially prepared octohedral oxide has a sp. gr. of 5.11 (that of Senarmontite is 5.20); in the crystallised state it resists the action of ammonium sulphide, but is attacked by it when pulverised. The octohedral oxide, said to be obtained by crystallisation from alkaline solutions (i. 323), consists, according to Terreil, of hydrated sodium antimonite.

Antimonites.—A solution of antimonious oxide in caustic soda yields crystals of sodium antimonite containing 1 or 3 at. antimony to 1 at. sodium, according to the degree of concentration. The *mono-antimonite* $\text{NaSbO}_2 \cdot 3\text{H}_2\text{O}$ or $\text{Na}^+\text{O} \cdot \text{Sb}^3+\text{O}_3 \cdot 6\text{H}^+\text{O}$, which is the salt most frequently obtained, crystallises in octohedrons, apparently trimetric; they are colourless, have a strong lustre and a sp. gr. of 2.864. When heated they give off their water and become opaque. They dissolve with difficulty in boiling water, and separate almost completely as the solution cools. The solution, which is usually opalescent, has an alkaline reaction and is not precipitated by acids, alkalis, or alkaline earths; by barium chloride, only after addition of ammonia. With plumbic, cupric, mercurous, and ferric salts, it forms precipitates soluble in nitric acid; with argentic nitrate, a white precipitate which is soluble in dilute nitric acid, and is first turned brown by ammonia, then decolorised and dissolved. Hydrogen sulphide colours the aqueous solution yellow. The *triantimonite* $\text{Na}_3\text{SbO}_2 \cdot \text{Sb}_2\text{O}_3 \cdot \text{H}_2\text{O}$ or $\text{Na}_2\text{O} \cdot 3\text{Sb}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$ forms less easily than the mono-antimonite, and is obtained only from very concentrated alkaline solutions, in rather large crystals, also belonging to the trimetric system, and having a sp. gr. of 5.05. They are nearly insoluble in water. By ammonium sulphide, they are first coloured brown-red and then dissolved, a character which distinguishes them from the octohedral oxide. *Potassium antimonite* has not been obtained in crystals. Those which frequently separate from a solution of antimonious oxide in potash-ley consist of the sodium salt, and arise from the presence of soda in the potash-ley; they are also gradually formed on adding a sodium salt to a solution of pure potassium antimonite (Terreil).

Antimonic Oxide and Acid.—Antimonic oxide or acid is reduced by stannous chloride in acid solution to antimonious oxide (Streng, *Pogg. Ann.* xciv. 493); and this, according to Kessler (*Jahresb.* 1861, p. 265), is not further altered, even by boiling in a concentrated acid solution with excess of stannous chloride. According to Schiff (*Ann. Ch. Pharm.* cxi. 47; *Jahresb.* 1861, p. 277), antimonic acid treated with stannous chloride at ordinary temperatures is converted into a yellow substance, which, if the action be allowed to continue at 80° , becomes deeper in colour, and after about an hour's heating changes into red hydrated stannous antimonate, $\text{SnSbO}_4 \cdot 2\text{H}_2\text{O}$ or $\text{SnO} \cdot \text{Sb}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$, which becomes yellowish-grey when deprived of its water. There appears also to be a stannous di-antimonate, $\text{SnO} \cdot 2\text{Sb}_2\text{O}_4$. When anhydrous antimonic oxide is heated for 8 or 10 hours with stannous chloride to

35°–40° a yellow substance is obtained, agreeing approximately with the formula $2\text{SnO} \cdot 3\text{Sb}^{\circ}\text{O}^{\circ} \cdot 4\text{H}^{\circ}\text{O}$; anhydrous antimonious oxide did not yield a brick-red tin salt.

Potassium antimonate heated in vapour of carbon bisulphide yields a dark-brown product, probably consisting of potassium sulphantimonite, KSbS°_2 , formed according to the equation:

Ammonium antimonate is converted by heating with carbon bisulphide into a volatile ammonium polysulphide and fused antimonious sulphide (W. Müller, *Pogg. Ann.* cxxvii. 404).

ANTOZONE. See OZONE (iv. 302).

ANTOZONITE. A name applied by Schönbein to a variety of fluor-spar, found at Wülsendorf in the Bavarian Oberpfalz, and at Joachimsthal in Bohemia, in which Schrötter had demonstrated the presence of a small quantity of ozone, the mineral emitting the odour of ozone when heated, and liberating iodine from potassium iodide, and chlorine from sodium chloride. Schönbein supposed that it contained the electro-positive variety of oxygen, which he designated as antozone (*Jahresb.* 1860, p. 58; 1861, p. 1034; 1863, p. 842).

APPLE. See FRUIT (ii. 710).

APPLE-TREE BARK. The aqueous decoction of the root-bark of this tree yields with neutral lead-acetate a precipitate, the greater part of which dissolves in acetic acid. On decomposing the insoluble portion with hydrogen sulphide and evaporating the filtrate, a syrupy residue is obtained, which when treated with alcohol is resolved into insoluble pectin and a small quantity of a substance which crystallises from the alcoholic solution on evaporation in a vacuum. This last substance gives off 6.74 p. c. water at 100°, and its composition then agrees with the formula $\text{C}^{24}\text{H}^{30}\text{O}^{27} = \text{C}^6\text{H}^8\text{O}^6 + 3\text{C}^6\text{H}^8\text{O}^6$. The acetic acid solution of the lead precipitate yields with basic lead acetate a small additional quantity of the lead-compound of this body. The liquid filtered therefrom yields on addition of ammonia a copious precipitate; and by decomposing this precipitate in like manner with hydrogen sulphide and evaporating the filtrate, crystals of calcium-phloretin are first obtained, from which the phloretin (iv. 492) may be separated by hydrochloric acid. The mother-liquor separated from the calcium-compound yields with ammonium sulphide a precipitate from which (by solution in water containing acetic acid, precipitation with lead acetate, and decomposition of the washed precipitate with hydrogen sulphide) a tannin is obtained identical with that which is contained in horse-chestnut bark. The stem-bark of the apple-tree contains a yellow colouring matter (Reichler, *J. pr. Chem.* xlviii. 205; *Jahresb.* 1866, p. 694).

APHRODESEIN. A substance contained, according to Reichler, in the cotyledons of the horse-chestnut (iii. 172).

APIUM. When an aqueous extract of celery-root (*Apium graveolens*) is subjected to dialysis, a solution of pure mannite first passes through the parchment-paper, then a solution of extractive matter and potassium salts of vegetable acids, whilst a liquid remains behind, containing a substance intermediate in its properties between gum and pectin, and gelatinising when mixed with alcohol (H. Reinsch, *Jahresb.* 1863, p. 612).

APLYSIA. The colouring matter secreted by a vesicular organ of the sea-owl or lump-fish (*Aplysia depilans*), a gasteropod occurring on the coasts of the Mediterranean and of Portugal, is, according to Ziegler (*J. pr. Chem.* ciii. 63), a concentrated solution of aniline red and aniline violet. In the dissolved state this offensive-smelling colouring matter decomposes very readily. On precipitating it by sulphuric acid, and then again from alcoholic solution by common salt, a substance is obtained which exhibits all the reactions of aniline violet. The red colouring matter, which remains in solution after the precipitation by common salt, and may be separated by tannic acid, is, like fuchsine, decolorised by ammonia and turned red again by acetic acid.

APOCODEINE. See CODEINE.

APOMORPHINE. See MORPHINE.

APOSORBIC ACID. $\text{C}^6\text{H}^8\text{O}^6$.—An acid produced, together with severe modifications of tartaric acid, by the action of nitric acid upon sorbin. The acid syrup remaining after the dextro- and lævo-tartaric acids have been separated as completely as possible as acid ammonium salts, contains aposorbic and mesotartaric acids (v. 688) which may be separated, though not very completely, with calcium acetate and less

acetate. The apisorbic acid, which is contained chiefly in the lead precipitate, crystallises in confused laminæ, more rarely in thin acute rhombohedrons. It dissolves in 1·63 pts. water at 15°; does not lose weight at 100°; melts at about 110° with loss of water; boils and becomes coloured at 170°; and decomposes at 200°, leaving a black blistered mass, and yielding a distillate which does not contain pyrracemic acid.

Silver aposorbate, $C^8H^8Ag^2O^7$, does not crystallise. The calcium salt contains $C^8H^8Ca^2O^7 \cdot 4H^2O$, the lead salt $C^8H^8Pb^2O^7 \cdot PbO$. The ammonium salt, which crystallises in silky needles, is easily soluble, and is not precipitated either by potassium acetate or by mercuric nitrate; the calcium salt however, like the tartrate, is soluble in sal-ammoniac and in potash (Dessaigues, *Rép. Chim. pure*, v. 41; *Ann. Ch. Pharm. Suppl.* ii. 242).

AQUACREPTITE. A magnesio-ferrie silicate from Chester Co., Pennsylvania, so called from its property of disintegrating with decrepitation when thrown into water. It occurs in a narrow band of serpentine. It is compact, opaque, fragile, with slightly conchoidal fracture; adheres to the tongue; has a yellowish-brown colour, and yields an orange-yellow powder. Hardness = 2·5. Sp. gr. = 2·05–2·08. After calcination it dissolves in nitronitric acid, the silica however separating in flocks; gives by analysis 41·00–43·03, SiO^2 , 17·60–19·58 MgO , 12·30–13·30 ferrie oxide, 4·00–6·71 alumina, and 16 to 23 water (C.U. Shepard, *Sill. Am. J.* Sept. 1858, p. 256; *Bull. Soc. Chim.* [2] xi. 242).

ARACHIDIC ACID. $C^{20}H^{40}O^2$ (melting at 75°), is obtained nearly pure, together with a very small quantity of oleic acid, by saponifying the fat obtained from the kernels of the fruits of *Nephelium lappaceum*, an East Indian plant. This fat melts at 65°, and after recrystallisation at 68·5° (Oudemans, *J. pr. Chem.* xcix. 407; *Jahresb.* 1866, p. 696).

ARAUCARIA. In the juice of *Araucaria brasiliana*, which solidifies to a resin, Peckolt (*Chem. Centr.* 1865, p. 1070) found—besides gum, sugar, vegetable mucilage, and extractive-matter—a volatile oil smelling like oil of juniper, and several resins partly soluble in cold, partly in boiling alcohol.

ARBUTIN. $C^{12}H^{16}O^7$.—This substance, discovered by Kawaller in the leaves of the red bearberry, *Arctostaphylos Uva Ursi* (i. 354), has been further examined by Strecker (*Ann. Ch. Pharm.* cvii. 229), and by Zwenger and Himmelmann (*ibid.* cxxix. 203), who have likewise obtained it from the leaves of a species of winter-green, *Pyrola umbellata*. It is prepared by precipitating the aqueous decoction of the leaves of either of these plants with basic lead-acetate, filtering, removing the excess of lead with hydrogen sulphide, and either treating the filtrate with animal charcoal and leaving it to crystallise (Strecker), or evaporating and digesting the residue with a mixture of 8 pts. ether and 1 pt. alcohol, which dissolves out the arbutin, and deposits it on evaporation in the crystalline state (Zwenger a. Himmelmann).

Arbutin crystallises in tufts of colourless silky needles, having a bitter taste, easily soluble in alcohol and in boiling water, very sparingly soluble in ether, melting at 170°. When dried at 100° it exhibits the following composition:—

Calculation.	Analyses.					
	Kawaller.		Strecker.		Zwenger a. Himmelmann.	
C^{12} — 144 — 52·6	52·4	52·6	52·5	53·1	52·5	
H^{16} — 16 — 5·9	6·2	6·1	5·9	5·9	6·3	
O^7 — 112 — 41·5						
272 — 100·0						

Kawaller represented it by the formula $C^{12}H^{16}O^{18}$, requiring 52·5 C and 6·0 H; but this formula, though it agrees closely with his analyses, does not explain the transformations of arbutin so well as the formula $C^{12}H^{16}O^7$ proposed by Strecker.

Crystallised arbutin (air-dried) contains 51·0 p. c. carbon and 6·3 hydrogen, agreeing nearly with the formula $2C^{12}H^{16}O^7 \cdot H^2O$ (Strecker); the water of crystallisation (3·2 p. c.) goes off at 100°.*

The solution of arbutin is not precipitated by plumbic or ferrie salts, and does not reduce an alkaline solution of cupric oxide. When boiled with dilute sulphuric acid,

* Zwenger a. Himmelmann obtained, with arbutin prepared from winter-green (but not with that prepared from bearberry), crystals containing 2 at. or 11·7 p. c. water.

or subjected in aqueous solution to the action of emulsin, or of an analogous ferment contained in the bearberry, it is resolved into glucose and hydroquinone (Kawaler's arcturin):

Hydroquinone—but not its isomeride, pyrocatechin—is also found among the products of the dry distillation of arbutin (Zwenger a. Himmelmann).

The resolution of arbutin into glucose and hydroquinone is analogous to that of salicin, $C^{12}H^{18}O^7$, into glucose and saligenin, $C^6H^6O^2$. Salicin in fact differs from arbutin, and saligenin from hydroquinone by C^6H^6 (Strecker).

Arbutin oxidised with manganese dioxide and sulphuric acid, yields quinone, $C^6H^4O^2$, and formic acid. On passing chlorine through its aqueous solution, the liquid turns yellow or red, and after a while deposits yellow shining laminae of chlorinated quinone—probably a mixture of $C^6H^2Cl^2O^2$ and $C^6H^2Cl^4O^2$. It dissolves in strong nitric acid, and on adding alcohol to the liquid, yellow needles are deposited, which when purified by recrystallisation exhibit the composition of dinitro-arbutin, $(C^6H^4(NO^2)^2O^2)$. This substance is very soluble in water, less soluble in alcohol, insoluble in ether. It melts when heated and recrystallises on cooling. Its solutions are not precipitated by metallic salts. By boiling with acids, it is resolved into glucose, and an easily soluble crystallisable substance, probably consisting of dinitro-hydroquinone, $C^6H^4(NO^2)^2O^2$ (Strecker). The relations between salicin and arbutin may be represented by the following formulae:

The hydrogen in the hydroxyls of the glucosic portion of arbutin may in fact be replaced by acid radicles, just as in the case of salicin (Zeitschr. [2] v. 1, 52); moreover, the hydrogen belonging to the hydroquinone in arbutin is easily replaceable, whereas in salicin the hydrogen belonging to the saligenin is not capable of substitution.

Benzoyl-arbutins are obtained by means of benzoyl chloride; *acetyl-arbutins*, with acetyl chloride or acetyl oxide, which act at 60° – 80° . The ultimate products of the reaction separated from the resulting solutions, after cooling, by means of ether, contain free acid radicles, and have the following composition:

They are colourless bodies, insoluble in water, slightly soluble in ether, more soluble in hot alcohol, from which they crystallise on cooling in small shining needles. The acid radicles may easily be taken out again by boiling with weak bases. Together with the pentabenzoylated compound, Schiff likewise obtained *dibenzoyl-arbutin*, in which the hydrogen might be further replaced by acetyl.

Dinitro arbutin dissolves easily in acetic oxide, and is converted into

which may be separated from the acetic acid solution by water, and crystallised from hot alcohol in fine needles, insoluble in water, slightly soluble in ether. The alcoholic solution heated with sulphuric acid yields glucose, acetic ether, and dinitrohydroquinone, easily recognisable by the splendid colour which it gives with caustic alkalis. Dinitro-arbutin forms with basic lead acetate a crystalline orange-coloured lead-compound, in which the hydrogen of the hydroxyl is replaced by lead. Arbutin gives no precipitate, even with an ammoniacal solution of lead-acetate.

Recently precipitated silver oxide is reduced, even at ordinary temperatures, by an aqueous solution of arbutin. On adding freshly prepared silver carbonate to a solution of arbutin heated to 50° – 60° as long as carbonic acid is evolved, and heating for a short time with excess of the silver carbonate, a yellow solution is obtained, which no longer contains arbutin; but on separating the dissolved silver with a few drops of

hydrochloric acid, and filtering, a solution is obtained, from which alcohol precipitates white flocks consisting of a compound formed by the union of 2 mols. of arbutin minus 2 at. of hydrogen, viz.,

This compound may be regarded as the glucoside of quinhydrone (green hydroquinone); it is related to arbutin in the same manner as heliocidin to salicin. Glycoquinhydrone is not at all bitter; it forms acetyl-derivatives when treated with acetic oxide, and an orange-coloured nitro-product with nitric acid. The latter, when decomposed in alcoholic solution by sulphuric acid, does not yield any substance that turns violet with potash. By means of zinc and sulphuric acid, hydrogen may again be added, and dinitro-hydroquinone thereby produced (H. Schiff, *Zeitschr. f. Chem.* [2] v. 519).

ARBUTUS UNEDO. The ripe fruits of this tree contain a considerable quantity of inverted sugar, parapeetin, a yellow waxy substance, a colouring matter which is turned violet by alkalis and yellow by acids; also metapeptic acid and traces of starch (Filhol, *Compt. rend.* l. 1185).

ARCTUVIN. The name given by Kavalier to hydroquinone produced by the decomposition of arbutin (p. 191).

ARGENTACETYL-COMPOUNDS. Syn. with ARGENTOVINYL-COMPOUNDS. See ACETYLENE (p. 36).

ARGENTALLYLENE. See ALLYLENE (p. 97).

ARGYRÆSCITIN } See HORSE-CHESTNUT (iii. 172).
ARGYRÆSCIN }

ARIBINE. $\text{C}^{23}\text{H}^{20}\text{N}^4$.—A base extracted from the bark of *Araribra rubra*, a tree growing in Brazil. (See ADDITIONS, vol. v. p. 1087.)

ARISUTITE. A fluoride occurring in Greenland together with cryolite. It is a white, highly lustrous, crystallo-granular mineral, having a sp. gr. of 3.029 to 3.175 and the hardness of cryolite. It gives by analysis 51.03 p. c. fluorine, 17.87 aluminium, 23.00 sodium, 7.01 lime, 0.57 water, and 0.74 insoluble matter (= 100.22), agreeing nearly with the formula $\text{Al}^2\text{F}^6.2(\text{Ca};\text{Na}^2)\text{F}^2$ (Hagemann, *Sill. Am. J.* [2] xlii. 93).

ARNICA MONTANA. Both the root-stock and the flowers of this composite plant, which grows chiefly on upland meadows in the middle and south of Europe, are official. The root-stock has a faint aromatic odour, and a persistently sharp aromatic taste, slightly inclining to bitter. It contains resin, tannin, fat, colouring matter, and about 1 p. c. of a heavy yellowish volatile oil different from that which is contained in the flowers. According to Walz (*N. Jahrb. Pharm.* xiii. 175; *Jahresh.* 1860, p. 544), the oil from the root has the composition of hexyl caproate, $\text{C}^{12}\text{H}^{24}\text{O}^2$ or $\text{C}^6\text{H}^{12}.\text{C}^6\text{H}^{12}\text{O}^2$. The fat of the root contains, according to the same authority, a fatty acid, $\text{C}^{23}\text{H}^{36}\text{O}^2$, the magnesium salt of which may also be extracted from the leaves.

The flowers, which have a peculiar but not unpleasant odour, yield in the dry state from 1 to 2 tenths per thousand of volatile oil; in the fresh state a proportionally larger quantity. This oil has an acid reaction, a yellowish, bluish, or greenish colour, and smells like chamomile. Walz also found in the flowers two different resins, crystallisable fat and wax, tannin, and a yellow colouring matter.

The flowers, herb, and root of arnica contain also a yellow non-crystallisable bitter substance, which appears to be the active principle of the plant. This substance, arnicin, is easily soluble in ether, slightly soluble in water, and is precipitated from its alcoholic solution by tannin or by water; it has the characteristic odour and sharp taste of arnica. It is decomposed by dilute acids. Walz assigns to arnicin the formula $\text{C}^{20}\text{H}^{30}\text{O}^4$, which however requires confirmation. The flowers yield 1 p. c. less of it than the root-stock or the herb (Walz, *N. Jahrb. Pharm.* xiii. 175; xiv. 79; xv. 329; *Jahresh.* 1860, p. 544; 1861, p. 753).

According to Bastick (*J. Pharm.* [3] xix. 454), arnica flowers contain a non-volatile bitter alkaloid, arnicine, which is soluble in alcohol and ether, very slightly soluble

in water, decomposed by alkalis, but capable of forming crystallisable salts with acids. It was prepared by macerating the plant in alcohol acidulated with sulphuric acid, treating the solution with lime and afterwards with alkaline carbonates to separate resinous matters, agitating the filtrate with ether, and leaving the ethereal solution to evaporate.

Peretti (*Bull. della Correspondenza scient. di Roma*, 1861, No. 30) stated that *arnica* yields, by distillation with potash or lime, a peculiar volatile base; but Hesse (*Ann. Ch. Pharm.* cxxix. 254) has shown that the plant thus treated yields nothing but ammonia, with traces of trimethylamine.

AROMATIC SERIES. This term is applied to a group of compounds which range themselves round the hydrocarbons C^6H^{2n-6} . Originally given to the bodies of the benzoic group, on account of the aromatic odours possessed by some of them, as benzoic acid and bitter almond oil, it is now extended to several series of compounds homologous with these.

The aromatic compounds form a group running parallel, as it were, with the fatty bodies, and like the latter including hydrocarbons, alcohols, acids, amines, &c. They resemble the fatty bodies in many of their chemical relations, but they likewise exhibit decided peculiarities, which distinguish them from all other bodies and mark them as a natural family.

Transformations of fatty bodies into compounds belonging to the aromatic group by simple and definite reactions are not known to occur. It is true that particular aromatic bodies, as benzene and phenol, may be formed by the action of a strong heat on many compounds, and even very simple ones, belonging to the fatty series; but these are not, for the most part, simple metamorphoses in which the quantitative relations between the material and the product can be exactly estimated and the transformations represented by equations. On the other hand, aromatic substances when treated with powerful chemical reagents, especially oxidisers, frequently yield bodies belonging to the fatty series; but even in these cases there is always formed, in addition, at least one product belonging to the aromatic series, unless indeed a complete breaking up of the molecule takes place, resulting in the formation of the very simplest organic compounds, such as carbonic acid and oxalic acid.

To obtain an insight into the constitution of the aromatic bodies, the following facts must be taken into account.

The aromatic bodies are derived from the fundamental hydrocarbons, C^6H^{2n-6} , and the simplest of them are those which contain 6 atoms of carbon, or are derived from benzene, C^6H^6 . Now these hydrocarbons are far from containing the maximum quantity of hydrogen required to saturate the n atoms of carbon contained in their molecules; in fact, if the carbon-atoms were united together in these molecules in the same manner as in the fatty series, the general formula of the saturated hydrocarbons would be C^6H^{2n+2} , and the compounds C^6H^{2n-6} would be octivalent radicles, capable of taking up 8, 6, 4, or 2 additional atoms of hydrogen or other monatomic element; and in fact they are capable, under certain circumstances, of uniting directly with chlorine, bromine, and other haloid elements: thus benzene forms with chlorine a crystalline hexachloride, $C^6H^6Cl^6$. But in the greater number of their chemical relations, these hydrocarbons exhibit the characters of saturated molecules, which, like the paraffins, can take up other elements only in exchange for a part or the whole of their hydrogen.

To account for this property, Kekulé supposes* that the atoms of carbon in benzene, the fundamental hydrocarbon of the series, are united among themselves by one and two units of equivalence alternately, so that the constitution of this body is represented by the formula:

* *Lehrbuch der organischen Chemie*, II. 196, et seq.

In the molecule thus represented, each of the carbon-atoms has all its four units of affinity satisfied, and the six carbon-atoms form, as it were, a closed chain or circle. We shall see in the sequel that from this formula of benzene the formulæ of nearly all the known bodies of the aromatic group can be formed by substitution, and that the formulæ thus obtained afford satisfactory explanations of the modes of formation and transformation, and of the isomeric relations of these bodies.

The sexvalent character of the benzene molecule might be explained by many other modes of linking together of the carbon-atoms, besides that proposed by Kekulé. Consider, for example, the modes of connection illustrated by the three following diagrams (the carbon-atoms being supposed to occupy the angles of the hexagon) :

In the first and second of these modes of grouping, every carbon-atom is linked to three others, to each by one unit of affinity, and therefore, as in the arrangement previously considered, each has one unit free; in the third figure, the first and fourth carbon-atoms are linked to three others (two adjacent and one opposite), each by one unit of affinity, while the carbon-atoms 2, 3, 5, and 6 are each connected with two others, by one and by two units of affinity. The last arrangement differs therefore from the rest in not being symmetrical. It has been suggested as affording an explanation of a peculiar case of isomerism among the chlorinated derivatives of benzene, viz. the existence of two modifications of pentachlorobenzene, C^5HCl^5 . Now according to the mode of linking of the carbon-atoms in Kekulé's diagram, or indeed in any other perfectly symmetrical arrangement, there should be but one such compound, inasmuch as the result must be the same whichever of the hydrogen-atoms of the benzene molecule is left in its place while the others are replaced by chlorine. But if we suppose the carbon-atoms to be linked as in diagram No. III. the properties of the molecule, C^5HCl^5 , may be different accordingly as the remaining hydrogen-atom is situated, on the one hand, at 1 or 4, or, on the other, at 2, 3, 5, or 6. It must be observed, however, that the existence of the two modifications of pentachlorobenzene is not positively established, and, on the whole, the phenomena exhibited by aromatic bodies are best explained by supposing the carbon-atoms in the benzene molecule to be linked together symmetrically. The arrangements represented in the other two diagrams above given (Nos. I. and II.) exhibit this symmetry as well as that of Kekulé; but they do not explain so readily as the latter the formation of the additive compounds of benzene and the other aromatic hydrocarbons (p. 196) (Kekulé, *Deut. Chem. Gesells.* Berlin, 1869, p. 362).

Benzene, the fundamental hydrocarbon of the aromatic group, gives rise to a numerous series of derivatives, by taking up other elements or compound radicles in exchange for one or more of its hydrogen-atoms. If the element which thus enters the molecule is monatomic, it simply takes the place of the hydrogen, satisfying the affinity of the carbon-atoms in the same way: thus, when benzene is acted upon by bromine or chlorine, one or more hydrogen-atoms are removed in the form of hydrobromic or hydrochloric acid, and bromobenzenes or chlorobenzenes are produced, viz. C^6H^5Br , $C^6H^4Br^2$, $C^6H^3Cl^3$, &c. But if the element which replaces the hydrogen is polyatomic, as O , N , or C , only one of its units of affinity can be satisfied by combination with the unit of affinity of the carbon-atom which was previously satisfied by the displaced hydrogen, and consequently the polyatomic element can bring other atoms of hydrogen, or of equivalent elements or radicles, into the molecule to satisfy its remaining units of affinity. (See ATOMICITY.) Thus oxygen, which is diatomic or bivalent, brings with it one atom of hydrogen, the result being the same as if an atom of hydrogen in the benzene molecule were replaced by the univalent radicle hydroxyl, OH . The product thus formed is a phenol, monatomic, diatomic, or triatomic, according to the number of hydrogen-atoms replaced: thus

Phenol.

Hydroquinone.

Pyrogallol.

In like manner, nitrogen, entering as a trivalent element, introduces two atoms of hydrogen, the result being the replacement of one or more atoms of hydrogen in the benzene molecule by amidogen, (NH^2) . In this manner are formed from benzene, amidobenzene or aniline, $\text{C}^6\text{H}^5(\text{NH}^2)$, and diamidobenzene or phenylenediamine, $\text{C}^6\text{H}^4(\text{NH}^2)^2$.

Aniline.

Phenylene-diamine.

In the nitrobenzenes the nitrogen may be supposed to enter either as a trivalent or as a quinquivalent element: thus mononitrobenzene, $\text{C}^6\text{H}^5(\text{NO}^2)$, may be represented by either of the following formulæ:

Lastly, *carbon*, which is quadrivalent, brings into the benzene molecule three atoms of hydrogen, the result being the replacement of one or more hydrogen-atoms in the benzene by the univalent radicle methyl, CH^3 , or the addition of one or more equivalents of CH^3 , whereby there is formed a series of hydrocarbons homologous with benzene: thus

C^6H^6	Benzene.
C^6H^5 or $\text{C}^6\text{H}^4(\text{CH}^3)$	Methyl-benzene or Toluene.
C^6H^4 or $\text{C}^6\text{H}^3(\text{CH}^3)^2$	Dimethyl-benzene or Xylene.
C^6H^3 or $\text{C}^6\text{H}^2(\text{CH}^3)^3$	Trimethyl-benzene.

The three unattached units of affinity in the carbon-atom which enters the benzene-molecule may also be partly satisfied by a bivalent radicle, or wholly by a trivalent radicle, as in the following compounds:

$(\text{C}^6\text{H}^5)-\text{C}\begin{Bmatrix} \text{O}^+ \\ \text{H} \end{Bmatrix}$	Benzoic aldehyde.
$(\text{C}^6\text{H}^5)-\text{C}\begin{Bmatrix} \text{O}^+ \\ \text{OH} \end{Bmatrix}$	Benzoic acid.
$(\text{C}^6\text{H}^5)-\text{C}\begin{Bmatrix} \text{S}^+ \\ \text{OH} \end{Bmatrix}$	Thiobenzoic acid.
$(\text{C}^6\text{H}^5)-\text{CN}^{\sim}$	Cyanobenzene or Phenyl cyanide.

Under certain circumstances also the aromatic hydrocarbons can take up other molecules by direct addition. Thus benzene, when subjected to the action of chlorine or bromine in sunshine, combines directly with those elements, forming the compounds $C^6H^6Cl^2$ and $C^6H^6Br^2$. In this case we may suppose that the chlorine or bromine acts in such a manner as to loosen the bonds of connection between some of the carbon-atoms, so that the atoms of the entire chain become united by one bond only, and each of them has one unit of affinity left free and ready to take up an atom of chlorine or bromine, thus (the dots in the second figure indicating unsaturated affinities):

This partial separation of carbon-atoms, or opening out of the group, is not peculiar to the aromatic bodies, but frequently takes place in other series. Ethylene, for example,

in the free state may be regarded as \parallel , its two carbon-atoms being linked together by two units of affinity; but under the influence of chlorine or bromine, the connection is partially severed, and the molecule becomes $\begin{array}{c} CH^2 \\ | \\ CH^2 \end{array}$, in which state it is bivalent,

and capable of taking up 2 at. chlorine, forming the compound $\begin{array}{c} CH^2Cl \\ | \\ CH^2Cl \end{array}$.

In the explanation thus afforded of the formation of additive compounds, the formula of benzene proposed by Kekulé has the advantage of all the others above considered, inasmuch as if any one of the latter be adopted, we must suppose that chlorine or bromine can sever the connection between carbon-atoms united by only one unit of affinity, an effect of which no example has yet been observed in other series.

The aromatic hydrocarbons can also unite directly with *hypochlorous acid*. Benzene, for example, can take up 3 molecules of this acid, forming the crystalline compound $C^6H^6\{Cl^2(OH)\}^3$ (Carius, *Ann. Ch. Pharm.* cxxvi. 195; cxxvii. 324).

Isomerism in the Aromatic Series.

The replacement of one atom of hydrogen in benzene by chlorine, bromine, hydroxyl, amidogen, methyl, &c., must evidently yield the same result, whichever of the hydrogen-atoms may be thus replaced, inasmuch as the molecule is perfectly symmetrical. Accordingly there is but one monochlorinated or monobrominated benzene, one monatomic alcoholic derivative, viz. phenol, $C^6H^5(OH)$, one monatomic amidated derivative, viz. aniline, $C^6H^5(NH^2)$, one monomethyl derivative, viz. toluene, $C^6H^5(CH^3)$, &c.

But when two or more atoms of hydrogen in the benzene molecule are thus replaced, isomeric modifications become possible, accordingly as the elements or radicles which take the place of the hydrogen are contiguous, or are separated from one another by smaller or larger intervals. This will be more clearly understood if we represent the molecule of benzene by a hexagon, the six angles of which are occupied by the hydrogen-atoms numbered from 1 to 6. It will then be seen that the derivatives formed by successive substitution exhibit the following modifications:

AROMATIC SERIES.

157

a. The hydrogen-atoms are successively replaced by the same element or compound radicle (lateral chain). In this case the number of modifications is as follows:—

	Number of hydrogen-atoms replaced	Number of modifications	Places of the replaced H-atoms.
a	one	one	1
b	two	three	1,2 1,3 1,4
c	three	three	1,2,3 1,2,4 1,3,5
d	four	three	1,2,3,4 1,2,4,5 1,3,4,5
e	five	one	1,2,3,4,5
f	six	one	

b. The hydrogen-atoms are replaced by different elements or radicles.

If only two hydrogen-atoms are thus replaced, the number of possible modifications remains the same as above, viz. three: for the reversal of the order (AB or BA) can make no difference in the result.

But if three or more hydrogen-atoms are replaced by different radicles, the number of possible modifications becomes larger, inasmuch as the order of succession of the radicles introduced by substitution may then exert an influence on the nature of the product. Thus for a benzene-derivative represented by the general formula $C^6H^3A^2B$ we find:

α ,	corresponding to 1, 2, 3 (see c above);	$C^6H^3A^2B$ C^6H^2ABA
β ,	" 1, 2, 4 (");	C^6H^2AHAB C^6H^2AHBA C^6H^2BHAA
γ ,	" 1, 3, 5 (");	C^6H^2AHAB C^6H^2AHBA C^6H^2BHAH

In the present state of our knowledge, we cannot in all cases assign to the several radicles which replace the hydrogen in benzene their exact relative positions in each isomeric modification; but, inasmuch as a given modification of a benzene-derivative may in many cases be converted by simple metamorphoses into a particular modification of another benzene-derivative, we may conclude that in the two derivatives thus producible one from the other, the radicles which have replaced two or more atoms of hydrogen occupy corresponding places. Accordingly, the derivatives of benzene containing a given number of replaced hydrogen-atoms may be divided into groups, each containing those modifications which can be formed one from the other, and in which, therefore, the radicles which have replaced the hydrogen-atoms may be supposed to be similarly situated.

The bi-derivatives of benzene, e.g. bichlorobenzene, $C^6H^4Cl_2Cl$, chlorobromobenzene, C^6H^4ClBr , chlorophenol, $C^6H^4Cl(OH)$, chlorobenzoic acid, $C^6H^4Cl(CO^2H)$, &c., may be divided into three such groups, in which the radicles replacing the two hydrogen-atoms occupy the places (1 : 2), (1 : 3), and (1 : 4) respectively, or, in other words, are placed contiguously, or separated by one or by two atoms of hydrogen.* Chlorobromobenzene, for example, exhibits the three following modifications:

$C^6H^4HHCIBr$	$C^6H^4HHHCIBr$	$C^6H^4HCIBHBr$
1 : 2	1 : 3	1 : 4

the hydrogen-atoms in the benzene molecule C^6H^6 being numbered from right to left.

Similar examples are afforded by the three diatomic phenols $C^6H^3\{OH\}_2$ viz. hydroquinone, pyrocatechin, and resorcin; the three modifications of the acid $C^6H^3\{OH\}_2CO^2H$, viz. oxybenzoic acid, salicylic acid, and para-oxybenzoic acid; and those of the amidated acid $C^6H^3\{NH^2\}_2CO^2H$, viz. amidobenzoic acid, amidosalicylic or anthranilic acid, and amidodracrylic acid.

* It is clear that these are all the possible arrangements, inasmuch as (2 : 3), (3 : 4), (4 : 5), (5 : 6), and (6 : 1) are identical with (1 : 2); (2 : 4), (3 : 5), and (4 : 6) with (1 : 3); (2 : 5) and (3 : 6) with (1 : 4).

The manner in which the members of a particular group are producible one from the other may be illustrated by the following examples:

Iodaniline prepared from nitro-iodobenzene is converted by treatment with nitrous acid, into diazo-iodobenzene, $C^6H^4N^2I$, from which, by boiling its sulphate with water, iodophenol, $C^6H^4I(OH)$, is produced; and this, when fused with potash, is converted by exchange of I for OH into hydroquinone, $C^6H^4(OH)^2$. From the same diazo-iodobenzene may also be obtained di-iodobenzene, $C^6H^4I^2$, chloriodobenzene, C^6H^4ClI , and bromiodobenzene. All these derivatives of benzene belong to the same group, the replacement of the hydrogen in them occurring in corresponding places. The nitraniline* obtained from nitrated anilides (iv. 445) yields a diazo-derivative, the decomposition of which yields the same nitro-iodobenzene as that above mentioned; it therefore belongs to the same series. Moreover, since chloraniline and bromaniline are evidently analogous to iodaniline, and their generators, nitrochlorobenzene and nitro-bromobenzene, are analogous to nitro-iodobenzene, these bodies, and therefore also all bi-derivatives of benzene which can be obtained from them by simple transformation, belong to the same series; consequently, diazo-chlorobenzene, dichlorobenzene, chlorobromobenzene, diazobromobenzene, and dibromobenzene. To the same group belong nitrobenzoic acid, formed by the action of fuming nitric acid on benzoic acid; amidobenzoic acid, obtained from it by reduction; and oxybenzoic acid, formed from the latter by the action of nitrous acid. This series of bi-derivatives of benzene is called the *Ortho*-series.

A second series of bi-derivatives of benzene—the *Para*-series—is produced from dinitrobenzene. From this compound is obtained *para*-nitraniline,† which may be converted into para-diazonitrobenzene, and from this may be prepared parachloronitrobenzene, parabromonitrobenzene, and para-iodo-nitrobenzene. These last compounds may be converted by reducing agents into parachloraniline, parabromaniline, and para-iodaniline, which again may be converted into the corresponding paradiazobenzenes. The paradiazo-iodobenzene thus obtained is converted by decomposing its sulphate with water into para-iodophenol, which when fused with potash yields resorcin, $C^6H^4(OH)^2$, isomeric with hydroquinone. In all these bi-derivatives of benzene the substitution evidently takes place in corresponding parts of the molecule. To the same series belong paranitrobenzoic or nitrodacrylic acid, formed by oxidation of bromotoluene; also its reduction-derivative, amidodacrylic acid, and paraoxybenzoic acid, produced from the latter by the action of nitrous acid (iv. 353).

The third series of bi-derivatives of benzene—the *Meta*-series—includes salicylic acid and its derivatives, chlorosalicylic, amidosalicylic, or anthranilic acid; also an iodophenol different from para- or ortho-iodophenol, formed, together with the latter, by treating phenol with iodine and iodic acid, and converted by fusion with potash into pyrocatechin.

The question as to the relative positions of the radicles in these three groups of compounds—whether, for example, the arrangement 1 : 2 exists in the ortho-, the meta-, or the para-series, has lately been the subject of considerable discussion, and may now be regarded as at least approximately settled.

Phthalic acid, $C^6H^4 \begin{Bmatrix} CO^2H \\ CO^2H \end{Bmatrix}$, is formed by oxidation of naphthalene, $C^{10}H^8 = C^6H^4(C^4H^2)$, two of the four groups CH being completely eliminated from the molecule in the form of carbon dioxide and water, while the two others remain in the form of carboxyl, CO^2H :

Now, from the structure of the molecule of naphthalene, as recently determined by Grube (p. 212), it appears most probable that the two groups CH thus oxidised to CO^2H occupy contiguous places; that is to say, the positions 1 : 2. But nitrophthalic acid is converted by reduction with tin and hydrochloric acid into amidobenzoic acid, which, when treated with nitrous acid yields oxybenzoic acid, and these compounds belong to the ortho-group. In this group, therefore, the radicles which replace two of the hydrogen-atoms of the benzene molecule occupy contiguous places, that is 1 : 2. This conclusion is corroborated by the constitution of hydroquinone, $C^6H^4 \begin{Bmatrix} OH \\ OH \end{Bmatrix}$, which is formed from ortho-iodophenol, and is converted by oxidation

into quinone, $C^6H^4 \begin{Bmatrix} O \\ \diagup \quad \diagdown \\ O \end{Bmatrix}$, whereas its isomerides, pyrocatechin and resorcin, do not yield quinone by oxidation; this difference of reaction points to the conclusion that

* Hofmann's β -nitraniline (iv. 445).

† Hofmann's α -nitraniline (iv. 445).

the two groups OH are contiguous in hydroquinone, and not in its two isomerides. (See QUINONE.)

Baeyer has shown (*Ann. Ch. Pharm. Suppl.* v. 79) that mesitylene, C^6H^3 , is a symmetrically constituted trimethyl-benzene, $C^6H^3(CH^3)^3$, that is to say that the three methyl-groups contained in it are separated by equal intervals, or occupy the positions 1, 3, 5. Consequently in isoxylene or dimethyl-benzene, $C^6H^4(CH^3)^2$, which is formed from it (from mesitylenic acid), the two methyl-groups must be separated by one interval, or occupy the places 1, 3. Now isoxylene is converted by oxidation into isophthalic acid, $C^6H^4(CO^2H)^2$, in which therefore the two groups CO^2H occupy the positions 1, 3. Hence for the third modification of the acid, $C^6H^4(CO^2H)^2$, or terephthalic acid, there remains only the arrangement 1, 4. But terephthalic acid belongs to the para-series, being formed from bromotoluene, $C^6H^4Br(CH^3)$, which is convertible by oxidation into parabromobenzoic or bromodiacrylic acid. In the para-series, therefore, the elements or radicles which replace the hydrogen-atoms occupy the positions 1, 4; so that for the meta-series there remains only the position 1, 3. The principal representatives of the three series are the following:

Ortho 1, 2	Meta 1, 3	Para 1, 4
Hydroquinone.	Pyrocatechin.	Resorcin.
Oxybenzole acid.	Salicylic acid.	Para-oxybenzole acid.
Phthalic acid.	Isophthalic acid.	Terephthalic acid.

Further developments of these views will be given in connection with the individual compounds of the aromatic series. See especially BENZENE, HOMOLOGUES OF, and BENZOIC ACID.

The bodies of the aromatic series exhibit also another kind of isomerism distinct from that above described. Consider first the hydrocarbons. Benzene and toluene are not susceptible of isomeric modifications: for the first is perfectly symmetrical, and in the formation of the second, or methyl-benzene, $C^6H^5(CH^3)$, the substitution of methyl for hydrogen may take place indifferently in any part of the molecule. But any further substitution of methyl for hydrogen may be made either within the phenyl-group C^6H^5 , or in the methyl-group CH^3 , and the result will not be the same in the two cases; hence the hydrocarbon C^8H^{10} exhibits the two modifications, dimethyl-benzene or xylene, $C^6H^4(CH^3)^2$, and ethyl-benzene, $C^6H^5(CH^2CH^3)$:

In molecules thus constituted, the six carbon-atoms of the benzene group, with their accompanying hydrogen-atoms, are said to form the principal chain, while the alcohol-radicles or their modifications substituted for any of these hydrogen-atoms constitute lateral chains; thus methyl-benzene and ethyl-benzene have each only one lateral chain, whereas dimethyl-benzene has two.

The constitution of these hydrocarbons is determined: *a. By synthesis.*—Thus toluene is produced by the action of sodium on a mixture of bromobenzene and methyl-iodide: hence it has the constitution of methyl-benzene:

Ethyl-benzene is formed in like manner from bromobenzene and ethyl-iodide. Xylene, which is a constituent of light coal-naphtha, is produced synthetically by the action of sodium on a mixture of bromo-toluene and methyl-iodide; hence it consists of methyl-toluene or dimethyl-benzene:

B. By oxidation.—Methyl-benzene and ethyl-benzene both yield by oxidation benzoic acid, $C^6H^5.CO^2H$, which, like these hydrocarbons themselves, contains only one lateral chain; but dimethyl-benzene (xylene) and methyl-ethyl-benzene, when oxidised with

dilute chromic acid, yield terephthalic acid, $C^8H^4 \left\{ \begin{smallmatrix} CO^2H \\ CO^2H \end{smallmatrix} \right\}$ which contains two lateral chains. Hence it is inferred that the acid or acids produced by the oxidation of an aromatic hydrocarbon contain as many lateral chains as the hydrocarbon itself. This law affords the means of determining the constitution of certain aromatic hydrocarbons which have not yet been formed synthetically, as in the following cases:

The hydrocarbon C^9H^{12} exhibits the three following modifications:

$C^9H^4(C^3H^7)$
Propyl-benzene.

$C^9H^4(CH^3)(C^2H^5)$
Methyl-ethyl-benzene.

$C^9H^4(CH^3)^3$
Trimethyl-benzene.

All three have been prepared synthetically: the first, by the action of sodium on a mixture of monobromobenzene and normal propyl-iodide; the second, in like manner from monobromo-toluene and ethyl-bromide; the third, from monobromoxylene and methyl-iodide. This last compound, also called *coal-tar cumene* or *pseudocumene*, exists in coal-tar oil, and is obtained therefrom by fractional distillation; it boils at about 166° ; methyl-ethyl-benzene at 159° ; propyl-benzene at 157° . Coal-tar cumene is not however a perfectly definite substance, but a mixture of three isomeric modifications of trimethyl-benzene differing from one another in the relative position of the methyl-atoms. (See BENZENE, HOMOLOGUES OF.) Cumene produced by distilling cumic acid with excess of lime boils at 151° – 151.5° , and is therefore different from either of the preceding compounds. Nevertheless, it agrees with propyl-benzene, $C^9H^4 \cdot CH^2CH^2CH^3$, in yielding only benzoic acid by oxidation, and therefore contains but one lateral chain: hence it may be supposed to consist of isopropyl-benzene, $C^9H^4 \cdot CH(CH^3)^2$, a view of its constitution which is in accordance with its lower boiling point; but isopropyl-benzene has not yet been prepared synthetically (Fittig, Schäffer & König, *Ann. Ch. Pharm.* cxlix. 324). All the higher aromatic hydrocarbons containing the radicle C^9H^7 are susceptible of similar modifications.

The following table exhibits the metameric modifications of all the aromatic hydrocarbons, C^9H^{2n-6} , at present known:

C^6H^6 Benzene.				
C^8H^8	$C^8H^8(CH^3)$ Methyl-benzene * (toluene).			
C^8H^{10}	$C^8H^8(CH^2CH^3)$ Ethyl-benzene. *	$C^8H^4(CH^3)^2$ Methyl-toluene * (xylene).		
C^9H^{12}	$C^9H^4(C^3H^7)$ Propyl-benzene * (cumene).	$C^9H^4 \left\{ \begin{smallmatrix} CH^3 \\ C^2H^5 \end{smallmatrix} \right\}$ Ethyl-toluene. *	$C^9H^4(CH^3)^3$ Trimethyl-benzene * (pseudocumene).	
$C^{10}H^{14}$		$C^9H^4 \left\{ \begin{smallmatrix} C^3H^7 \\ C^2H^5 \end{smallmatrix} \right\}$ Methyl-propyl-benzene * (α cymene).	$C^9H^4 \left\{ \begin{smallmatrix} (CH^3)^2 \\ C^2H^5 \end{smallmatrix} \right\}$ Ethyl-xylene. *	$C^9H^4(CH^3)^4$ β cymene (from coal-tar).
$C^{11}H^{16}$	$C^9H^4(C^3H^7)^2$ Amyl-benzene. *		$C^9H^4 \left\{ \begin{smallmatrix} CH^3 \\ (C^2H^5)^2 \end{smallmatrix} \right\}$ Diethyl-xylene (laurene).	
$C^{12}H^{18}$		$C^9H^4 \left\{ \begin{smallmatrix} CH^3 \\ C^3H^7 \end{smallmatrix} \right\}$ Amyl-toluene.		
$C^{13}H^{20}$			$C^9H^4 \left\{ \begin{smallmatrix} (CH^3)^2 \\ C^3H^7 \end{smallmatrix} \right\}$ Amyl-xylene. *	

* The hydrocarbons with asterisks attached to their names are those which have been formed synthetically.

The constitution of these hydrocarbons is determined on the principles above explained. Some of them, viz. dimethyl-benzene and trimethyl-benzene, are also known to exhibit isomeric modifications depending on the relative position of the methyl-atoms. Their modes of formation and properties will be described in detail in the article BENZENE, HOMOLOGUES OF.

The hydrocarbon C^6H^5 , formed by abstraction of $2HCl$ from methyl-benzylal chloride, $C^6H^5Cl^2$ (with alcoholic potash), and in other ways (p. 5), is also related to the aromatic group, though it does not belong to the homologous series C^6H^{2n-2} , having the composition of acetenyl-benzene, $C^6H^5(C^2H)$.

The derivatives of toluene and its higher homologues, formed by replacing one or more atoms of hydrogen with chlorine, bromine, hydroxyl, amidogen, &c., likewise exhibit the isomerism or metamerism just noticed in the hydrocarbons, depending upon the position of the substituted radicle in the principal or in one or more of the lateral chains. Thus toluene or methyl-benzene, $C^6H^5.CH^3$, forms two monochlorinated derivatives, viz.,

and three dichlorinated derivatives, viz.,

and the higher derivatives admit of still more numerous modifications. Similarly with the bromides and iodides. (See *TOLUENE*, v. 852.)

Those derivatives in which the substitution of the chlorine, &c., takes place in the lateral chains are altogether more active compounds than those in which it takes place in the principal chain. It fact, the chlorine in such a compound as benzyl chloride, $C^6H^5.CH^2Cl$, occupies a position similar to that which it takes up in the chlorinated compounds of the fatty series, so that the compound in question is an alcoholic chloride, capable of readily exchanging its chlorine for other radicles by double decomposition, and being thereby converted into the corresponding alcohol, amine, ethers, &c. On the other hand, the chlorine or other haloid element which takes the place of hydrogen in the principal chain, as in chlorotoluene, $C^6H^4Cl.CH^3$, dichlorotoluene, $C^6H^3Cl^2.CH^3$, &c., is more surrounded by carbon-atoms, like the chlorine-atoms in the corresponding derivatives of benzene itself; and under these circumstances the compound is found to be more stable, the chlorine, bromine, &c., showing but little tendency to separate from it by double decomposition; in other words, the compounds in question do not exhibit the characters of alcoholic chlorides.

In like manner, toluene yields two derivatives by substitution of one atom of *hydroxyl* for hydrogen, viz.,

The first of these compounds, and its homologues, xylyl alcohol, $C^6H^4.CH^2OH$, &c., are true alcohols, resembling the primary alcohols of the fatty series in having two atoms of hydrogen in immediate connection with the group OH , and being consequently capable of yielding by oxidation the corresponding aldehydes and acids. But *cresol* and its homologues, in which the hydroxyl enters into the principal chain, are not true alcohols, but phenols, homologous with the typical 6-carbon phenol, $C^6H^5(OH)$, and, like that compound, not convertible by oxidation into aldehydes and acids of analogous constitution.

The phenols further differ from the true alcohols in the following respects: 1. They are not converted into ethers by the action of acids. The 6-carbon phenol, for example, does not yield phenyl chloride or monochlorobenzene, C^6H^5Cl , by distillation with strong hydrochloric acid, but only when subjected to the action of phosphorus pentachloride: in like manner, to obtain phenyl benzoate, $C^6H^5.C^7H^5O^2$, phenol must be distilled, not with benzoic acid, but with benzoic chloride (iv. 390).—2. The true alcohols when treated with *nitric acid* are either oxidised to aldehydes and acids, or converted into nitric ethers, which are neutral, and may be saponified by alkalis like other compound ethers, reproducing the acid and the alcohol. But the phenols, under the influence of nitric acid, yield products in which not merely one, but two or three atoms of hydrogen may be replaced by nitryl, NO^2 , the products possessing decided acid properties, and not being saponifiable, like compound ethers.—3. The phenols treated with *chlorine* yield substitution-products in which 1, 2, or 3 atoms of hydrogen are replaced by chlorine.—4. The phenols have a much more decidedly acid character

than the true alcohols, forming salts with alkaline hydrates by double decomposition, a reaction exhibited only exceptionally by true alcohols.—5. The phenates of alcohol-radicles, such as methyl phenate or anisol, $C^6H^5(CH^3)O^2$, differ from mixed ethers (like methyl ethylate, $C^2H^5(CH^3)O$) in this respect, that under the influence of powerful reagents, such as nitric acid, they yield a single product—anisol for instance, when treated with nitric acid yielding nitranisol, dinitranisol, or trinitranisol—whereas the mixed ethers split up under similar circumstances, yielding compounds corresponding to each of the alcohol-radicles which they contain.

The following table exhibits the formulæ of the known monatomic hydroxyl derivatives of the aromatic series, together with the hydrocarbons from which they are derived:

<i>Hydrocarbons.</i> C^6H^6	<i>Alcohols.</i>	<i>Phenols.</i> $C^6H^5(OH)$
Benzene. C^6H^6, CH^3 Methyl-benzene or Toluene.	$C^6H^5.CH^2(OH)$ Benzyl alcohol.	$C^6H^4(OH).CH^3$ Cresol.
$C^6H^5.CH^2CH^3$ Ethyl-benzene.	—	$C^6H^4(OH).CH^2CH^3$ Ethyl-phenol or Phlorol.
$C^6H^4.(CH^3)^2$ Dimethyl-benzene or Xylene.	$C^6H^4.CH^2.CH^2(OH)$ Xylol alcohol.	$C^6H^3(OH).(CH^3)^2$ Dimethyl-phenol.
$C^6H^4.CH^3.C^3H^7$? Cymene.	$C^6H^4.C^3H^7.CH^2OH$ Cymyl alcohol.	—
$C^6H^4.(CH^3)^2$ Diethyl-benzene.	—	$C^6H^3(OH).(C^2H^5)^2$ Thymol.
$C^{10}H^{18}$ Sycococene.	$C^{10}H^{17}(OH)$ Sycoceryl alcohol.	—

The replacement of two hydrogen-atoms in toluene by hydroxyl may give rise to three isomeric diatomic alcohols:

The first of these, which has not yet been obtained, has the constitution of a glycol; the second, which is saligenin (v. 172), possesses an alcoholic and a phenolic hydroxyl, and may accordingly be called a glycephenol: it is intermediate in its properties between the alcohols and the phenols, being converted, on the one hand, into the corresponding aldehyde, viz. salicylol, $C^7H^6O^2$, by the action of chromic acid and other oxidising agents, and on the other, into benzoyl-saligenin, $C^7H^7(C^7H^5O)O^2$, by the action of benzoyl chloride (v. 173). The third of the above formulæ, $C^6H^3(OH)^2.CH^3$, is that of a diatomic phenol, and probably represents the constitution of orcin.

The following table exhibits the composition of the diatomic hydroxyl derivatives of benzene at present known:

Hydroquinone (1 : 2)	}	$C^6H^4O^2 = C^6H^4(OH)^2$
Oxyphenol or Pyrocatechin (1 : 3)		
Resorcin (1 : 4)	}	$C^6H^4O^2 = C^6H^4(OH).CH^2(OH)$
Saligenin		
Orcin	}	$C^6H^3O^2 = C^6H^3(OH)^2.CH^3$
Guaiacol (in part)		
Cresol	}	$C^6H^3O^2 = C^6H^3(OH)^2$
Veratrol		

The three modifications of the 6-carbon diatomic phenol are produced, as above mentioned (p. 198), by the action of fusing caustic potash on the three corresponding modifications of iodophenol:

Pyrocatechin is also formed by heating oxysalicylic acid, $C^7H^5O^4$, just as phenol is produced from salicylic acid, $C^7H^5O^3$. In like manner orcin is produced from orsellinic acid, $C^8H^6O^4$, and veratrol from veratric acid, $C^8H^6O^4$. Saligenin is formed from its aldehyde, salicylol, $C^7H^6O^2$, by the action of nascent hydrogen, also by the action of acids or of emulsin on salicin. Guaiacol and cresol are obtained from guaiacum; the latter also from beech-tar creosote.

Intimately connected with the diatomic phenols are the quinones, which are compounds derived from the aromatic hydrocarbons by substitution of O^2 for H^2 , the two

atoms of oxygen thus introduced being linked together by one of their affinities so as to form a bivalent group or radicle: thus,

Quinone, $\text{C}^6\text{H}^4\text{O}^2$, is formed by oxidation of hydroquinone, $\text{C}^6\text{H}^4(\text{OH})^2$, the two hydrogen-atoms of the hydroxyl being removed and the two oxygen-atoms then uniting together; thus:

Pyrocatechin and resorcin are not converted by oxidation into quinone; this difference affords a confirmation of the view that in hydroquinone the two hydroxyl groups are contiguous, whereas in pyrocatechin and resorcin they are separated and occupy the relative positions 1, 3 and 1, 4.

Of triatomic phenols, three bodies are known, having the composition $\text{C}^6\text{H}^3\text{O}^3 = \text{C}^6\text{H}^3(\text{OH})^3$, viz. *pyrogallol* or *pyrogallie acid*, *phloroglucin* and *frangulin*. (See the several articles in the Dictionary.)

The amidated derivatives of toluene, viz.,

exhibit differences of character similar to those of the hydroxyl derivatives above considered, according to the position occupied by the amidogen. Benzylamine is a much stronger base than toluidine; resembles the bases of the fatty series in its reactions; and, like those bases, may be produced, together with di- and tri-benzylamine, by heating benzyl chloride with ammonia; whereas toluidine is not producible by any such reaction, but only by the action of reducing agents on nitrotoluene, in the same manner as aniline, of which it is the true homologue, is formed from nitrobenzene. (For details respecting these compounds, see vol. v. p. 865-868; also the articles *BENZYLAMINE* and *TOLUIDINE* in this volume.)

Toluidine admits of three modifications according to the relative positions of the groups NH^2 and CH^3 , and two of these (ortho and para) one crystalline, the other liquid, are actually known, being obtained by reduction of the corresponding nitrotoluenes.

Xylidine, $\text{C}^6\text{H}^4(\text{NH}^2)$, *cumidine*, $\text{C}^6\text{H}^3(\text{NH}^2)$, and *cymidine*, $\text{C}^6\text{H}^2(\text{NH}^2)$, are of course susceptible of a larger number of modifications. Two modifications of xylidine have been obtained, but the higher bases are known only in one form.

The aromatic acids also exhibit metameric modifications according as the radicle COOH replaces a hydrogen-atom in the principal or in the lateral chains. This kind of isomerism is exhibited in the first instance by toluic acid, $\text{C}^6\text{H}^4\text{O}^2$ (benzoic acid, $\text{C}^6\text{H}^5\text{O}^2 = \text{C}^6\text{H}^5\text{.CO}^2\text{H}$, does not admit of isomeric modifications), which may be derived from the hydrocarbon C^6H^6 by substitution of $\text{O}(\text{OH})$ for H^2 . Now, the hydrocarbon itself exists in the two modifications, dimethyl-benzene or xylene, $\text{C}^6\text{H}^4(\text{CH}^3)^2$, and ethyl-benzene, $\text{C}^6\text{H}^5\text{.CH}^2\text{CH}^3$. Making the substitution just mentioned in these two formulæ, we obtain the two acids:

The constitution of these two acids is shown by their synthetical formation, the first being produced (as a sodium-salt) by the action of sodium and carbon dioxide on bromotoluene (Kekulé, *Bull. Soc. Chim.* 1866, ii. 47):

This method succeeds not only in the aromatic series strictly so called, but also in the neighbouring series, as those of diphenyl and of naphthalene; thus diamido-diphenyl or benzidine (iv. 411), treated with nitrous acid, yields diazobenzidine or tetrazo-diphenyl:

and diazobenzidine boiled with water is converted into a diatomic phenol, $\text{C}^{12}\text{H}^{10}\text{O}^2$, with evolution of nitrogen:

(Griess, *Phil. Trans.* 1864, pt. iii. p. 740).

B. By treating an aromatic hydrocarbon with sulphuric acid, whereby a sulpho-acid is produced, which when fused with potash yields the potassium-salt of the corresponding phenol; and by dissolving the salt in water and precipitating with an acid, the phenol is obtained in the free state: thus

(Wurtz, *Bull. Soc. Chim.* [2] viii. 197; Kekulé, *ibid.* p. 198; Dusart, *ibid.* p. 200).

The phenols are also formed by the destructive distillation of organic bodies, as phenol, $\text{C}^6\text{H}^5\text{O}$, from salicylic acid, $\text{C}^7\text{H}^5\text{O}^2$. Some of them exist ready-formed in plants, as thymol in oil of thyme, or are produced by the decomposition of certain proximate principles of plants, as pyrogallol from gallic acid and orcin from erythrin:

(See also p. 202.) Ordinary phenol has been found by Berthelot among the products formed by passing the vapour of alcohol through a red-hot tube.

III. The modes of formation of the aromatic bases have been already mentioned (p. 203).

IV. Of Aromatic Acids: 1. *Monatomic*.—These acids are obtained by several processes similar to those which yield the fatty acids, viz.: a. By oxidation of the corresponding alcohols or aldehydes.—b. By treating an aromatic hydrocarbon with carbonyl chloride, and decomposing the resulting acid chloride with water (Harnitz-Harnitzky; see p. 39).—c. By the action of nascent hydrogen on less hydrogenated acids, as when cinnamic acid, $\text{C}^9\text{H}^7\text{O}^2$, is converted into alphasxylic acid, $\text{C}^8\text{H}^5\text{O}^2$ (Erlenmeyer's homotoluic acid, *Jahresb.* 1862, p. 365; 1863, p. 352; Schmitt's cumoylic acid, *ibid.*; Swart's hydrocinnamic acid, *Ann. Ch. Pharm.* cxxxvii. 229), by the action of sodium amalgam (Erlenmeyer; Schmitt), or of hydriodic acid (Popoff, *Bull. Soc. Chim.* [2] iv. 375).—d. By heating the hydrocyanic ethers of the aromatic alcohols with alcoholic potash, whereby ammonia is evolved and the potassium salt of an aromatic acid is produced, containing one atom of carbon more than the alcohol-radicle of the cyanide; the acids thus produced are *a*-toluic acid and its homologues: e.g.,

The following methods of formation are peculiar to the aromatic series:

e. Several acids of this series are obtained by oxidation of the hydrocarbons. In this manner toluic acid is produced from cymene, $\text{C}^{10}\text{H}^{14}$, benzoic acid from cumene, $\text{C}^{10}\text{H}^{12}$, &c.—f. By passing a current of carbon dioxide into a brominated aromatic hydrocarbon in which sodium is dissolved. This process yields isomeric products accordingly as the bromine has taken the place of hydrogen in the principal or in one of the lateral chains (Kekulé): thus, for example,

g. As ethers, by treating the monobrominated derivatives of the aromatic hydrocarbons with a chlorocarbonic ether and sodium-amalgam: e.g.,

Bromotoluene treated in like manner yields ethyl toluate (Wurtz, *Compt. rend.* lxxviii, 1298).

h. Hofmann (*Proc. Roy. Soc.* xvi, 484) describes a method of obtaining the monatomic aromatic acids from the monamines containing one atom of carbon less. Aniline distilled with one molecule of oxalic acid yields phenyl-formamide:

together with a number of secondary products resulting from the decomposition of the formamide, and among them benzonitrile or phenyl cyanide:

the quantity of which may be increased by distilling the product with hydrochloric acid. The benzonitrile, distilled with potash, easily yields benzoic acid. In like manner, toluidine distilled with oxalic acid yields tolyl-formamide, the decomposition of which furnishes toluonitrile, $\text{C}^6\text{H}^5\text{N}$, and this by distillation with potash yields toluic acid, $\text{C}^6\text{H}^5\text{O}^2$.

i. These acids may also be obtained from the phenols. Potassium phenylsulphate treated with potassium cyanide yields phenyl cyanide or benzonitrile, from which benzoic acid is produced in the manner just mentioned. Similarly toluic acid may be formed from cresyl-sulphuric acid.

k. Several monatomic aromatic acids exist as natural products, or are formed by oxidation of natural aldehydes; thus benzoic acid exists ready formed in gum benzoin, and is produced by oxidation of bitter almond oil.

2. *Diatomic and Monobasic.*—a. All the known acids of this group which contain a phenic hydroxyl (except phloretic acid, for which the method has not been tried) are produced by the simultaneous action of sodium and carbon dioxide on the phenols (Kolbe & Lautemann, *Ann. Ch. Pharm.* cxv, 205): e.g.,

Phloretic acid is produced by decomposition of phloretin, which is itself a product of the decomposition of phlorizin.

8. These acids are also produced by the action of nitrous acid on solutions of the mono-amidated acids of the same series in boiling nitric acid:

It is better, however, to direct the nitrous acid vapour into a cooled solution of the amidated acid in nitric acid. A diazo-acid is then formed, and this, when boiled with water, gives off nitrogen, and yields the diatomic acid sought:

γ. An acid isomeric with oxybenzoic acid, viz. salicylic acid, is produced by oxidation of saligenin, which is a glycophenol (p. 202). The homologues of salicylic acid have not been obtained, because we are as yet unacquainted with any homologue of saligenin, unless it be arbutin (p. 191).

ε. The acids of this group may be formed by the oxidation of certain hydrocarbons, as paraoxybenzoic acid from toluene, or by further oxidation of certain oxygenated products, as anisic (methyl-paraoxybenzoic) acid by oxidation of anise oil (Saytzeff, *Ann. Ch. Pharm.* cxxxvii, 129; Ladenburg, *Bull. Soc. Chim.* [2] v, 257).

Only one diatomic and monobasic acid is known containing an alcoholic and an acid hydroxyl, viz. formobenzoic or mandelic acid, $\text{C}^6\text{H}^5\text{O}^2 = \text{C}^6\text{H}^5.\text{CHOH}.\text{COOH}$, which is produced by the simultaneous action of hydrochloric and hydrocyanic acids

on oil of bitter almonds dissolved in water. This reaction, however, according to Louguine and Naquet, does not take place with cuminic aldehyde, on account of its almost total insolubility in water; it is moreover the same as that by which acetic aldehyde in the fatty series is converted into lactic acid.

3. *Of Monobasic acids whose atomicity is greater than three.*—Oxysalicylic and gallic acids have been obtained by processes similar to those employed in the fatty series, viz. by treating monobromo- and dibromo-salicylic acids with silver oxide and water (Lautemann, *Ann. Ch. Pharm.* cxx, 300).

4. *Polybasic.*—There is a series of polybasic aromatic acids intermediate in composition and basicity between benzoic acid (monobasic) and mellitic acid (sexbasic). The pentabasic acid has not yet been obtained; of the bi-, tri-, and quadribasic acids each admits of three modifications, depending upon the relative positions of the groups CO^2H :

	Ortho.	Meta.	Para.
$\text{C}^6(\text{CO}^2\text{H})^6$	Mellitic		
$\text{C}^6\text{H}(\text{CO}^2\text{H})^5$	Unknown		
$\text{C}^6\text{H}^2(\text{CO}^2\text{H})^4$	Isopyromellitic	Unknown	Pyromellitic acid
$\text{C}^6\text{H}^3(\text{CO}^2\text{H})^3$	Hemimellitic	Trimellitic	Trimesic
$\text{C}^6\text{H}^4(\text{CO}^2\text{H})^2$	Phthalic	Isophthalic	Terephthalic
$\text{C}^6\text{H}^5(\text{CO}^2\text{H})$	Benzoic		

The sexbasic acid, mellitic acid, has not been formed synthetically, and is known only as a natural product obtained from honeystone; the bi-, tri-, and quadribasic acids are formed from it by a regular series of transformations. Thus mellitic acid treated with sodium-amalgam takes up 6 at. hydrogen, yielding hydromellitic acid, $\text{C}^6\text{H}^6(\text{CO}^2\text{H})^6$, which when heated with strong sulphuric acid gives up the 6 at. H and 2 mols. CO^2 , and is converted into isopyromellitic acid. This acid treated with sodium-amalgam yields hydro-isopyromellitic acid, $\text{C}^6\text{H}^4(\text{CO}^2\text{H})^4$, which when treated with sulphuric acid is converted by loss of H² and CO^2 into hemimellitic acid, $\text{C}^6\text{H}^3(\text{CO}^2\text{H})^3$; and this latter might by a repetition of these operations be converted into bibasic phthalic acid. For further details, see MELLITIC ACID. The bibasic acids, isophthalic and terephthalic, are produced by oxidation of aromatic hydrocarbons containing two lateral chains—*isophthalic acid* from isoxylene, $\text{C}^8\text{H}^4(\text{CH}^3)^2$; and *terephthalic acid* from methyl-toluene, amyl-toluene, and diethyl-benzene. Phthalic acid is produced in like manner by oxidation of naphthalene (p. 212).

Azo- and Diazo-compounds of the Aromatic Series.

1. *Diazo-compounds.*—The amidated acids and bases of the aromatic series, though similar in composition to those of the fatty series, differ remarkably from them in many of their properties, and especially in their behaviour with nitrous acid. The amidated acids and bases of the fatty series, when treated with nitrous acid, give off water and nitrogen, and reproduce the acid or alcohol whose radicals they contain; thus:

Now the amidated bases of the aromatic series are sometimes decomposed by nitrous acid in the same way, aniline for example being converted into phenol, with elimination of nitrogen (iv. 423), but more frequently intermediate products are formed, containing not only the nitrogen of the aromatic base or acid, but also that of the nitrous acid, so that no evolution of nitrogen takes place. The final result is the substitution of N for H² in one or in two molecules of the amidated base. Thus aniline or amidobenzene, $\text{C}^6\text{H}^5\text{N}$, yields by the first of these modes of transformation, diazobenzene or azophenylamine, $\text{C}^6\text{H}^4\text{N}^2$ or $\text{C}^6(\text{H}^4\text{N})^2\text{N}$, and by the second, diazo-amidobenzene or azodiphenyldiamine, $\text{C}^{12}\text{H}^{11}\text{N}^3$ or $\text{C}^{12}(\text{H}^{11}\text{N})^3\text{N}$.

The compounds of diazobenzene treated with various reagents give rise to a number of remarkable products discovered by Griess, and described in vol. iv. pp. 430-434.

The bases derived from the nitroderivatives of the higher hydrocarbons of the aromatic series give rise to similar but less known products when treated with nitrous acid; but no such products are formed from the amines of the fatty series or from benzylamine, which, as already observed, is analogous in constitution to the latter.

The amidated acids of the aromatic series react with nitrous acid in the same

manner as the bases, exchanging N for H³ in two molecules or in a single molecule, and giving rise to unstable compounds, capable, under the influence of various reagents, of forming chlorinated, brominated, or iodated derivatives of the primitive acid, or an acid more highly oxygenated than that primitive acid. Thus, amidobenzoic or oxybenzoic acid, C⁷H⁵(NH²)O², treated with nitrous acid, yields

diazo-amidobenzoic acid, C⁷H⁴N²O² = $\begin{cases} \text{C}^7\text{H}^4\text{N}^2\text{O}^2 \\ \text{C}^7\text{H}^4\text{NO}^2 \end{cases}$. This latter treated

with haloïd acids, yields a hydrochloride, hydrobromide, or hydriodide of amidobenzoic acid, together with chloro-, bromo-, or iodo-benzoic acid. Diazo-amidobenzoic acid treated with alkalis fixes an alkaline molecule, gives off nitrogen and ammonia, and produces a salt of oxybenzoic acid:

Oxybenzoic acid is also produced, though in smaller quantity, by the direct action of nitrous acid on amidobenzoic acid. (See OXYBENZAMIC, OXYCUMINAMIC, OXYTOLUAMIC ACIDS, iv. 290, 297, 322.)

When these amidated acids are treated with sodium-amalgam and water, in a cooled vessel, ammonia is given off, and the group NH² is replaced by H. In this manner bromamidobenzoic, anthranilic, and amidobenzoic acids have been converted into benzoic acid (Hübner a. Petermann, *Zeitschr. f. Chem.* [2] iv. 548).

2. *Monazo-* or simply *Azo-compounds*.—These bodies are derived from the aromatic hydrocarbons by substitution of N for H in one molecule, or rather of N² for H² in two molecules of the hydrocarbon.

Mitscherlich in 1834 obtained azobenzene, C⁶H⁴N or C¹²H¹⁰N² (i. 478), by treating nitrobenzene with alcoholic potash and subjecting the product to distillation. Zinin in 1845 showed that the first product of this reaction is azoxybenzene, C¹²H¹⁰N²O, which, as well as azobenzene, is converted by reducing agents into the basic compound benzidine, C¹²H¹²N². Hofmann in 1863 (*Proc. Roy. Soc.* xii. 576) showed, however, that the direct product of this reduction is not benzidine, but the isomeric compound hydrazobenzene, capable of passing into benzidine by molecular transformation.

The following formulæ show that the azo-derivatives of benzeno are intermediate in composition between nitrobenzene and aniline. In their successive formation, oxygen is first removed, and then hydrogen is added, the product of complete reduction being aniline:

	Empirical formula.	Molecular formula.
Nitrobenzene	C ⁶ H ⁵ NO ₂	= C ⁶ H ⁵ NO ₂
Azoxybenzene	C ⁶ H ⁵ NO ₂	= C ¹² H ¹⁰ N ² O
Azobenzene	C ⁶ H ⁵ N	= C ¹² H ¹⁰ N ²
Hydrazobenzene (and Benzidine)	C ⁶ H ⁶ N	= C ¹² H ¹² N ²
Aniline	C ⁶ H ⁷ N	= C ⁶ H ⁷ N.

The same bodies can also be produced, as Glaser has shown (*Ann. Ch. Pharm.* cxlii. 364) by successive oxidation, starting from aniline.

Azoxybenzene treated with nitric acid yields a mononitro-derivative, of which there are isomeric modifications (i. 480); with a mixture of strong nitric and sulphuric acids, it yields a trinitrated compound. Azobenzene yields two nitro-derivatives, C¹²H⁹(NO²)²N² and C¹²H⁸(NO²)²N². The latter treated with ammonium sulphide is reduced to diamido-azobenzene or diphenine, C¹²H⁸(NH²)²N² (ii. 336). The former has not yet, with certainty, been reduced to amido-azobenzene, C¹²H⁹(NH²)N²; but this compound is obtained, together with amido-azoxybenzene, C¹²H⁹(NH²)N²O, by reduction of mononitro-azoxybenzene (G. A. Schmidt); also by the action of various oxidising agents upon aniline (Martius a. Griess), and by the action of aniline and its salts on diazo-amidobenzeno (Kekulé).

Compounds homologous with azobenzene have recently been obtained from nitrotoluene, nitroxyloene, and even from nitrocumene and nitrocymene. For the particular descriptions of these compounds, see the several hydrocarbons.

The following theory of the constitution of the azo- and diazo-compounds is given by Kekulé (*Lehrbuch d. org. Chemie*, ii. 689, 715, 741; *Zeitschr. f. Chem.* 1866, pp. 308, 689, 700).

The azo-compounds contain a group of two nitrogen-atoms united to one another by a part of their combining capacities, and therefore capable of acting only with the remainder. In the azo-compounds these two nitrogen-atoms are directly combined with the carbon of a benzene residuo; in azobenzene they act as a bivalent group, in azoxybenzene and hydrazobenzene as a quadrivalent group; while on further addition

of hydrogen all the combining units of the nitrogen become active, and the molecule splits into two; thus:

The diazo-compounds likewise contain the bivalent group (NN)^{''}, but only one of the nitrogen-atoms is directly combined with the carbon of a benzene residue, while the free affinity of the other is satisfied, either by haloids or by acid residues, or amidogen, or generally in some way different from the first. From the chemical relations of the diazobenzene-compounds in particular, Kekulé infers that diazo-benzene in the free state consists, not of $\text{C}^6\text{H}^5\text{N}_2$, as supposed by Griess, but of the hydrate corresponding to the potash and silver-oxide compounds of diazobenzene (iv. 434); thus:

According to this view, the relation of the azo-compounds to the diazo-compounds is similar to that of the alcoholic oxides, or simple ethers, to the haloid ethers and oxacid ethers: e.g.,

The relation between the isomeric compounds amido-azobenzene (amido-diphenyl-imide) and diazo-amidobenzene may be represented by the following formulæ:

Both these bodies contain the group $(\text{C}^6\text{H}^5)-\text{N}=\text{N}-$ joined to a residue containing $\text{C}^6\text{H}^5\text{N}$; but in amido-azobenzene the nitrogen group NN is joined to this residue by an atom of carbon; whereas in diazo-amidobenzene the connection is made through the medium of a third atom of nitrogen. Diazo-amidobenzene is in fact converted into amido-azobenzene by the action of an aniline-salt, the aniline-residue $\text{NH}(\text{C}^6\text{H}^5)$

Sup.

P

attached to the molecule through the medium of the nitrogen being thereby displaced, and another aniline-residue of the same composition entering into combination with the group —N=N— through the medium of its carbon-atom. Hence in this reaction a quantity of aniline is always set free equal to that contained in the aniline salt which is decomposed, so that a small quantity of aniline-salt suffices for the conversion of a large quantity of diazo-amidobenzene into amido-azobenzene (Kekulé, *Zeitschr. f. Chem.* [2] i. 689).

The isomerism between hydrazobenzene and benzidine (or diamido-diphenyl) may be represented in a similar manner, the two halves of the molecule being united in the one instance through the medium of nitrogen, and in the other through the medium of carbon:

or, in more condensed form :

Azobenzoic acid, $\text{C}^7\text{H}^5\text{N}^2\text{O}^4$, related to benzoic acid in the same manner as azobenzene to benzene, is produced by the action of sodium-amalgam on a solution of sodium nitrobenzoate; and this acid treated at the boiling heat with soda-ley and ferrous sulphate takes up an additional molecule of hydrogen and is converted into hydrazobenzoic acid, $\text{C}^7\text{H}^7\text{N}^2\text{O}^4$. Lastly, by heating an alcoholic solution of nitrobenzoic acid with solid potash, azoxybenzoic acid, $\text{C}^7\text{H}^5\text{N}^2\text{O}^5$, is produced, with evolution of ammonia and aldehyde (Griess, *Ann. Ch. Pharm.* cxxxi. 92):

The constitution of these acids may be represented by formulæ similar to those above given for azobenzene, hydrazobenzene, and azoxybenzene: viz.,

APPENDIX TO THE AROMATIC SERIES.

Cinnamic Acid, $C^9H^8O^2$, belongs to a series of bodies related to the aromatic compounds in the same manner as the acrylic to the fatty series (p. 41). This acid in fact differs from xylic acid, $C^9H^{10}O^2$, by a deficiency of 2 at. hydrogen, just as acrylic acid differs from propionic acid. Moreover, cinnamic acid has the composition of phenyl-acrylic acid, $C^9H^3(C^6H^5)O^2$, and when fused with caustic alkalis is resolved into acetic and benzoic acids, just as angelic acid, which has the composition of ethyl-acrylic acid, is resolved into acetic and propionic acids:

Most of the transformations of cinnamic acid may be explained by supposing it to contain the same nucleus, C^6 , as the bodies of the aromatic series; it may in fact be represented by the following formula, in which a carbon-atom belonging to the lateral chain has two unsatisfied units of affinity:

Atropic acid, produced by decomposition of atropine (v. 895), has the same composition as cinnamic acid, but its properties are not sufficiently known to enable us to decide whether it belongs to the same series.

Coumaric acid, $C^9H^8O^3$, has the composition of oxycinnamic acid. (See COUMARIC ACID; also SALICYL-COMPOUNDS.)

Cinnamene or *Styrol*, C^9H^8 , and *cinnyllic alcohol* or *styrone*, $C^9H^{10}O$, are related to cinnamic acid in the same way as benzene and phenol to benzoic acid.

2. **Diphenyl**, $C^{12}H^{10}$ or $C^6H^5-C^6H^5$, is composed of two benzene-residues united in the manner represented by the following formula:

Its derivatives, diphenylic phenol, benzidine or diamido-diphenyl (iv. 411), benzoin or benzilic aldehyde, benzilic acid, benzilic anhydride or benzile, and benzilic chloride, are related to it in the manner shown by the following formulæ:

Diphenylic phenol	$C^{12}H^{10}O^2$	$= C^6H^5 \begin{Bmatrix} OH \\ OH \end{Bmatrix}$
Benzidine	$C^{12}H^{12}N^2$	$= C^6H^5 \begin{Bmatrix} NH^2 \\ NH^2 \end{Bmatrix}$
Benzilic aldehyde or Benzoin	$C^{14}H^{12}O^2$	$= C^6H^5 \begin{Bmatrix} OH \\ COH \\ CH^3 \end{Bmatrix}$
Benzilic acid	$C^{14}H^{12}O^3$	$= C^6H^5 \begin{Bmatrix} OH \\ COOH \\ CH^3 \end{Bmatrix}$
Benzilic chloride	$C^{14}H^{11}O^2Cl$	$= C^6H^5 \begin{Bmatrix} OH \\ COCl \\ CH^3 \end{Bmatrix}$
Benzilic anhydride or Benzile	$C^{14}H^{10}O^3$	$= C^6H^5 \begin{Bmatrix} O \\ \text{C}=\text{O} \\ CH^3 \end{Bmatrix}$

It is easy to see that these compounds admit of numerous isomeric modifications according to the relative position of the group OH, NH², CO²H, &c., in one or both of the associated benzene residues.

3. Naphthalene. C¹⁰H⁸.—This hydrocarbon, in its chemical relations, exhibits a very close analogy to benzene. It forms numerous bromo-, chloro-, and nitro-derivatives; its hydroxide, naphthol, C¹⁰H⁷(OH), is a true phenol; its mono-nitro-derivative reduced by nascent hydrogen yields a base, C¹⁰H⁷(NH²), analogous to aniline, and undergoing transformations similar to those of the latter under the influence of nitrous acid. Moreover, naphthylamine distilled with oxalic acid yields naphthyl-formamide, C¹¹H⁹NO, the dehydration of which gives rise to the corresponding nitrile, C¹¹H⁸N; and by distilling this compound with potash, naphthoic acid, C¹¹H⁹O², is obtained, which is related to naphthylamine in the same manner as benzoic acid to aniline.

The structure of the naphthalene molecule is deduced by Graebe (*Ann. Ch. Pharm.* exlix. 20) from the following considerations. Naphthalene is converted by oxidation into phthalic or benzene-dicarboxylic acid, C⁸H⁴(CO²H)², two of its carbon-atoms being removed as carbon dioxide, while two others remain in the form of carboxyl:

Hence naphthalene contains a benzene-residue, C⁶H⁴, and may be represented by the formula C⁶H⁴(C⁴H⁴). But phthalic acid is likewise produced by oxidation of dichloronaphthoquinone, C¹⁰H⁴Cl²(O²)²; consequently, this compound has its two chlorine-atoms and two oxygen-atoms associated with the four carbon-atoms which undergo oxidation, and may be represented by the formula C⁶H⁴[C⁴Cl²(O²)²]. By the action of phosphorus pentachloride, the two oxygen-atoms are replaced by two chlorine-atoms, and at the same time one of the four hydrogen-atoms is replaced by chlorine, the result being pentachloronaphthalene, C¹⁰H³Cl(C⁴Cl⁴). If now, when this last compound is oxidised, the same four carbon-atoms were attacked as in the case of dichloronaphthoquinone, the result would be monochlorophthalic acid, C⁸H³Cl(CO²H)²; but Graebe has shown that the actual product of the oxidation of pentachloronaphthalene is tetrachlorophthalic acid, C⁸Cl⁴(CO²H)². In this reaction, therefore, two of the carbon-atoms belonging to the left-hand group in the molecule C⁶H³Cl(C⁴Cl⁴) are removed as carbon dioxide, while two others yield the two groups CO²H, and the remaining two, together with the four standing on the right, form the benzene nucleus C⁶Cl⁴ of tetrachlorophthalic acid.

These transformations show that the molecule of naphthalene is symmetrical, and composed of two benzene-nuclei united in the manner represented by the following figure:

In the oxidation of this molecule to phthalic acid, two of the carbon-atoms from one benzene-nucleus may be supposed to go out as CO², while the other two, which are in immediate connection with the second benzene-nucleus, yield the two carboxyl-groups; thus:

The mode of this transformation shows that the two carboxyl-groups in phthalic acid are contiguous, or occupy the position 1, 2; and this, combined with other considerations, leads, as already explained (p. 198), to a determination of the

relative positions of the radicles in the ortho-, meta-, and para-compounds of the benzene group.

The relations between naphthalene and its above-mentioned derivatives may also be represented by the following condensed formulae:

The structural formula of naphthalene above given leads to the inference that there must be two series of isomeric compounds formed by the replacement of a single atom of hydrogen in naphthalene by chlorine, bromine, hydroxyl, &c., inasmuch as the hydrogen-atoms adjacent to the two carbon-atoms which are common to both the benzene-nuclei, may be supposed to differ in their functions from the other four. In this manner two isomeric compounds may be formed; thus:

The two naphthalene monosulpho-acids discovered by Faraday (v. 561) afford an instance of this isomerism. (See NAPHTHALENE-COMPOUNDS.)

More complicated cases of isomerism arise when two hydrogen-atoms belonging to the same or to different benzene-residues in the naphthalene molecule undergo replacement. The existence of such isomerides may in general be detected by oxidising them, and examining the phthalic acid thereby produced. There will probably be four cases of isomerism in which both the replacing radicles enter into the same benzene nucleus, and eight in which they enter both nuclei. If the hydrogen-atoms in naphthalene be numbered from 1 to 8, thus:

the twelve cases of isomerism will be as follows:

1, 2	1, 3	1, 4	2, 3				
1, 5	1, 6	1, 7	1, 8	2, 5	2, 6	2, 7	2, 8.

4. **Anthracene and Alizarin.** The synthesis of anthracene, $\text{C}^{14}\text{H}^{10}$, from benzyl-chloride, $\text{C}^6\text{H}^5\cdot\text{CH}^2\text{Cl}$ (p. 176), might lead to the conclusion that it is made up of two benzene-residues, C^6H^5 , connected by two atoms of carbon, or, in other words, that it is a phenylated-acetylene, $\text{C}^6\text{H}^5-\text{C}\equiv\text{C}-\text{C}^6\text{H}^5$; but the formation of phthalic acid, $\text{C}^4\text{H}^4(\text{CO}^2\text{H})^2$, by oxidation of a derivative of anthracene, viz. alizarin, $\text{C}^{14}\text{H}^8(\text{OH})^2(\text{O}^2)''$, is not compatible with this formula. Moreover, as benzene, C^6H^6 , naphthalene, C^{10}H^8 , and anthracene, $\text{C}^{14}\text{H}^{10}$, form a series whose common difference is C^4H^2 , and as naphthalene is made up of two benzene-rings, it is very probable that anthracene is made up of three such rings united together thus:

or, in more condensed form :

This structural formula affords an easy explanation of the production of anthracene from two molecules of benzyl chloride, $\left\{ \text{C}^6\text{H}^4(\text{H})-\text{CH}(\text{HCl}) \right\}$. Each of the two benzene-residues, C^6H^5 , loses an atom of hydrogen (indicated by the brackets), and the two residues, C^6H^4 , then unite together. At the same time, each of the lateral chains, CHHCl , loses a molecule of hydrochloric acid, and the two carbon-atoms then attach themselves to each other by two units of affinity.

The formation of phthalic acid by oxidation of alizarin, $\text{C}^{14}\text{H}^8(\text{OH})^2(\text{O}^2)^2$, shows that in this compound the two quinonic oxygen-atoms and the two hydroxyls are contained in the middle and one of the external benzene-rings, so that the formula of alizarin is one of the two following:

According to either of these formulæ, the formation of phthalic acid from alizarin is explained by supposing that the benzene nuclei containing the oxygen are oxidised, and converted into the two carboxyls, which remain combined with the third nucleus, and into oxalic or carbonic acid which separates. If all the oxygen-atoms of alizarin were contained in one of the external nuclei, the product of the oxidation would be a naphthalene-dicarboxylic acid, $\text{C}^{14}\text{H}^4(\text{CO}^2\text{H})^2$; and if the quinonic oxygen-atoms and the hydroxyls were distributed between the two exterior nuclei, the oxidised product would be a substituted phthalic acid or a benzene-tetracarboxylic acid.

Of the two formulæ of alizarin above given (1) appears to be the more probable, for the following reasons:—Benzene cannot be directly oxidised to quinone, and naphthalene is with difficulty oxidised to naphthoquinone; but anthracene is very easily oxidised to anthraquinone. This seems to show that the formation of a quinone is facilitated by accumulation of carbon-atoms; but in anthracene the hydrogen-atoms belonging to the middle ring are more surrounded by carbon than the rest, and will therefore be the most readily oxidised. This view is further corroborated by the great stability of anthraquinone; if the two oxygen-atoms in this body were contained in one of the external nuclei, it would probably oxidise more easily, yielding a naphthalene-dicarboxylic acid. Finally, the formation of anthraquinone from dibromanthracene by the action of oxidising agents which do not convert dibromobenzene or dibromonaphthalene into the corresponding quinones, renders it probable that the two bromine-atoms in this compound have replaced the hydrogen-atoms belonging to the middle ring. On these grounds the brominated and quinonic derivatives of anthracene may be formulated as follows:

(Graebe a. Liebermann, *Zeitschr. f. Chem.* [2] iv. 279; vi. 262).

ARSENIC. According to Ludwig (*Arch. Pharm.* [2] xcvi. 23), sublimed arsenic may be obtained with a perfectly bright surface by heating it in a test-tube with a small quantity of iodine, which converts the thin crust of suboxide usually present into arsenious oxy-iodide, $2\text{AsI}^3 \cdot \text{As}^2\text{O}^3$, the vapour of the iodide protecting the residual arsenic from oxidation. It then resembles freshly granulated zinc, and has a density of 5.395.

Under ordinary circumstances metallic arsenic sublimes at 180° without previous fusion; but when heated to low redness under pressure it melts into globules (Landolt, *Jahresb.* 1859, p. 182). According to Hittorf (*ibid.* 1865, p. 133), it sublimes without the slightest sign of fusion when heated in a vacuum glass tube.

According to Bettendorff (*Ann. Ch. Pharm.* cxliv. 110), when arsenic is sublimed in a tube of hard glass through which a stream of hydrogen is passing, it condenses near the heated part of the tube in hexagonal crystals, and at some distance beyond in an amorphous black glassy crust, while the furthest portion of the tube becomes coated with a powder which appears yellow at first, but quickly turns grey. The condition essential to the deposition of the amorphous vitreous arsenic is the cooling of the vapour to 210° – 220° . This amorphous arsenic is most easily obtained by sublimation in an exhausted tube or in a combustion-tube bent U-shape at one end, and dipping at this end into an oil-bath heated to 220° , while the arsenic lying just above the bend is volatilised in the stream of hydrogen; the U-tube then becomes lined with a specular coating of amorphous arsenic, which may be loosened by a few blows. Its sp. gr. is 4.710 to 4.716 (4.69 according to Hittorf, *Jahresb.* 1865, p. 130), therefore much below that of the crystalline variety. When heated to 360° it is converted, with evolution of heat, into crystalline arsenic, and if the heat be quickly applied, the change is accompanied by a hissing noise and formation of vapour. It is somewhat less oxidisable than crystalline arsenic, changes but slowly in damp air, and is attacked with difficulty even by dilute nitric acid. The mirror of arsenic obtained in Marsh's apparatus appears to belong to the same modification. The pulverulent arsenic above mentioned exhibits under the microscope the form of spherules strung together like pearls. Its sp. gr. is 4.710 at 14° (4.72 according to Hittorf). At 360° it passes, with great rise of temperature, into the crystalline modification, but it is more readily oxidisable than the amorphous vitreous variety. The yellow powder deposited at the beginning of the process is perhaps a third modification, but it was not obtained pure. Pure crystalline arsenic, after repeated sublimation in a stream of hydrogen, has, according to Bettendorff, a sp. gr. of 5.726–5.728 at 14° .

The specific heat of crystallised arsenic repeatedly sublimed in a stream of hydrogen is 0.0830; that of amorphous arsenic prepared from the crystallised variety by sublimation in a vacuum tube at a low temperature is 0.0758 (Bettendorff a. Wüllner, *Zeitschr. f. Chem.* [2] iv. 560).

An aqueous solution of arsenious fluoride yields by electrolysis a scaly precipitate of metallic arsenic exhibiting faint thermic properties analogous to those of amorphous antimony (Gore, *Chem. Soc. J.* [2] i. 365).

According to Le Roux (*Compt. rend.* li. 171), the vapour of arsenic has a lemon-yellow colour.

Metallic arsenic heated to 200° in a sealed tube with solution of sulphurous acid, yields arsenious oxide, sulphuric acid, and free sulphur, but no sulphide of arsenic (Gittner, *Jahresb.* 1864, p. 143).

Detection of Arsenic. a. *Reinsch's test.*—A solution containing arsenic acid or an alkaline arsenate mixed with sulphuric acid does not produce any deposit on metallic copper, even after long boiling, unless the quantity of arsenic present is somewhat considerable; the deposition may however be ensured by adding sulphurous acid or a sulphite, whereby the arsenic acid is reduced to arsenious acid (G. Werther, *J. pr. Chem.* lxxxii. 286; *Jahresb.* 1861, p. 851). The grey deposit formed on copper in a solution of arsenious acid is not pure metallic arsenic, but an arsenide of copper, Cu^2As^2 (containing 32 p. c. arsenic). When ignited for some time in a stream of

hydrogen, it gives off part of its arsenic and is reduced to $\text{Cu}^{\text{a}}\text{As}^{\text{z}}$ (G. Lippert, *J. pr. Chem.* lxxxi. 168; *Jahresb.* 1860, p. 170).

B. Marsh's test.—E. Davy (*Jahresb.* 1858, p. 609) recommends the use of *platinum* in the form of thick plate (not thin foil) instead of porcelain or glass for receiving the spots formed by ignited arsenetted hydrogen. The spots adhere closely to the metal, and disappear with garlic odour when gently heated. Antimony spots received on platinum do not disappear when heated over a spirit-lamp.

Very small arsenic spots on porcelain or platinum may be recognised by volatilising them and receiving the vapours on the object-glass of a microscope. Spots of pure arsenic or of arseniferous antimony thus treated yield a deposit of octohedral arsenious oxide, whereas spots of pure antimony do not yield any deposit on the object-glass (Hewlig, *Das Microscop in der Toxicologie*).

According to Blondlot (*Jahresb.* 1863, p. 681), the presence of nitric acid in the liquid, even in small quantity, prevents the formation of gaseous hydride of arsenic, the solid hydride, $\text{As}^{\text{a}}\text{H}^{\text{z}}$, being then deposited in brown flocks upon the zinc.

Roussin (*Jahresb.* 1866, p. 801) recommends the use of *magnesium* instead of zinc in Marsh's apparatus. Arsenic and antimony are thereby evolved as hydrogen-compounds, while any non-volatile metals that may be present are thrown down in the form of a metallic precipitate, which may be collected on a filter and further examined. If the magnesium contains silicon, siliciuretted hydrogen will be evolved; but the spots which this gas produces on porcelain are easily distinguished from arsenic and antimony spots by their insolubility in nitric acid, nitromuriatic acid, and sodium hypochlorite.

Arsenetted hydrogen is easily converted into an iodide of arsenic by passing it over gently heated iodine. If a small quantity of iodine be introduced into the tube of Marsh's apparatus and gently warmed, so as to form on cooling a deposit on the part of the tube on which the arsenic mirror is usually produced, then, if a stream of hydrogen containing arsenic be passed through the tube while still lukewarm, iodide of arsenic will be formed, as a yellow deposit consisting of microscopic laminae, very much like iodoform, and the iodine will disappear completely. Antimonious hydride acts upon iodine in a similar manner, but less quickly, the iodine uniting into a deep-coloured ring, which gradually becomes brown towards the drawn-out end of the tube, and orange-yellow towards the apparatus. This coloured ring does not spread itself further, and the iodine does not disappear completely. The two iodides may also be readily distinguished by their behaviour when heated. The yellow iodide of arsenic then partly sublimes unaltered, and is partially converted, with liberation of iodine, into a red iodide, indicating the previous formation of arsenic iodide, AsI^{z} . The iodide of antimony, on the other hand, gives off red vapours and leaves reduced antimony (C. Nilsson, *Compt. rend.* lxxvii. 56).

γ. Zenger's process (*Zeitschr. Chem. Pharm.* 1862, p. 38; *Jahresb.* 1862, p. 595).—This method consists in the production of a specular deposit of arsenic by reducing magnesium arsenate with *sodium oxalate* in a sealed tube filled with carbon dioxide. The substance under examination is repeatedly distilled with a mixture of equal volumes of strong hydrochloric acid and water; the arsenic is precipitated from the distillate as sulphide; the precipitated arsenious sulphide is evaporated down with nitric acid free from chlorine; and the residue is fused with pure sodium nitrate. From the sodium arsenate thus obtained the arsenic is precipitated as ammonio-magnesium arsenate; the precipitate after drying at 100° is mixed with a little anhydrous sodium carbonate to make it more manageable, and then ignited to expel the ammonia; and the magnesium arsenate thus produced is mixed with 10 times its weight of dry sodium oxalate, and a little charcoal powder to colour the mixture. On the other hand, 20 parts of dry sodium oxalate are introduced into a tube of thin, easily fusible glass, 3 millimetres in diameter and sealed at one end; the blackened mixture, weighing about 11 pts., is introduced above the oxalate; and the tube, after the empty part has been carefully cleaned, is drawn out to a fine neck. The tube is next heated, first at the bottom to evolve carbon monoxide and expel the air, the heat being gradually extended up to the coloured mixture; after which the tube is sealed, and heat is applied to the arseniferous mixture. The smallest quantity of arsenic is thereby deposited close above the mixture, in a beautiful, compact, metallic ring. The sealing of the tube prevents loss of arsenic.

δ. Bettendorff's process (*Zeitschr. f. Chem.* [2] v. 492).—When a solution of *stannous chloride* in fuming hydrochloric acid is added to a solution of arsenious or arsenic oxide in the same acid, a brown precipitate is formed, which, after proper washing and drying, consists of metallic arsenic mixed with a small quantity of stannic oxide. In an aqueous solution of arsenious or arsenic acid, stannous chloride produces no precipitate; but on adding strong hydrochloric acid till the liquid fumes slightly, precipitation

takes place. Arseniferous hydrochloric acid of sp. gr. 1.182 to 1.135 gives an immediate precipitate; the same diluted to sp. gr. 1.115 gives imperfect precipitation after some time; and in a similar solution of sp. gr. 1.100 no precipitation takes place. From this it may be inferred that the reaction occurs only between stannous chloride and arsenious chloride; further, that in a solution of arsenious acid in hydrochloric acid of sp. gr. 1.115 part of the arsenic is present as chloride, but that hydrochloric acid of sp. gr. 1.100 dissolves arsenious acid as such, without converting it into chloride. The reaction above described is extremely delicate and capable of detecting 1 pt. of arsenic in a million parts of solution. On antimony-compounds stannous chloride exerts no reducing action, even after prolonged heating: hence the above-described reaction may be used to detect the presence of arsenic in antimony-compounds, the solution being previously saturated with hydrochloric acid gas. Another useful application of the same reaction is to the preparation of hydrochloric acid free from arsenic. 421 grms. of crude hydrochloric acid of sp. gr. 1.164 were mixed with a fuming solution of stannous chloride, the precipitate separated by filtration after 24 hours, and the hydrochloric acid distilled, the receiver being changed after the first tenth had passed over, and the remaining liquid distilled nearly to dryness. The acid thus obtained gave not the slightest indications of arsenic, either by Marsh's test or by precipitation with hydrogen sulphide.

In testing for arsenic acid with silver nitrate, the delicacy of the reaction is impaired by the solubility of silver arsenate, not only in free nitric acid and free ammonia, but also in ammonium nitrate. According to C. Avery (*Sill. Am. J.* [2] xvii. 25), the reaction is greatly facilitated by adding to the solution of arsenic acid in nitric acid a few drops of a strong solution of an alkaline acetate, and then a drop or two of ammoniacal silver nitrate. Another very good mode of testing is to drop the nitric acid solution of arsenic acid on recently prepared silver carbonate, the red silver arsenate then showing itself very conspicuously on the white ground.

Metallic arsenic and arsenious acid are easily oxidised by a mixture of potassium chlorate and nitric acid to arsenic acid, which may then be easily estimated as ammonio-magnesian arsenate (A. H. Pearson, *Sill. Am. J.* [2] xviii. 190).

Compounds of Arsenic.

Bromide. AsBr_3 .—Prepared by adding pulverised arsenic to a mixture of 1 pt. bromine and 2 pts. carbon bisulphide, agitating till the liquid becomes colourless, then adding more bromine, then again arsenic, and so on till the solution is saturated, i.e. till it is no longer decolorised on further addition of arsenic. Crystallises in deliquescent colourless prisms, having a strong arsenical odour, volatilising undecomposed, and yielding a crystalline sublimate. Decomposed by water with separation of arsenious oxide. In contact with sodium hyposulphite, it first forms arsenious oxybromide, and then becomes covered with arsenious sulphide. It unites with the bromides of the alkali-metals, forming rather unstable crystallisable compounds (Nicklès, *J. Pharm.* [3] xli. 142). Its specific gravity at mean temperatures is 3.66 (Bödeker, *Jahresb.* 1860, p. 17).

Chloride. AsCl_3 .—This compound is formed, together with arsenious arsenate, $2\text{As}_2\text{O}_3 \cdot \text{As}_2\text{O}_5$, when dry chlorine is passed over pulverised and gently heated arsenious oxide:

(Bloxam, *Chem. Soc. J.* [5] iii. 62). Also by the action of 2 at. arsenic on 3 at. sulphur dichloride, sulphur being separated at the same time, partly in opaque prisms, partly in bulky transparent octohedrons (Chevrier, *Compt. rend.* lxiii. 1003; *Jahresb.* 1866, p. 212):

Arsenious chloride is also produced by distilling a mixture of arsenious sulphide and mercuric chloride (Ludwig, *Jahresb.* 1859, p. 187).

A compound of arsenious chloride with alcohol, apparently $\text{AsCl}_3 \cdot \text{C}_2\text{H}_5\text{O}$, is produced by mixing the chloride with absolute alcohol, and passes over on distillation at 148° ; also by passing hydrochloric acid gas into alcohol containing arsenious oxide in suspension, and subjecting the lower of the two resulting liquids to fractional distillation. It is a colourless liquid which fumes in the air; is decomposed by water or by atmospheric moisture into hydrochloric acid, arsenious acid, and alcohol; and absorbs hydrochloric acid gas abundantly and with rise of temperature, giving it up again on distillation. It is partially decomposed by repeated distillation, yielding ethyl chloride, &c. Arsenious chloride appears to form similar compounds with methylic and amylic alcohols (V. de Luynes, *Compt. rend.* l. 831).

regular octohedrons, or in crystals belonging to the rhombic system, the latter being produced for the most part at high, the former at low temperatures. Prismatic arsenious oxide occurs in the mines of St. Domingo in Portugal, forming thin plates, some of which are more than an inch long. The crystals are not perfectly developed, but some of them exhibit hemitropy similar to that of gypsum. They are colourless, semitransparent, nacreous, tough, flexible, and easily split into thin lamellæ. Sp. gr. = 3.85. Hardness = 2.5 (ordinary arsenious oxide gave 2.76 p. c.). The crystals sublime without residuum when heated, but cannot be obtained again in the prismatic form, either by sublimation or by crystallisation from solution (F. Claudet, *Chem. Soc. J.* [2] vi. 179). Prismatic arsenious oxide has also been found by Scheurer-Kestner (*Zeitschr. f. Chem.* [2] v. 486) in a furnace used for the roasting of pyrites. F. Ulrich (*Jahresb.* 1858, p. 173) describes crystals of arsenious oxide occurring as a roasting product of the Rammelsberg ores at the Oker works in the Harz, which were externally rhombic ($\infty P \cdot \infty P \infty \cdot mP \infty$), but appeared to consist internally of regular octohedrons.

Arsenious oxide dissolves abundantly in water at 250°, and the solution, as it cools, first deposits a few microscopic prisms, afterwards octohedrons. When either the vitreous or the crystalline oxide is heated in a sealed glass tube placed upright in a sand-bath, so that it is heated to about 400° in the lower, and 200° in the upper part, and then left to cool slowly, the oxide solidifies in the vitreous form at the lower part, in prismatic crystals in the middle, and in octohedrons at the upper part, a few octohedrons being also implanted on the prisms. A comparatively high temperature is therefore, at least in the dry way, an essential condition for the formation of the prismatic crystals, whereas the octohedrons are formed only at lower temperatures. In the wet way, on the other hand, the nature of the solvent appears also to exert some influence on the crystallisation, inasmuch as the oxide crystallises in prisms from its solution in potash, even at comparatively low temperatures (Debray, *Bull. Soc. Chim.* [2] ii. 9; *Jahresb.* 1861, p. 236). Nordenskiöld (*Jahresb.* 1861, p. 263) obtained it, by cooling and slow evaporation of a warm potash-solution supersaturated therewith, in six-sided trimetric crystals, $\infty P \cdot \infty P \cdot \infty P \infty$, having the horizontal axes in the ratio of 1 to 0.5776. A solution of arsenious oxide in ammonia, saturated while hot and kept for some time at the boiling heat, the ammonia being replaced as it evaporates, deposits arsenious oxide in the rhombic modification (together with octohedral crystals); but when the same solution is left to cool slowly, the oxide is deposited in large octohedral crystals (Hirzel, *Jahresb.* 1852, p. 378). The deposition of octohedral crystals from the ammoniacal solution has also been observed by Wöhler (*Ann. Ch. Pharm.* ci. 365). According to De Luynes (*Compt. rend.* xlv. 1353), a solution of arsenious oxide in ammonia prepared at 70°–80° deposits on cooling needle-shaped crystals of ammonium arsenite, $As(NH_4O)_2$, which however gradually redissolve, if left, together with the supernatant liquid, in an open vessel, so that the ammonia can evaporate from the latter; and the liquid ultimately deposits octohedral crystals of arsenious oxide. According to Scheurer-Kestner (*Zeitschr. f. Chem.* [2] v. 487), a concentrated solution of arsenic acid supersaturated with arsenious oxide deposits the latter in acicular prisms.

Solubility.—Bacalogo (*J. pr. Chem.* lxxxiii. 111) found that a solution of arsenious oxide saturated in the cold and left for ten months at 10°–20°, in contact with excess of the oxide, contained 1.2 p. c. As^2O^3 ; solutions saturated while hot contained, a few days after saturation, from 2.25 to 2.5 p. c. As^2O^3 ; a solution in which traces of hydrochloric acid were present contained 3.8 p. c. As^2O^3 . A solution of vitreous arsenious oxide saturated while hot contained at 24°, four days after saturation, 2.4 p. c. As^2O^3 ; after eighty-two days, at 14°, 1.5 p. c. As^2O^3 ; after four months, at 12°, 1.3 p. c. As^2O^3 . The presence of arsenic, phosphoric, sulphuric, and other mineral acids, increases the solubility of arsenious oxide in water. The crystals of prismatic arsenious acid from Portugal, above mentioned, were found by Claudet to dissolve in cold water to the amount of 1 p. c.; when pulverised, 1.75 p. c.; a solution saturated while hot contained after cooling 2.74 p. c. *

The following determinations of the solubility of arsenious oxide in alcohol have been made by Girardin (*J. Pharm.* [3] xlvii. 269):

100 pts. alcohol of	56	79	84	86	88	100 vol. p. c.

Of the vitreous	{	at 15°	0.504	0.540	0.565	— 0.717 1.060
oxide:						

Reactions.—1. Perfectly dry arsenious oxide subjected to the action of *chlorine* at a gentle heat, gives off arsenious chloride, and leaves a sintered mass consisting chiefly of arsenic oxide, which when the heat is increased is likewise converted into arsenious chloride (R. Weber, *Pogg. Ann.* cxii. 619). According to Bloxam, the residue consists of arsenious arsenate, $2\text{As}^2\text{O}^3 \cdot \text{As}^2\text{O}^3$.—2. Heated with *sal-ammoniac* it yields arsenious chloride and ammonia, which afterwards react on one another, with formation of white fumes (Luynes, *Compt. rend.* xlv. 1354).—3. *Phosphorus pentachloride*, according to Persoz a. Bloch (*Jahresb.* 1849, p. 246), forms with arsenious oxide a definite oxychloride, boiling at 110° ; but according to Hurtzig a. Geuther (*Ann. Ch. Pharm.* cx. 159; *Jahresb.* 1859, p. 186), even when the two substances are mixed in equivalent proportions, the only products formed are arsenious chloride and phosphorus oxychloride, which separate on fractional distillation:

4. With *arsenious chloride* the oxide unites directly, forming an oxychloride, AsClO or $\text{AsCl}^3 \cdot \text{As}^2\text{O}^3$ (i. 386).—5. Solutions of arsenious oxide treated with *stannous chloride*, yield stannic chloride, metallic arsenic, and gaseous hydride of arsenic (Kessler, *Jahresb.* 1861, p. 265).—6. The same solutions reduce *potassio-cupric tartrate* with separation of cuprous oxide (Terrell, *Bull. Soc. Chim.* 1862, p. 64).—7. Aqueous arsenious oxide heated to 200° with *phosphorus*, yields phosphide of arsenic (Oppenheim, *Bull. Soc. Chim.* [2] i. 163).

Combinations with other Acid Oxides.—The compound of arsenious with arsenic oxide, $2\text{As}^2\text{O}^3 \cdot \text{As}^2\text{O}^3$, which Bloxam obtained by the action of chlorine on arsenious oxide, has been already mentioned. It may also be formed by heating arsenic oxide with an excess of arsenious oxide. It is transparent at first, but solidifies after a few days to a glass, having the aspect of porcelain.

With *sulphuric oxide*, arsenious oxide forms the compound $\text{As}^2\text{O}^3 \cdot \text{SO}^3$, in small tabular crystals, which sometimes occur as a product of the roasting of native metallic sulphides containing arsenic. They deliquesce in moist air, decomposing into sulphuric acid and arsenious oxide. Heated in a tube, they are resolved into sulphuric oxide, which volatilises, and a residue of arsenious oxide (Reich, *J. pr. Chem.* xc. 176). Laurent, by heating arsenious oxide with sulphuric acid, obtained shining rectangular prisms consisting of $3(\text{As}^2\text{O}^3 \cdot \text{SO}^3) \cdot \text{H}^2\text{SO}^4$ (*J. Pharm.* [3] xlv. 184).

Acetic oxide at the boiling heat dissolves arsenious oxide in the proportion of CH_3CO^2 to As^2O^3 , forming a colourless syrupy liquid, which solidifies on cooling to a vitreous mass. The compound quickly absorbs moisture; is instantly decomposed by water into acetic acid and arsenious oxide; and when heated to 220° gives off a large quantity of carbon dioxide, with traces of arsenetted hydrogen, while acetic acid passes over, and metallic arsenic remains behind (Schützenberger, *Compt. rend.* liii. 538).

ARSENITES. The experiments of Bloxam (*Chem. Soc. J.* xv. 281), compared with those of other chemists, appear to show that arsenious acid is tribasic, forming

Trimetallic salts, M^3AsO^3 or $\text{M}^3(\text{AsO}^3)^2$

Dimetallic salts, M^2HAsO^3 or M^2HAsO^3

Monometallic salts, MHAsO^3 or $\text{M}^+\text{H}(\text{AsO}^3)^2$.

There are also a few salts, which may be called pyro-arsenites, having the composition $2\text{M}^2\text{O} \cdot \text{As}^2\text{O}^3$ or $\text{M}^4\text{As}^2\text{O}^3$, and acid arsenites, $\text{M}^2\text{O} \cdot 2\text{As}^2\text{O}^3$ and $2\text{M}^2\text{O} \cdot 3\text{As}^2\text{O}^3$, which may be regarded as compounds of meta-arsenites; MAsO^3 , with free arsenious oxide:

Solutions of the alkaline arsenites when exposed to the air, gradually absorb oxygen and are partially converted into arsenates (Fresenius, *Jahresb.* 1855, p. 382; Croft, *ibid.* 1858, p. 173; Ludwig a. Macdonnell, *ibid.* 1859, p. 194; F. Kessler, *ibid.* 1861, p. 262).

Ammonium salt.—The formula NH^4AsO^3 , assigned to this salt by Pasteur (*Jahresb.* 1847–48, p. 424) and by De Luynes (*ibid.* 1857, p. 269), has been confirmed by Bloxam.

The *barium salt*, obtained by adding barium chloride to a solution of arsenious oxide in ammonia, or by precipitating the sodium salt $\text{NaAsO}^2 \cdot \text{As}^2\text{O}^3$ with 1 at. barium chloride, appears to have, when dried at 100° , the composition $\text{Ba}^+\text{H}^+(\text{AsO}^3)^2$ (Bloxam).

Copper salts.—On mixing a dilute solution of potassium diarsenite, $2\text{KAsO}^2 \cdot \text{As}^2\text{O}^3$, with cupric sulphate till the precipitation is complete, the precipitate dried at 100°

consists of a mixture of the salt $\text{Cu}^{\text{II}}\text{HAsO}_3$ with arsenious oxide. The acid filtrate, mixed with an additional quantity of cupric sulphate and neutralised with ammonia, gives a precipitate consisting mainly of $\text{Cu}^{\text{II}}\text{HAsO}_3$. The precipitate obtained with the salt $4\text{NaAsO}_2 \cdot \text{As}_2\text{O}_3$ was found to contain 2.35 at. Cu to 1 mol. of As_2O_3 and 0.92 mol. of water. Scheele's green appears to have a similar composition. Aqueous arsenious acid forms with sulphate of cuprammonium a precipitate which when air-dried consists of $\text{Cu}^{\text{II}}\text{HAsO}_3 \cdot \text{H}_2\text{O}$, and after drying in a vacuum over oil of vitriol, of $\text{Cu}^{\text{II}}\text{HAsO}_3$ (Bloxam).

Lead salt.—The salt $\text{Pb}^{\text{II}}\text{H}(\text{AsO}_3)$ is obtained by precipitating potassium diarsenite, $2\text{KAsO}_2 \cdot \text{As}_2\text{O}_3$, with lead nitrate. A *diplymbic salt* or *plumbic pyroarsenite*, $\text{Pb}^{\text{IV}}\text{As}_2\text{O}_7$ or $2\text{PbO} \cdot \text{As}_2\text{O}_5$ (at 100°), is formed on mixing a solution of 2 mols. lead acetate containing excess of ammonia with an aqueous solution of 1 mol. arsenious oxide.

Magnesium salt.—A cold-saturated aqueous solution of arsenious oxide is not precipitated by magnesium sulphate till after the addition of sal-ammoniac and ammonia; but precipitation then takes place, even in very dilute solutions. The precipitate dried at 100° consists of $\text{MgHAsO}_3 \cdot \text{H}_2\text{O}$; at 205° , of MgHAsO_3 ; and above 205° , of $2\text{MgO} \cdot \text{As}_2\text{O}_5$ (Bloxam).

Potassium salts.—The acid *monopotassic salt* $2\text{KH}^2\text{AsO}_3 \cdot \text{As}_2\text{O}_5$ (or $\text{K}_2\text{O} \cdot 2\text{H}_2\text{O} \cdot 2\text{As}_2\text{O}_5$ + aq.) is obtained by digesting potassium carbonate at 100° with arsenious oxide; * it forms rectangular prismatic crystals, which give off water at 100° , and are converted into a compound of an acid pyroarsenite with arsenious oxide, $\text{K}^{\text{II}}\text{H}^2\text{As}_2\text{O}_7 \cdot \text{As}_2\text{O}_3$. Heated more strongly in a current of dry air, it gives off another molecule of water, and melts to a yellow liquid, which solidifies to a yellow viscous mass, consisting of a metarsenite combined with arsenious oxide, $2\text{KAsO}_2 \cdot \text{As}_2\text{O}_3$ (or $\text{K}_2\text{O} \cdot 2\text{As}_2\text{O}_5$). When potassium carbonate is boiled with arsenious oxide, the latter expels only three-fourths of the carbonic acid, and the solution when concentrated yields crystals of the salt $2\text{KH}^2\text{AsO}_3$ above described; but if the whole be evaporated at 100° , a crystalline mass is obtained, consisting of the pyroarsenite combined with metarsenous acid, $\text{K}^{\text{II}}\text{H}^2\text{As}_2\text{O}_7 \cdot \text{HAsO}_2$ (or $2\text{K}_2\text{O} \cdot 3\text{As}_2\text{O}_5$ + $3\text{H}_2\text{O}$). This last salt does not give off its water till raised to a higher temperature, but ultimately solidifies to a crystalline mass (Bloxam).

Silver salts.—A dilute solution of the acid potassium salt KH^2AsO_3 gives with silver salts a bulky yellow precipitate, which becomes crystalline, and appears to be a mixture of the triargentite salt Ag_3AsO_3 with arsenious oxide. The filtered liquid is acid, and gives with ammonia and excess of silver nitrate a yellow precipitate of triargentite arsenite.

Sodium salts.—Arsenious oxide reacts with sodium carbonate in the same manner as with potassium carbonate, but the sodium arsenites have not been obtained in definite crystals. When the mass obtained with excess of arsenious oxide was dried at 100° , the residue exhibited the composition $\text{Na}_2\text{O} \cdot 2\text{As}_2\text{O}_5$ or $2\text{NaAsO}_2 \cdot \text{As}_2\text{O}_3$. On evaporating a solution of 3 mol. arsenious oxide with 2 mol. sodium carbonate, a black syrup was obtained, which became colourless when left to evaporate, and when dried at 100° yielded a confusedly crystalline mass of the salt $2\text{Na}_2\text{O} \cdot 3\text{As}_2\text{O}_5$ or $4\text{NaAsO}_2 \cdot \text{As}_2\text{O}_3$ (Bloxam).

Zinc salts.—A solution of zinc sulphate mixed with ammonia and sal-ammoniac and filtered, forms with a saturated aqueous solution of arsenious oxide, a bulky precipitate, which afterwards changes to microscopic spherical groups of crystals; at 100° it forms a nacreous powder, consisting of $\text{Zn}^{\text{II}}(\text{AsO}_3)_2$. The liquid filtered therefrom yields, on partial neutralisation with sulphuric acid, a precipitate similar in composition to the preceding; on neutralising it completely, a salt was obtained containing excess of arsenious oxide (Bloxam).

ETHYL ARSENITE. $(\text{C}_2\text{H}_5)_3\text{AsO}_3$.—Produced: 1. By the action of arsenious oxide on ethyl silicate at 220° , and separated by distillation.—2. By heating ethyl iodide with yellow silver arsenite.—3. Together with ethyl oxide, ethylene gas, and silica, by heating arsenic oxide with ethyl silicate to a temperature above 220° ; on distilling the product, the ethyl oxide passes over first, then the ethyl arsenate between 160° and 200° . Ethyl arsenate is a liquid boiling without decomposition at 166° – 168° , and having a density of 1.224 at 0° . Vapour-density = 7.197 at 233° ; 7.380 at 267° ; by calculation (2 vol.) = 7.267. It is instantly decomposed by water, with precipitation of arsenious oxide. It is not acted upon by alcohol, ether, or ethyl acetate (Crafts, *Bull. Soc. Chim.* [2] viii, 206).

* This salt appears to be identical with Pasteur's acid salt obtained by boiling caustic potash with excess of arsenious oxide, and precipitating with alcohol (i. 377).

ARSENIC OXIDE, ACID, and SALTS.—For the preparation of arsenic acid on the large scale, Girardin (*J. Pharm.* [3] xlvii. 269) recommends a process which consists in treating a concentrated solution of arsenious oxide in hydrochloric acid with chlorine gas, and subsequently distilling the liquid to the crystallising point.

The specific gravities of solutions of arsenic acid of various strengths have been determined by H. Schiff (*Ann. Ch. Pharm.* cxiii. 183):

Percentage of H^3AsO^4	Sp. gr. at 15°
67.4	1.7346
45.0	1.3973
30.0	1.2350
22.5	1.1606
15.0	1.1052
7.5	1.0495

Arsenic oxide treated with phosphorus pentachloride, yields arsenious chloride, phosphorus oxychloride, and free chlorine (Hurtzig a. Geuther, *Ann. Ch. Pharm.* cxi. 159):

Arsenic acid boiled with very strong hydrochloric acid is gradually converted into arsenious chloride:

but with more dilute hydrochloric acid (1 pt. acid of sp. gr. 1.2 and 2 pts. water) no volatilisation of arsenic takes place (Souhay, *Zeitschr. anal. Chem.* i. 189).

Arsenic acid in solutions containing soluble chlorides is not converted into arsenetted hydrogen by the action of nascent hydrogen, as in Marsh's apparatus; but when no chlorine is present, as in a solution of ammonio-magnesian arsenate in dilute sulphuric acid, arsenic acid likewise yields arsenetted hydrogen, though less quickly and abundantly than arsenious acid. Hence the addition of sulphurous acid or hydrogen sulphide to reduce the arsenic to arsenious acid, necessary when hydrochloric acid is present, is useful also in other cases (Bloxam, *Pharm. J. Trans.* [2] iii. 607).

Arsenic acid treated in the cold with stannous chloride, yields a white precipitate of stannic arsenite, $2\text{SnO}_2 \cdot \text{As}_2\text{O}_3$, or stannous pyroarsenate, $\text{Sn}_2\text{As}_2\text{O}_7$ or $2\text{SnO} \cdot \text{As}_2\text{O}_3$ (Schiff, *Jahresh.* 1861, p. 278). In warm solutions metallic arsenic is deposited and arsenetted hydrogen evolved (Kessler, *ibid.* p. 265).

ARSENATES. Most insoluble arsenates are obtained by precipitation in the amorphous state, but they may sometimes be rendered crystalline by keeping them for some time at the temperature of 100°. In this manner Debray has obtained the crystallised arsenates of magnesia and zinc, $\text{MnHAsO}_4 \cdot \text{H}_2\text{O}$ and $\text{ZnHAsO}_4 \cdot \text{H}_2\text{O}$. Crystallised arsenates may also be prepared by the action of arsenic acid in solution on the corresponding carbonates. In this manner the minerals olivenite, $\text{Cu}^2(\text{AsO}_4)^2 \cdot \text{CuH}_2\text{O}_2$, and haidingerite, $\text{CaHAsO}_4 + \frac{2}{3}\text{H}_2\text{O}$, have been produced with their natural characters. Some arsenates heated with the corresponding chlorides produce arsenato-chlorides with the characters of native minerals, e.g. mimetosite, $\text{Pb}^2(\text{Cl}^2(\text{AsO}_4)^4)$ (Debray, *Ann. Ch. Pharm.* cxv. 50; cxxxiii. 230; *Ann. Ch. Phys.* [3] lxi. 419). Lechartier (*Bull. Soc. Chim.* [2] viii. 334), by fusing calcium arsenate with chloride and fluoride of calcium together, has obtained crystals having the form of apatite and the composition of calcium arsenato-chloride, with the chlorine partly replaced by fluorine, viz. $\text{Ca}^2(\text{AsO}_4)^2 \cdot \text{Ca}(\text{Cl}^2; \text{F}^2)$. In like manner, by fusing magnesium arsenate with chloride and fluoride of magnesium, the compound $\text{Mg}^2(\text{AsO}_4)^2 \cdot \text{Mg}(\text{Cl}^2; \text{F}^2)$ is obtained, having the form of wagnerite.

The estimation of arsenic in the arsenates of manganese, iron, zinc, lead, and copper may be easily and very exactly performed, according to H. Rose (*Pogg. Ann.* cxvi. 453), by igniting the salt, mixed with sulphur, in a covered porcelain crucible through which a stream of hydrogen is passed, till the residual metallic sulphide exhibits a constant weight. For the arsenates of nickel and cobalt, simple ignition with sulphur in the crucible suffices, but the weight of the metal cannot be calculated from that of the residual sulphide. The sulphide of cobalt, however, even after repeated treatment with sulphur, retains traces of arsenic, which can only be removed by solution in nitric acid, and ignition of the evaporated residue with sulphur. From silver arsenate also it is not possible to remove the whole of the arsenic by ignition with sulphur in a stream of hydrogen; similarly with the arsenate of aluminium, and the arsenate of magnesium and ammonium.

The arsenates of alkali-metal are easily and completely converted into chlorides by ignition with sal-ammoniac; those of the alkali-earth metals less easily; magnesium

arsenate retains part of its arsenic, even after ignition with sal-ammoniac in a stream of hydrogen; so likewise do the arsenates of the heavy metals, as iron, cobalt, or nickel. Acid ammonium sulphate decomposes arsenates more easily and completely than sal-ammoniac; but the fused salt attacks the porcelain crucible so strongly that the quantity of the residual metallic sulphate comes out too high. Arsenate of magnesium and ammonium, and the arsenates of sodium, calcium, and lead, are converted into sulphates free from arsenic, even by a single fusion with acid ammonium sulphate (Rose).

Ammonium Arsenates.—The crystalline precipitate produced by adding concentrated aqueous ammonia to a solution of diammonic arsenate, $(\text{NH}_4)_2\text{HAsO}_4$, consists of the triammonic salt, and after drying between bibulous paper has the composition $(\text{NH}_4)_3\text{AsO}_4 \cdot 3\text{H}_2\text{O}$ (Uelsmann, *Jahresh.* 1859, p. 185). Triammonic arsenic is likewise obtained by saturating with ammonia a solution of arsenic acid sufficiently concentrated to yield a crystalline precipitate on cooling (Salkowski, *J. pr. Chem.* civ. 129; *Bull. Soc. Chim.* [2] 447). According to Schiff (*ibid.* 16), the sp. gr. of the diammonic salt is 1.989; of the monammonic salt, $(\text{NH}_4)\text{H}_2\text{AsO}_4$, 2.249.

Barium Arsenates.—The tribasic salt $\text{Ba}^3(\text{AsO}_4)_2$, obtained by precipitating an ammoniacal solution of arsenic acid with barium chloride, becomes perfectly anhydrous at a little above 100° . It is nearly insoluble in water containing ammonia, more soluble in pure cold water, still more in water containing sal-ammoniac (Field, *Chem. Soc. J.* xi. 6).

The monobasic salt $\text{BaHAsO}_4 \cdot \text{H}_2\text{O}$ is obtained in quadratic octahedrons by dissolving precipitated amorphous barium arsenate in acetic acid, and leaving the solution to evaporate (Schiefer, *Jahresh.* 1864, p. 237). The same salt is obtained by precipitating a solution of disodic arsenate with barium chloride. By digestion with ammonia it is more or less converted into the tribasic salt $\text{Ba}^3(\text{AsO}_4)_2$. The monobasic salt dissolved in hydrochloric acid and mixed with sal-ammoniac, gives with ammonia a precipitate of an arsenate-chloride, $\text{BaCl}_2 \cdot 3\text{Ba}^3(\text{AsO}_4)_2$ (Salkowski).

Bismuth Arsenate, Bi^3AsO_4 , is obtained as a precipitate by adding to an acid solution of bismuth nitrate either a solution of disodic or trisodic arsenate or of arsenic acid. The whole of the bismuth is thereby precipitated, so that the reaction may be made available for the quantitative estimation of that metal. The salt dried at 100° – 120° retains $\frac{1}{3}\text{H}_2\text{O}$. It is quite insoluble in nitric acid, slightly soluble in excess of bismuth salt; it dissolves in hydrochloric acid, but the solution is completely precipitated by water, and by repeating the precipitation several times the precipitate may be completely deprived of arsenic acid (Salkowski).

Cadmium Arsenates.—The salt $5\text{CdO} \cdot 2\text{As}_2\text{O}_3 + 3\text{aq.}$, or perhaps $\text{Cd}^2(\text{AsO}_4)_2 \cdot 2\text{CdHAsO}_4 + 4\text{aq.}$, is precipitated on adding disodic arsenate to cadmium sulphate. The tricadmian salt $2\text{Cd}^3(\text{AsO}_4)_2 \cdot 3\text{aq.}$ is formed by precipitating a cadmium solution with trisodic arsenate (Salkowski).

Calcium Arsenates.—Debruy (*Ann. Ch. Pharm.* cxv. 50), by digesting calcium carbonate with aqueous arsenic acid at ordinary temperatures, has obtained the salt CaHAsO_4 with various quantities of water according to the temperature, viz. $\text{CaHAsO}_4 \cdot 1\frac{1}{2}\text{aq.}$ (haidingerite) at ordinary temperatures; $\text{CaHAsO}_4 \cdot \text{aq.}$ at 70° ; CaHAsO_4 at 100° . Salkowski obtains this salt with 1 mol. water by precipitating calcium chloride with disodic arsenate; it gives off this molecule of water at 160° , and at 240° begins to change into pyroarsenate. On adding calcium chloride to an excess of disodic arsenate, a precipitate is formed having the more complex composition $\text{Ca}^2\text{H}^2\text{Na}^2(\text{AsO}_4)_3 \cdot 8\text{aq.}$ This salt gives off $4\text{H}_2\text{O}$ at 130° . The slightly acid liquid filtered from this precipitate becomes cloudy on boiling, but clear again on cooling. On filtering it at the boiling heat, the salt $\text{CaHAsO}_4 \cdot \text{aq.}$ is left on the filter. The trivalent salt $\text{Ca}^3(\text{AsO}_4)_2$ is nearly insoluble in water containing ammonia. Ammonio-calcic arsenate, $\text{Ca}(\text{NH}_4)\text{AsO}_4$, is easily prepared by mixing a solution of calcium chloride with a large excess of ammonia and tri-ammonic arsenate; it separates from dilute solutions in large needles, from concentrated solutions as a white crystalline powder; dried at 100° it contains $2\text{Ca}(\text{NH}_4)\text{AsO}_4 \cdot \text{aq.}$; at 140° it becomes anhydrous. It is nearly insoluble in ammoniacal water, more soluble in pure water, still more in water containing sal-ammoniac (Field).

Cupric Arsenates.—The salt $2\text{CuHAsO}_4 \cdot 3\text{aq.}$ is obtained in the crystalline form by digesting cupric carbonate with aqueous arsenic acid at 70° . By digesting amorphous cupric arsenate (tribasic) with solution of cupric nitrate or sulphate, crystallised salts are obtained, viz. $\text{Cu}^2(\text{AsO}_4)_2 \cdot 4\text{aq.}$ at 70° , and $\text{Cu}^2(\text{AsO}_4)_2 \cdot \text{CuHPO}_3$ (olivinite) at a little above 100° . The last-mentioned product is obtained more distinctly crystallised by performing the digestion in sealed tubes at 160° – 160° . It may also be prepared from the former hydrate, $\text{Cu}^2(\text{AsO}_4)_2 \cdot 4\text{aq.}$, by digestion with

water containing cupric nitrate or sulphate at 250° – 270° (Debray, *Jahresb.* 1860, p. 72). Cupric sulphate precipitated by diammonio arsenate yields the salt $6\text{CuO} \cdot 2\text{As}_2\text{O}_5 \cdot 3\text{aq.}$ or $\text{Cu}^2(\text{AsO}_4)^2 \cdot 2\text{CuHAsO}_4 \cdot 2\text{aq.}$ By adding ammonia to the mixture a cupric-ammonio arsenate is obtained (Sulkowski).

Ferroso-ferrio Arsenate.—To prepare this salt, which is used in medicine, Wittstein (*Zeitschr. f. Chem.* 1866, p. 256) precipitates a solution of 3 pts. crystallised ferrous sulphate in 60 pts. water with 2 pts. dry sodium arsenate in 40 pts. water in the cold, and dries the washed white precipitate in the air on plates: it then remains in dark lumps of a deep grass-green colour, which yield an olive-green powder. The reaction is represented by the equation

The composition of the air-dried preparation is represented by the formula

It gives off part of its water at 100° , and the rest at a red heat, without loss of acid. The solution filtered from the precipitate gradually deposits yellowish white ferric arsenate, $\text{Fe}^{\text{III}}(\text{As}_2\text{O}_5)^2 \cdot 8\text{H}_2\text{O}$ or $\text{Fe}_2\text{O}_3 \cdot \text{As}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, which when ignited leaves the brown compound $3\text{Fe}_2\text{O}_3 \cdot 2\text{As}_2\text{O}_5$.

Lead Arsenates.—According to Sulkowski, the salt PbHAsO_4 is precipitated on mixing the solutions of lead acetate and disodic arsenate. Most authorities however state that the triplumbic salt $\text{Pb}_3(\text{AsO}_4)^2$ is formed under these circumstances (i. 382).

Lithium Arsenates.—The salt $2\text{Li}^2\text{AsO}_4 \cdot \text{aq.}$ is obtained as a pulverulent precipitate by saturating arsenic acid with lithium carbonate and adding ammonia. A solution of this salt in free arsenic acid yields by spontaneous evaporation deliquescent rhombic prisms (of about 142°) of the *monolithic salt* $2\text{LiH}^2\text{AsO}_4 \cdot 3\text{aq.}$, which is decomposed by water into arsenic acid and the trilithic salt (Rammelsberg, *Pogg. Ann.* cxxviii. 311; *Jahresb.* 1866, p. 160).

Magnesium Arsenate.—According to Schiofer (*Jahresb.* 1864, p. 237), the salt obtained by dissolving the residue left on igniting ammonio-magnesium arsenate in acetic acid, and leaving the solution to evaporate, has the composition $\text{MgHAsO}_4 \cdot 5\text{aq.}$ A solution of magnesium in an equivalent quantity of aqueous arsenic acid yielded a crystalline highly deliquescent salt, supposed by Schiofer to consist of $\text{MgH}^4(\text{AsO}_4)^2$. According to Reischauer (*Jahresb.* 1865, p. 175), magnesium arsenate obtained by precipitation has, when air-dried, the composition $2\text{MgHAsO}_4 \cdot 13\text{aq.}$, and after drying in a vacuum, $2\text{MgHAsO}_4 \cdot 5\text{aq.}$

Ammonio-magnesium arsenate, $\text{Mg}(\text{NH}_4)\text{AsO}_4$, is very slightly soluble in pure water, nearly insoluble in water containing ammonia, more soluble in solution of sal-ammoniac. From the recent experiments of Fresenius (*Zeitschr. anal. Chem.* iii. 206), it appears that 1 pt. of the salt dried at 100° ($\text{Mg}^2\text{HAsO}_4 \cdot \frac{1}{2}\text{aq.}$) dissolves:

- a. In 2,656 pts. water at 15° .
- b. " 15,038 " dilute aqueous ammonia (1 pt. aqueous ammonia of sp. gr. 0.96 to 3 pts. water).
- c. " 843.9 " concentrated solution of sal-ammoniac (1 pt. NH_4Cl to 7 pts. water).
- d. " 1,315 " dilute solution of sal-ammoniac (1 pt. NH_4Cl to 70 pts. water).
- e. " 2,874 " mixture of 60 pts. water, 10 pts. aqueous ammonia of sp. gr. 0.96, and 1 pt. sal-ammoniac.

Consequently 1 pt. of the anhydrous salt $\text{Mg}(\text{NH}_4)\text{AsO}_4$ requires for dissolution the following quantities of the solvents above mentioned:

a.	b.	c.	d.	e.
2,788	15,786	886	1,380	3,014 pts.

See also Field (*Chem. Soc. J.* xi. 6).

From the observations of H. Rose (*Zeitschr. anal. Chem.* i. 413), confirmed by Wittstein (*ibid.* ii. 19), it appears that ammonio-magnesium arsenate when heated, cautiously at first, afterwards till the crucible is almost red-hot, gives up all its water and ammonia, and leaves pure dimagnesium arsenate, $\text{Mg}_2\text{As}_2\text{O}_7$ or $2\text{MgO} \cdot \text{As}_2\text{O}_5$. In estimating arsenic by precipitation as ammonio-magnesium arsenate, the precipitate may therefore be ignited without fear of losing arsenic, and the trouble of drying the precipitate in a vacuum or at 100° , as formerly recommended (i. 367), may be saved. The process thus conducted affords the quickest and most exact of all methods of estimating arsenic.

Manganese Arsenates.—*Monomanganous arsenate*, $\text{MnH}^4(\text{AsO}_4)^2$, separates on

evaporation from a solution of recently precipitated manganous carbonate in excess of arsenic acid, in deliquescent rectangular laminae (Schiefer). Igelström (*J. pr. Chem.* xvii. 60) describes, under the name of *Kondroarsenite*, a basic manganous arsenate, $2(5\text{MnO} \cdot \text{As}_2\text{O}_5) \cdot 5\text{H}_2\text{O}$ or $2\text{Mn}^{1/2}(\text{AsO}^{1/2})_2 \cdot 4\text{Mn}^{1/2}\text{H}^+\text{O}^{1/2} \cdot \text{H}_2\text{O}$, from an iron and manganese mine in Wermland, Sweden. The mineral is implanted in small yellow or reddish yellow, translucent friable grains on a heavy spar which traverses hausmannite in veins.

Nickel Arsenates.—The salts $\text{Ni}^2(\text{AsO}^{1/2})_2$ or $3\text{NiO} \cdot \text{As}_2\text{O}_5$ and $\text{Ni}^2(\text{AsO}^{1/2})_2 \cdot 2\text{NiO}$ or $5\text{NiO} \cdot \text{As}_2\text{O}_5$ have been recognised by Bergemann (*J. pr. Chem.* lxxv. 239) in a mineral from Johann-Georgenstadt; the former yellow and amorphous; the latter crystalline, opaque, and brownish. The trimetallous salt has also been found by D. Forbes (*Phil. Mag.* [4] xxv. 104) in a half-decomposed greenstone (traversing the Jura beds of the Atacama Desert, about twenty leagues east of the port of Flamenco). It occurs in sulphur-yellow amorphous crusts containing 50.53 p. c. As_2O_5 , 48.24 NiO, 0.21 CoO, 0.57 CuO, and 0.62 Bi^2O_3 (= 100.17).

A *nickel-cobalt arsenate*, $2(\text{NiO} \cdot \text{CoO}) \cdot \text{As}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, or perhaps $2\text{NiHASO}_4 \cdot 7\text{H}_2\text{O}$, occurs in the same locality, as a mineral of greyish-white colour, silky to resinous lustre, hardness 2.5, and sp. gr. 3.086. It gave by analysis 44.05 As_2O_5 , 19.71 NiO, 9.24 CoO, and 26.98 water (= 99.98).

Potassium Arsenates.—The monopotassic salt KH^2AsO_3 has, according to Schiff, a sp. gr. of 2.832.

Silver Arsenates.—According to Kühn (*Jahresb.* 1857, p. 257), the *triargentic salt* Ag^3AsO_4 may be obtained as a dark purple crystalline precipitate, by mixing solution of silver nitrate at the boiling heat with a concentrated, almost syrupy solution of arsenic acid. This salt is soluble in arsenic acid, and the solution, kept for some days in a warm place, deposits a white crystalline powder consisting of $\text{Ag}^2\text{O} \cdot 2\text{As}_2\text{O}_5$, or a compound of argentic metarsenate with arsenic oxide, $2\text{AgAsO}_3 \cdot \text{As}_2\text{O}_5$. Water, especially if hot, decomposes this salt into arsenic acid and the normal arsenate (Hurtzig u. Geuther, *Ann. Ch. Pharm.* cxi. 159).

Sodium Arsenates.—To prepare the ordinary *disodic arsenate*, Na^2HASO_4 , on the large scale, for use as a mordant, &c., Higgins (*Dingl. pol. J.* clxxiv. 323) dissolves arsenious oxide in soda-ley, evaporates the solution mixed with sodium nitrate, and calcines the mixture in a reverberatory furnace. The solution of the residue in aqueous sodium carbonate yields on evaporation crystals of the salt $\text{Na}^2\text{HASO}_4 \cdot 12\text{aq.}$ R. Wagner (*ibid.* clxxiv. 323) first prepares tricalcic arsenate by the action of iodine on a mixture of arsenious oxide and calcium hydrate:

then separates the dissolved calcium iodide (which is used in photography) from the undissolved calcium arsenate; and decomposes the latter by boiling with aqueous sodium carbonate. The same salt may be obtained from the arseniferous mother-liquors of the preparation of aniline red (p. 166) by adding a little sodium nitrate, evaporating to dryness, gently igniting the residue, redissolving it in water, and leaving the solution to crystallise by evaporation (E. Kopp, *Bull. Soc. Chim.* [2] ii. 158).

Sodio-ammonium Arsenate, $\text{Na}(\text{NH}^+)\text{HASO}_4 \cdot 4\text{aq.}$, may be prepared, not only by mixing the solutions of the disodic and diammonic salts (i. 384), but also by mixing the solutions of 6 pts. of the disodic salt $\text{Na}^2\text{HASO}_4 \cdot 12\text{aq.}$ with 1 pt. sal-ammoniac, leaving the liquid to crystallise by evaporation, after adding a little ammonia, and recrystallising from ammoniacal water. The concentrated solution of this salt mixed with saturated aqueous ammonia yields a precipitate consisting of faintly lustrous crystalline laminae, which, after washing with ammoniacal water and pressure between bibulous paper, consist of the *sodio-diammonic salt*, $\text{Na}(\text{NH}^+)\text{AsO}_4 \cdot 4\text{aq.}$ (Uelsmann, *Arch. Pharm.* [2] xcix. 138).

The specific gravities of the sodium-arsenates, as determined by Schiff (*Jahresb.* 1859, p. 16), are as follows:

$\text{NaH}^2\text{AsO}_4 \cdot \text{aq.}$	2.535	$\text{Na}^2\text{AsO}_4 \cdot 12\text{aq.}$	1.762
$\text{Na}^2\text{HASO}_4 \cdot 12\text{aq.}$	1.670	$\text{Na}(\text{NH}^+)\text{HASO}_4 \cdot 4\text{aq.}$	1.838
$\text{Na}^2\text{HASO}_4 \cdot 7\text{aq.}$	1.871	$\text{NaKHASO}_4 \cdot 7\text{aq.}$	1.884

Strontio-hydric Arsenate, $\text{SrHASO}_4 \cdot \text{aq.}$, crystallises from a solution of the precipitated salt in acetic acid, in oblique, nearly rectangular laminae (Schiefer). According to Salkowski, strontium chloride mixed with disodic arsenate yields a precipitate of *strontio-sodic arsenate*, $\text{SrNaAsO}_4 \cdot \text{aq.}$, and the filtrate on boiling deposits *strontio-hydric arsenate*, $\text{SrHASO}_4 \cdot \text{aq.}$

Sup.

Thallium Arsenates.—See THALLIUM (v. 753, 756).

Tin Arsenates.—On adding stannous chloride in excess to an acetic acid solution of potassium arsenate, a crystalline precipitate is formed, consisting of *stannous arsenato-chloride*, $\text{Sn}^2(\text{AsO}_4)^2 \cdot \text{SnCl}_2 \cdot \text{H}_2\text{O}$, which when heated out of contact with the air suddenly decomposes, with emission of white vapours and deposition of an arsenic mirror on the sides of the vessel. By adding a small quantity of solution of stannous chloride to a concentrated acetic acid solution of potassium arsenate, a white flocculent precipitate is formed, which when air-dried has the composition of *stannous pyro-arsenate*, $\text{Sn}^2\text{As}^2\text{O}_7$ or $2\text{SnO} \cdot \text{As}^2\text{O}_5$ (Lenssen, *Ann. Ch. Pharm.* cxiv. 113).

Zinc Arsenates.—The compound $4\text{ZnO} \cdot \text{As}^2\text{O}_5 \cdot \text{H}_2\text{O}$ occurs native as *adamine* (p. 57). By adding disodic arsenate to zinc sulphate, a bulky amorphous precipitate is formed, consisting of the salt $5\text{ZnO} \cdot 2\text{As}^2\text{O}_5$ with $4\text{H}_2\text{O}$ at 100° and $3\text{H}_2\text{O}$ at 120° , or of $\text{Zn}^2(\text{AsO}_4)^2 \cdot 2\text{ZnHAsO}_4$ with $3\text{H}_2\text{O}$ or $2\text{H}_2\text{O}$. The *trizincic salt* $\text{Zn}^2(\text{AsO}_4)^2 \cdot 3\text{H}_2\text{O}$ is obtained as a gelatinous precipitate on adding trisodic arsenate to zinc sulphate (Salkowski).

ETHYL ARSENATE. $(\text{C}_2\text{H}_5)^2\text{AsO}_4$.—Prepared by heating silver arsenate in slight excess with ethyl iodide mixed with two volumes of common ether. The product is washed with ether to dissolve the ethyl arsenate, the ether driven off at 100° , in a current of carbon dioxide, and the remaining liquid is distilled under reduced pressure. Ethyl arsenate has a density of 1.326 at 0° , 1.316 at 8° . Under a pressure of 60 millimetres it distils completely between 148° and 153° ; at 760 mm. it distils between 235° and 238° , but with partial decomposition towards the end of the operation, arsenic oxide being left behind. With water it forms a limpid solution which reacts like aqueous arsenic acid (Crafts, *Bull. Soc. Chim.* [2] viii. 206).

Sulphides. The precipitate formed by hydrogen sulphide in a solution of arsenic acid or of an arsenate acidulated with a mineral acid, is a mixture of sulphur and arsenious sulphide, As_2S_3 , in the proportion which would produce the pentasulphide (i. 391): the sulphur may be dissolved out by carbon bisulphide. According to Fuchs (*Zeitschr. anal. Chem.* i. 189), the pentasulphide As_2S_5 may be obtained as a light yellow precipitate by mixing a dilute solution of sodium sulpharsenate with dilute hydrochloric acid. According to Flückiger, on the other hand (*Jahresb.* 1863, p. 232), the precipitate thus obtained (or with acetic acid), though it dissolves completely in ammonia, nevertheless reacts in this solution like a mixture of the trisulphide and free sulphur, inasmuch as it soon deposits sulphur and leaves on evaporation a mixture of arsenite and hyposulphite of ammonium. An ammoniacal solution of the trisulphide does not by itself deposit any sulphur, but easily takes up 2 atoms of sulphur, and then reacts as above.

Trisodic Sulpharsenate, $2\text{Na}^+\text{AsS}^-\cdot 15\text{H}_2\text{O}$ or $3\text{Na}^+\text{S}^-\cdot \text{As}^2\text{S}^-\cdot 15\text{H}_2\text{O}$, is easily obtained in fine crystals by saturating a quantity of soda-ley containing 10 pts. of soda with hydrogen sulphide, and dissolving in the liquid, with aid of heat, 26 pts. of arsenious sulphide and 7 pts. of sulphur. The solution is evaporated, if necessary, till a few drops placed on a watch-glass crystallise, then filtered, and left to cool slowly; and the pale yellow crystals thus obtained are washed with a small quantity of water (Frobenius, *Zeitschr. anal. Chem.* i. 192).

ASAFETIDA. This gum-resin, purified by dissolving it in alcohol, distilling off the greater part of the alcohol, and precipitating the residue with water, gives off, when fused with 3 pts. of potassium hydrate, a thick aromatic vapour; and on dissolving the fused mass in water (4 pts. water to 1 pt. of potash used), acidulating the solution with dilute sulphuric acid, filtering to separate resin, and agitating the solution three times with an equal volume of ether, distilling the ethereal extracts, and evaporating, protocatechuic acid and resorcin are obtained in the proportion of 33 grms. of the former and 22 grms. of the latter to 11 ounces of the resin.

The protocatechuic acid is produced from an acid called ferulic acid, which exists ready-formed in asafetida, and is obtained as follows: The alcoholic tincture of the resin is precipitated with an alcoholic solution of neutral lead acetate; the light yellow precipitate is freed as completely as possible from adhering resin by repeated dissolution in alcohol and pressure; and decomposed, after suspension in warm water, by dilute sulphuric acid. The filtered liquid duly concentrated yields a crystalline mass of crude ferulic acid, which, after recrystallisation from alcohol and then from boiling water, forms long, colourless, four-sided needles belonging to the rhombic system, the faces of which taper to the apex without combination-edges.

Ferulic acid is tasteless, has an acid reaction, dissolves easily in cold alcohol, not very easily in ether, scarcely at all in cold water, but completely in boiling water, very easily and with yellow colour in alcohol. The aqueous solution is precipitated

by neutral lead acetate and ferric chloride; the ammoniacal solution forms with silver nitrate an egg-yellow precipitate quickly becoming darker on exposure to light. Strong sulphuric acid dissolves the crystals with yellow colour, and on heating, with brownish-red colour, the solution exhibiting a green fluorescence, which disappears on dilution with water.

The analyses of ferulic acid and of its salts lead to the formula $C^{10}H^{10}O^4$. The acid melts at 153° – 154° , and solidifies in the crystalline form; fused with potash, it yields as chief product protocatechuic acid, together with small quantities of oxalic, acetic, and carbonic acids. By dry distillation it yields a viscid oil smelling like phenol and guaiacol, in which, after long standing, crystals (probably of pyrocatechin) make their appearance.

Ammonium ferulate, $C^4H^4(NH^4)O^4$, separates from its solution by spontaneous evaporation in laminar crystals, which give off part of their ammonia at 100° . The potassium salt $C^4H^4K^2O^4$ is straw-yellow, deliquescent, and very sparingly soluble in alcohol. The silver salt $C^4H^4AgO^4$ is a lemon-yellow precipitate soon changing colour.

ASH OF ORGANIC BODIES. E. Reichardt recommends the following process for the preparation and analysis of ashes. The substance is charred at a low red heat in a loosely covered crucible; the charcoal is rubbed to powder, repeatedly boiled out with water, and the filtrate is immediately mixed with excess of silver nitrate. The residual charcoal is then exhausted with warm water containing nitric acid, and the extract, together with the wash-waters, is mixed with the first liquid. The charcoal is next incinerated, and the ash is exhausted, first with water, then with hot strong nitric acid. These solutions are mixed with those first obtained; the mixture is acidulated, if necessary; and the precipitate, consisting of silver chloride and sulphide (the latter formed from the metallic sulphides produced in carbonisation), is collected on a filter, weighed, and dried at 100° , and treated while still moist with ammonia to dissolve the silver chloride, which compound is to be reprecipitated from the filtrate by nitric acid. The weight of the silver sulphide dried at 100° gives by calculation a part of the sulphuric acid in the ash. The residue left on treating the ash with nitric acid is warmed with strong hydrochloric acid, diluted, filtered (any insoluble portion being examined for silica), and the filtrate is mixed with that which has run from the silver precipitate. Any silver still remaining dissolved is precipitated by hydrochloric acid; the filtrate is evaporated to dryness to separate silica; and the solution obtained by digesting the dried residue with acidulated water is divided into two portions, one of which is used for the determination of sulphuric acid and alkalis, the other for the remaining constituents, according to known methods.

Soda in Plant-ashes.—To detect the presence of soda in plant-ashes, Peligot (*Zeitschr. anal. Chem.* vi. 473; *Jahresb.* 1867, pp. 763, 832) mixes the aqueous extract of the ash with baryta-water, filters, and evaporates the filtrate after having thrown down the excess of baryta by carbonic acid. The filtered liquid is then supersaturated with nitric acid and evaporated to the crystallising point, whereupon potassium nitrate crystallises out. The mother-liquor is evaporated with sulphuric acid; the strongly ignited residue is dissolved in water; and the solution, after the greater part of the potassium sulphate has crystallised out, is left to evaporate spontaneously, whereupon, if soda is absent, nothing but transparent prisms of potassium sulphate make their appearance, whereas in the contrary case, efflorescent crystals of sodium sulphate will be obtained. These latter are distinctly recognisable even when the saline mixture contains only 2 p. c. of sodium sulphate.

By this method Peligot finds that the greater number of plant-ashes do not contain sodium. Such is the case, for example, with the following plants: Wheat and oats (grain and straw); potatoes (tubers and stems); oak and white beech (wood); tobacco, mulberry, peony, castor-oil plant (leaves); beans, vine-shoots, *Parietaria*, *Gypsophila pubescens*, *Chenopodium quinoa*, spinach, and parsnip. This last plant grew near others mostly belonging to the atriplicaceous and chenopodious families, which contain soda to a greater or less amount. In the ashes of the following plants, sodium was found (chiefly as chloride), though potassium salts predominated: Mangold-wurzel (leaves and roots), orache, *Atriplex hastata*, *Chenopodium murale*, *Mercurialis annua*, *Zostera*, and *Fucus*.

ASH, VOLCANIC. The following are analyses of volcanic ash from the islands of the East Indian Archipelago. Analyses by P. F. Maier: ash from the Gunung Guntur in Java, fallen, I. on January 4, 1843; II. on November 26, 1844. Analyses by Rost van Tonningen: III. ash from Merapi, fallen September 6, 1846; IV. from the volcano on Ternate, April 30, 1850; V. from the Tabacan (Tangi Islands), March

30, 1856; VI. from the Lamongau (on Probolinggo), February 28, 1859; VII. from the Arosbaja (Isle of Madeira), February 28, 1859 (*Jahresb. f. Chem.* 1860, p. 808):—

	I.	II.	III.	IV.	V.	VI.	VII.
SiO ²	34.23	51.77	43.13	31.66	50.40	44.37	49.35
Al ² O ³	37.50	25.77	32.90	46.48	27.49	15.58	17.63
Fe ² O ³	18.18	13.66	10.74	14.68	12.95	29.94	22.60
CaO	6.72	7.43	7.39	4.77	5.35	8.40	7.80
MgO	0.68	0.94	2.23	0.53	0.87	0.66	0.38
X*	1.74	0.30	1.42	1.60	3.21	0.18	0.66
H ² O	0.26	0.32	1.29	0.99	1.59	0.15	0.33

The ashes do not contain either phosphates or potassium salts; their specific gravity varies from 1.572 to 2.801.

O. Pröls (*Jahresb.* 1865, p. 919) found in a volcanic ash which was ejected in large quantity on January 3 and 4, 1864, from the volcano of Kloet in Java (after deduction of 1.25 p. c. water):

SiO ²	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O
53.86	20.41	8.62	7.30	5.37	1.13	3.81

The ash was a fine, sandy, light grey powder, exhibiting, when viewed by a lens, fragments of white labradorite, dark green augite, and granules of greenish yellow olivine, but no magnetic iron ore.

J. W. Young (*Chem. News*, xiii. 73) has analysed volcanic ash from the northern shore of the Isle of Arran, A; also two kinds of fossil wood, B and C, occurring therein:

	SiO ²	Al ² O ³	FeO	Mn ² O ³	CaO	MgO	CO ²	H ² O	Total
A { a.	13.20	8.13	18.26	0.78	13.47	5.06	8.40	3.23	99.97
b.	23.49	4.14	—	—	CaO	MgO	K ² O & Na ² O	FeS*	
					0.46	0.20	0.45	0.70	

a. Decomposable by hydrochloric acid. b. Undecomposable.

	95.30	1.00	0.73			2.35		
						= 99.38		

ASPARAGINE and ASPARTIC ACID. The relations of these compounds to malamide and malamic acid have already been considered under **MALIC ACID** (iii. 706). The following constitutional formulæ may throw additional light upon them:

These formulæ indicate that aspartic acid is bibasic, malamic acid and asparagine monobasic, malamide neutral. Asparagine is known to form salts by substitution of metals for one of its hydrogen-atoms. Aspartic acid was formerly regarded as monobasic, but the existence of the bimetallic aspartates obtained by Dessaignes (i. 424) clearly shows that it is bibasic. Malamide when treated with alkalis can exchange either one or both of its groups NH² for OH, producing, in the former case malamic acid, which is monobasic, and in the latter malic acid, which is bibasic; but asparagine, which is already monobasic, is converted by one such transformation into bibasic aspartic acid.

Asparagine occurs in considerable quantity in the expressed juice of the tubers of *Stigmaphyllon jatrophaefolium*, a malpighiaceae plant indigenous in Brazil (De Luca a. Ubaldini, *Compt. rend.* lix. 527).

Buchner (*Zeitschr. f. Chem.* 1862, p. 117) prepares asparagine by subjecting the concentrated aqueous extract of marsh-mallow root to the dialytic action of parchment-paper. The liquid which runs through in the course of a day or two yields on evaporation

* Soluble salts, sodium chloride, sulphate, &c.

a somewhat abundant crystallisation of asparagine. A further quantity may be obtained by renewing the water in the dialyser. By the same process Gorup-Besanez (*Ann. Ch. Pharm.* cxv. 291) obtained from two pounds of the fresh root of *Scorzonera hispanica* about 6 grms. of pure asparagine.

A cold saturated solution of asparagine is gradually oxidised, with rise of temperature, by potassium permanganate, yielding, as chief products, ammonia, formic acid, carbon dioxide, and hydrocyanic acid:

In presence of sulphuric acid the oxidation takes place according to the equation:

in presence of potash, thus:

neither carbonic nor hydrocyanic acid being formed in this case (Campani, *Zeitschr. f. Chem.* [2] vi. 87).

Aspartic acid is contained in somewhat considerable quantity in the juice of mangold-wurzel which has been treated with lime, and especially in the molasses (being formed therein by the decomposition of asparagine). To obtain it, the moderately dilute solution is precipitated with basic acetate of lead; the filtrate is mixed with mercurous nitrate; the impure mercurous aspartate thereby precipitated is decomposed by hydrogen sulphide; the filtrate is evaporated to a syrup; and the acid which crystallises out is purified by boiling with moderately strong alcohol, and re-crystallisation from alcohol. The presence of aspartic acid in the beet-juice is a source of error in the estimation of the sugar by the polariscope, inasmuch as alkaline solutions of asparagine and aspartic acid are laevogyrate, acid solutions dextrogyrate (C. Scheibler, *J. Pharm.* [4] iv. 152). In the beet-molasses of the years 1867 and 1868, Scheibler has found, instead of aspartic acid, an acid having the composition of its next higher homologue, $C^5H^6NO^4$ (*Deut. Chem. Ges. Berlin* 1869, 296).

Aspartic acid is produced (together with leucine and tyrosine) when animal proteides are boiled with sulphuric acid (Kreusler, *Zeitschr. f. Chem.* [2] vi. 93); also, together with glutamic acid, by boiling legumin or conglutin with sulphuric acid (Ritthausen, *ibid.* 126).

When dry acid barium aspartate is distilled with potassium ethylsulphate, alcohol is given off, and the residue contains, together with the sulphates of barium and potassium, a substance $C^4H^5NO^3$, which is also produced in the dry distillation of acid ammonium malate:

If the potassium sulphate be first dissolved out by water, the residue treated with hydrochloric acid, and water added to the resulting solution, a tasteless compound is obtained, insoluble in water and converted by boiling with hydrochloric acid into hydrochloride of aspartic acid (Dessaignes, *J. Pharm.* [3] xxxii. 49).

ASPEROLITE. A copper silicate from Tagilsk, so called on account of its brittleness. It forms kidney-shaped amorphous masses, having a vitreous lustre, blue-green colour, and conchoidal fracture; hardness = 2.5; sp. gr. = 2.306. Easily decomposed by hydrochloric acid, with separation of pulverulent silice. Contains 31.94 p. c. SiO^2 , 40.81 CuO, and 27.25 water, agreeing with the formula $CuSiO^3 \cdot 3H^2O$ or $CuO \cdot SiO^2 \cdot 3H^2O$. This mineral forms therefore the third member of the series of hydrated cupric metasilicates, the first term of which is formed by diopase, $CuSiO^3 \cdot H^2O$, and the second by chrysocolla, $CuSiO^3 \cdot 2H^2O$ (R. Hermann, *J. pr. Chem.* xxvii. 352).

ASPHODELUS. The root of *Asphodelus Kotchy* (*Rad. Carniola*), indigenous on the Antilebanon and Gauran, has been examined by Dragendorff (*Zeitschr. f. Chem.* 1866, p. 734), in comparison with salep-root. The following are the results:

<i>Radix Carniola.</i>		<i>Salep-root.</i>	
	p. c.		p. c.
Dextrin (with a little arabin)	20.9	Dextrin, arabin, and half-soluble	
Arabin (with a little dextrin)	31.2	vegetable mucilage	48.1
Insol. vegetable mucilage (cutin)	10.0	Starch	27.3
Sugar	3.8	Sugar	1.2
Cellulose	4.6	Cellulose	2.4
Protein substances	4.3	Protein substances	4.9

The ash of *Rad. Carniola* (A), amounting to 4.8 p. c., and that of salep-root (B), to 2.1 p. c., exhibited the following composition:

	A.	B.
K ² O	30.192	23.184
Na ² O	0.903	9.327
CaO	21.436	20.659
MgO	4.818	3.903
Fe ² O ³	0.323	0.722
SO ³	3.718	2.803
Cl	2.968	12.820
P ² O ⁵	4.606	28.792
CO ²	13.877	2.751
SiO ²	4.048	6.644
Insoluble	6.634	

ASPIDIUM FILIX MAS. Pavesi (*Arch. Pharm.* [2] cviii. 142) obtained from the root of this fern a thickish, oleo-resinous, yellowish mass, having a sharp bitter taste, insoluble in water, ammonia, potash, and soda, not attacked by dilute nitric, hydrochloric, or acetic acid, but soluble in alcohol and ether. To this substance, which he designates as *aspidin*, Pavesi ascribes the anthelmintic action of the root.

The ash of male fern root (freed from the leafy scales, but still covered with the brown epidermis) amounts, according to Spiess (*Chem. Centr.* 1860, p. 766), to 2.74 p. c. of the root dried at 100°. Its analysis gave 6.78 p. c. K²O, 1.17 Na²O, 37.73 CaO, 1.27 MgO, 2.67 Fe²O³, 0.07 Al²O³, 14.87 P²O⁵, 8.48 SiO², 9.08 SO³, 3.33 Cl, 12.80 CO² with 0.25 loss.

ASTACUS. The blood of the crawfish, *Astacus fluviatilis*, is, when it first flows out, colourless, limpid, mobile, very slightly alkaline, and gives with acetic acid a precipitate soluble in excess of that reagent. It coagulates to a jelly on exposure to the air, or when boiled, and consequently forms a clot and serum, like the blood of vertebrate animals; the clot consists of a substance resembling fibrin; the serum contains albumin. The blood contains 90.89 p. c. water, 1.55 salts, and 7.56 organic matter. The alkaline ash, free from carbonic acid, contains, in addition to the usual constituents of blood-ash, 2.49 p. c. cupric oxide (*E. Witting, J. pr. Chem.* lxxiii. 121).

The colouring matter of the crawfish is greenish-blue, with red patches, and in animals with comparatively old shells it is deposited between the shell and a thin membrane on the knobby parts of the shell; it is turned purple-red by ammonia. In crawfish with soft shells, the blue or brown-green colouring matter is situated upon or under a soft membrane between the shell and the flesh. The colouring matter dissolves in alcohol with bluish colour changing to red; it is turned crimson by ammonia, brick-red by acetic acid, or by boiling with water. The red colour produced by alkalis is destroyed by hydrochloric and by nitric acid: hence the brownish-green colour is perhaps the original (*Witting, loc. cit.*).

ASTROPHYLLITE. This mineral, occurring in the zircon-syenite at Barkerfjord on the Brevig fjord in Norway, accompanied by a black mica, an augite allied to ægyrin, also zircon, catapleiite, palæo-natrolite, elæolite, sodalite, cancrinite, and other minerals, has been analysed: *a*, by Pisani (*Compt. rend.* lvi. 846); *b*, by Scheerer, *Pogg. Ann.* cxxii. 107; *c*, by Meincke (*ibid.*); *d*, by Sieveking (*ibid.*).

	a.	b.	c.	d.
Silica	33.23	32.21	32.35	33.71
Titanic oxide	7.09	8.24	8.48	8.76
Zirconia	4.97	—	—	—
Alumina	4.00	3.02	3.46	3.47
Ferric oxide	3.75	7.97	8.05	8.51
Ferrous oxide	23.58	21.40	18.06	26.21
Manganous oxide	9.90	12.63	12.68	10.59
Lime	1.13	2.11	1.86	0.95
Magnesia	1.27	1.64	2.72	0.05
Potassium oxide	5.82	3.18	2.94	0.65
Sodium oxide	2.51	2.24	4.02	3.69
Lithium oxide	trace	—	—	—
Water	1.86	4.41	4.53	4.85
	99.11	99.05	99.15	100.44

From the last three analyses Scheerer deduces the formula 3(MO.2SiO²) + M²O³.2SiO², which, if M²O³ be equivalent to 3MO, may be reduced to 3MO.2SiO². The mineral appears therefore to differ in composition from ordinary mica, and,

according to Scheerer's observation (*Jahresb.* 1855, p. 951), it also differs from mica in crystalline form, exhibiting the monoclinic combination ∞P . [$\infty P\infty$]. PS . $\frac{1}{2}P\infty$, and always without the prism ∞P of nearly 120° which occurs constantly in mica. The crystals cleave parallel to ∞P , and are always elongated in the direction of the clinodiagonal. Twins occur; also stellate and cauliflower-like groups of radiate crystals. According to Descloizeaux, astrophyllite also differs from normal mica in its optical characters. It is brown-black, bronze-brown to brownish-golden yellow with metallic vitreous lustre. Sp. gr. 3.3 to 3.4. Tschermak (*Jahresb.* 1863, p. 321) regards astrophyllite as a somewhat altered anthophyllite.

ATACAMITE. This mineral occurs very abundantly in the copper mines of Algodon Bay in Bolivia. Selected crystalline splinters analysed by v. Bibra (*J. pr. Chem.* xvi. 193; *Jahresb.* 1865, p. 913) gave the following results:

CuO	Cu	Cl	H ² O	Total
52.54	13.33	14.96	19.17	= 100
53.65	14.75	16.56	15.13	= 100.09
50.32	14.55	15.90	19.23	= 100
52.40	14.00	15.07	18.53	= 100

Tschermak (*Chem. Centr.* 1865, p. 616) observed on crystals of atacamite the forms ∞P , $P\infty$, $\infty P\infty$, P , ∞P , $2P^2$. He finds that the atacamite sand of Chile always contains a perceptible quantity of sulphuric acid, arising from brochantite.

Respecting the formation of atacamite, see Field (*Chem. Gaz.* 1858, p. 430; *Phil. Mag.* [4] xxiv. 123).

ATHEROSPERMA. The bark of *Atherosperma moschatum* has been examined by N. Zeyer, who has found in it volatile oil, fixed oil, wax, albumin, gum, sugar, starch, butyric acid, oxalic acid, an aromatic resin, iron-greening tannic acid, and an alkaloid, which he designates as atherospermine. The lead-compound of the tannic acid was obtained by precipitating the clarified aqueous decoction of the bark with lead acetate, digesting the well-washed precipitate with acetic acid, and exactly saturating the filtrate with ammonia. The greyish-yellow precipitate thus formed gave, by analysis, after drying, numbers answering to the formula $C^{10}H^{14}Pb^2O^2$.

When the bark, after being boiled out with water and treated with dilute sulphuric acid, is exhausted with weak soda-ley, the aromatic resin passes into solution, and may be separated by precipitation with hydrochloric acid, and purified by treatment with alcohol and water. It is brown-red, has a faint aromatic odour, tastes distinctly like nutmeg and sassafras, melts at 114° , dissolves easily in alcohol and in alkaline hydrates and carbonates, with difficulty in ether and in turpentine oil. The analysis of the resin gave numbers according with the formula $C^{21}H^{22}O^3$ (Zeyer, *Jahresb.* 1861, p. 769).

The ash, amounting to 3.64 p. c. of the air-dried bark, and 4.06 p. c. of the bark dried at 100° , was found by Zeyer to contain 2.675 p. c. NaCl, 4.036 K²O, 8.321 Na²O, 45.445 CaO, 4.361 MgO, 0.191 Al²O³, 0.098 Fe²O³, 0.477 Mn²O³, 1.442 SO³, 1.186 P²O⁵, 1.396 SiO², and 30.005 CO².

The volatile oil (called *Victoria sassafras* oil), obtained by distilling the dried bark, is pale yellow, has a peculiar odour, distils almost wholly at 224° , and has a sp. gr. of 1.0425 at 15.5° (Gladstone). Respecting its optical properties, see OILS, VOLATILE (iv. 186).

ATHEROSPERMINE. The solution filtered from the impure lead-precipitate mentioned in the last article yields, on addition of ammonia, a precipitate, which, after washing and drying, digestion with alcohol, evaporation of the brown solution, mixing of the remaining mass with hydrochloric acid, and precipitation with ammonia, yields crude atherospermine; and by agitating this substance with carbon bisulphide, dissolving the mass left after evaporating off the carbon bisulphide in hydrochloric acid, and again precipitating with ammonia, the atherospermine is obtained in the pure state.*

Atherospermine forms a white, somewhat greyish, light, highly electric powder, inodorous, and having a pure bitter taste. It turns yellowish when exposed to sunshine, melts at 128° , and at a higher temperature emits an empyreumatic odour, takes fire, and burns away without residue; when slowly heated it gives off an odour of putrid meat, and afterwards of herrings (propylamine?). It is nearly insoluble in water, dissolves with difficulty in ether, more easily in alcohol, the solution having a distinct alkaline reaction; soluble also in chloroform, oil of turpentine, and other volatile oils. When dissolved in dilute acids, it neutralises them, with formation of

* The bark which had been boiled with water for the preparation of the tannic acid still retained a portion of the alkaloid, which was extracted therefrom by digestion with dilute sulphuric acid.

varnish-like salts. In contact with iodic acid and a little water, it liberates iodine with brown colour. The neutral solution of the alkaloid in hydrochloric acid is precipitated white by alkalis and alkaline carbonates, yellow by picric acid, yellowish white by tannic acid, dirty yellow by phosphomolybdic acid, pale yellow by platinic chloride; it likewise yields precipitates with iodide, ferrocyanide, and sulphocyanate of potassium, auric chloride, &c. The formula of atherospermine has not yet been determined (Zeyer, *loc. cit.*).

ATMOSPHERE. 1. *Variation in the amount of Carbon dioxide.*—Ch. Méne (*Compt. rend.* lvii. 155) infers, from a series of determinations made by passing air through baryta-water of known strength, and subsequently titrating the baryta with standard hydrochloric acid, that the proportion of carbon dioxide in the air varies at different seasons, being constant in December and January, increasing in February, March, April, and May, decreasing from June to August, increasing again from September till November, and attaining its maximum for the whole year in October. During the night the air contains more carbon dioxide than in the daytime, and even during the day it is not quite constant, a slight increase occurring about noon. The quantity is also slightly increased after rain.

From the observations of Lewy (*Ann. Ch. Phys.* [3] xvii. 5), made upon the air over the Atlantic Ocean, it had been concluded that air over the sea contains a larger proportion of carbon dioxide than that over the land, and that sea-air is richer in carbon dioxide during the day than during the night, the mean results obtained being 5.299 pts. in 10,000 for the day, and 3.459 pts. for the night. The observations of T. E. Thorpe, however (*Chem. Soc. J.* [2] v. 189), made on the air of the Irish Sea and of the Atlantic Ocean, have led to totally different conclusions. The mean of 26 determinations of the air over the Irish Sea (made in the month of August at 4 a.m. and 4 p.m.) gave 3.086 vols. carbon dioxide in 10,000 vols. of air (minimum 2.92; maximum 3.32). The air over the Atlantic Ocean was found to contain in 10,000 vols. a mean amount of 3.011 vols. carbon dioxide during the day (min. 2.85; max. 3.17); during the night 2.993 vols. (min. 2.70; max. 3.26); as the mean of the whole 61 experiments, 2.953 vols.; and as the general average of the results obtained over the ocean and over the Irish Sea, 3.00 vols. Hence it appears to be established that the proportion of carbon dioxide in sea-air, in various latitudes and at different times of the year, is nearly constant, does not vary perceptibly at different times of the day and night, and is always considerably less than in the air over the land, which, according to the general mean of the most trustworthy observations, is 4.04 p. c. The sea cannot therefore have any tendency to increase the proportion of carbon dioxide in the land-air. The higher results obtained by Lewy are attributed by Thorpe to the methods of analysis (Regnault's eudiometric method) which he employed. Thorpe's observations were made by Pettenkofer's method (absorption of the carbon dioxide by lime-water of known strength, and subsequent titration of the lime-water with oxalic or hydrochloric acid).

Thorpe has also determined the proportion of carbon dioxide in the air of tropical Brazil, at Para, 80 miles from the sea, on the borders of an extensive primeval forest, on the river Gram-Para, lat. $1^{\circ} 27' S.$, long. $48^{\circ} 28' W.$ The observations, made during the rainy season (April and May 1866), gave in 10,000 vols. of air, a minimum of 3.07 vols. carbon dioxide, maximum 3.49 vols., or as a mean of 31 determinations made on 17 days, 3.28 vols. carbon dioxide. This mean value is considerably lower than that determined by Lewy (*loc. cit.*) for the land-air of the tropics (3.822 in the rainy season, 4.573 during the dry season), and than the mean amount of the land-air in Europe. The difference is probably due to the united action of the tropical rains and of the luxuriant vegetation (*Chem. Soc. J.* [2] v. 109).

A. McDougall (*Chem. News*, ix. 30) has determined, under Roscoe's direction, the amount of carbon dioxide in the air of Manchester and its environs. On two different days the amount in 10,000 vols. of air was found to be:

	In Manchester	Four miles from Manchester
I.	3.90	3.85
II.	2.80	2.77

As the mean of 46 determinations, 10,000 vols. air from the centre of Manchester were found to contain 3.92 vols. carbon dioxide (min. 2.8; max. 5.6); the air outside the town contained, as a mean of eight determinations, 4.02 vols. From these results Roscoe concludes that in open places the influence of combustion and respiration processes is completely neutralised by the movements of the air.

R. Angus Smith, in an elaborate report on the air in mines and other confined places (London, 1864), has published numerous experiments on the amount of oxygen,

carbon dioxide, and dust in the air, the causes of its deterioration, and the influence of its alterations on the health of workmen. Taking as a standard air containing 20.9 vols. p. c. oxygen, Smith regards air containing 20.6 p. c. as decidedly impure, and air containing 20.5 p. c. as very bad, and dangerous if inhaled for any considerable time; air containing only 17.2 p. c. oxygen is difficult to endure even for a few minutes. In 10.7 p. c. of 393 samples of air from metal and coal mines, the proportion of oxygen was nearly normal; 24.7 p. c. were impure, and 64.6 p. c. very bad. The smallest amount of oxygen found in air from mines was 18.97 p. c.; the mean amount of carbon dioxide, 0.785 p. c. In closed ends of mines, in consequence of the combustion of illuminating material and of blasting powder, and of the respiration of the miners, the proportion of carbon dioxide sometimes reaches 2.1 p. c. The quantity of solid matter which, in the form of dust from the rock, and from the combustion of the powder, is inhaled by a workman in the course of a day amounts to about 90 grains.

In a well-ventilated room lighted with petroleum Smith found 20.84 p. c. oxygen, and after the lamp had burnt for six hours, 20.83 p. c.; in the pit of a theatre at half-past eleven in the evening, 20.74 p. c.; in the gallery, 20.36 p. c.

Ammonia.—A. Müller, by exposing dilute sulphuric acid to the air in shallow vessels placed in an elevated open situation, but protected from rain, found that it absorbed in four months only 28 milligrams of ammonia for every square foot of surface, corresponding to rather more than 4 kilograms per hectare (*J. pr. Chem.* xvi, 339).

In 1016 litres of the air of stables in which horses were kept, Clemm a. Erlenmeyer (*Zeitschr. f. Chem.* 1860, p. 52) found 0.0394 grms. ammonium carbonate, and 0.693 grms. of free carbon dioxide.

Saline particles.—Sodium salts, especially the chloride, are so constantly present in atmospheric dust that it is difficult to obtain a flame-spectrum in which the yellow sodium line is not more or less apparent. This dust of sodium salts is derived from the evaporation of the minutely divided particles of sea-spray, and from the transportation of the minute solid particles by the winds (v. 379). Gernez (*Compt. rend.* lxi, 289), by passing air in the open country through water which had been twice distilled from a platinum retort and collected in a platinum condenser, and then leaving a few drops of the water to evaporate on a glass plate, obtained efflorescent crystals of sodium sulphate recognisable by the microscope. According to Barral (*Compt. rend.* li, 769), atmospheric air also contains phosphorus-compounds. In the residue obtained by evaporating rain-water collected in platinum vessels, he found from 0.05 to 0.9 milligrams phosphoric oxide (P_2O_5) to the litre of rain-water, the amount being nearly the same whether the water was collected in the neighbourhood of Paris or in the country. De Luca (*Compt. rend.* lii, 1021), by observations made in Pisa in 1860–61, found that all the rain and snow-water there collected contained variable quantities of inorganic salts, nitrogenous organic matters, and nitric acid. The water collected at 54 and at 18 metres above the surface contained neither phosphates nor iodides, whereas these substances could be easily, though not always, detected in water collected near the surface.

Ozone.—As ordinary oxygen is known to be converted into ozone under the influence of electricity, and of a number of slow oxidising actions which are constantly taking place on the surface of the earth, it appears probable that ozone will be found to exist in the atmosphere, if not constantly, at least at certain times and in certain places. And in fact certain oxidising actions do take place on bodies exposed to the air, which are known to be produced by ozone, but not by ordinary oxygen: for example, the blueing of starch-paper impregnated with potassium iodide, the brown coloration of manganous sulphate, and the oxidation of black sulphide of lead into white sulphate (iv. 302). It has even been supposed that atmospheric ozone destroys the putrid miasmata and minute organisms which often render the air unhealthy; and observations made in India have indicated a relation between the diminution of the amount of ozone in the air and the increase of cholera, dysentery, and intermittent fevers in certain localities.

It has, however, been objected that the blueing of iodised starch-paper, and other oxidising actions attributed to ozone, may also be produced by nitrous acid and other oxygen-compounds of nitrogen, which are known to exist frequently, if not always, in the air, and that therefore these reactions cannot be looked upon as affording proof of the existence of atmospheric ozone, unless the action of the nitrogen oxides can be eliminated, or unless the evidence can be corroborated by other reactions which these

nitrogen-compounds are not capable of producing (Cloeaz, *Compt. rend.* xliii. 38; lii. 627; *Jahresb.* 1856, p. 267; 1861, p. 163. J. Piess a. V. Pierre, *Wien. Akad. Ber.* xxii. 211; *Jahresb.* 1857, p. 79. Zenger, *Wien. Akad. Ber.* xxiv. 78; *Jahresb.* 1857, p. 79).

In reply to these objections, Houzeau has shown (*Compt. rend.* xlv. 873; xlv. 89; *Jahresb.* 1857, p. 80; 1858, p. 61) that a neutral solution of potassium iodide exposed to the air in the open country, but protected from sun and rain, becomes alkaline, and exhibits after some time a diminished proportion of iodine, the potassium being in fact converted into potash by the oxidising action of ozone, while the iodine is set free and gradually escapes. That the alkalinity was not due to the absorption of ammonia by the solution, or to the falling in of alkaline dust, was shown by the fact that the solution did not lose its alkalinity when heated, and that distilled water placed side by side with the solution of potassium iodide did not become alkaline; it is evident also that the alkalinity could not arise from decomposition of the potassium iodide by nitrous acid.

Further, by comparative observations on the air at Paris, at Rouen, and in the open country, Houzeau has found that the colouring of potassium iodide solution, and of iodised starch-paper, takes place less strongly in proportion as the presence of acids in the air (indicated by permanent reddening of litmus-paper) becomes more perceptible (*Compt. rend.* lxi. 40; *Jahresb.* 1865, p. 122).

To detect ozone in the air, Houzeau passes the air first through water slightly coloured with wine-red tincture of litmus, and then through a similarly coloured solution of neutral potassium iodide. If the air contains ozone, but no nitrous acid, the colour of the latter solution changes to brownish- or yellowish-blue, while that of the water remains unaltered; if, on the other hand, the action of the ozone in the air is complicated by that of oxygen-acids of nitrogen, their presence is indicated by the reddening of the coloured water. For the quantitative estimation of ozone in the air, Houzeau passes it through a very dilute solution of potassium iodide containing a known quantity of sulphuric acid; afterwards expels the free iodine by boiling the liquid till it is decolorised; and estimates by titration the quantity of potash which has been set free by the ozone and partially neutralised by the sulphuric acid.

Paper soaked in solution of thallous oxide is recommended by Böttger (*J. pr. Chem.* xcv. 111) as the best reagent for the detection of ozone, because it is turned brown by ozone, but not affected by nitrous acid. According to Huizinga (*ibid.* cii. 193), it is even bleached by nitrous acid if previously coloured brown by ozone; accordingly the browning of thallium paper exposed to the air will in most cases be only the difference between the two opposite actions of ozone and nitrous acid, and sometimes will not take place at all, in consequence of the action of the latter equalling or exceeding that of the ozone (see also Schönbein, *J. pr. Chem.* ci. 321).

Andrews (*Phil. Mag.* [4] xxxiv. 315; *Jahresb.* 1867, p. 179) has shown that the constituent of the air which separates iodine from potassium iodide exactly resembles ozone in its action upon metallic mercury and manganese dioxide, and more especially in its behaviour when heated. Ozone is reconverted into ordinary oxygen at 237° (iv. 391), and active atmospheric air becomes inactive at the same temperature. When active air is passed at the rate of 3 litres per minute through a glass globe of about 5 litres capacity, and then through a U-tube a metre long connected therewith, and moistened within, iodised starch-paper held in the escaping current of air is turned blue so long as the apparatus is not heated; but if the globe be heated to 260°, while the U-tube is kept cool by immersion in cold water, the paper is no longer turned blue. Ozone is also reconverted into ordinary oxygen by contact with peroxides; and, in like manner, active atmospheric air passed over manganese dioxide loses its power of decomposing potassium iodide. Lastly, active atmospheric air oxidises metallic mercury in the same manner as electrolytic ozone; but this reaction is less characteristic and more difficult to recognise than those above mentioned.

Daubony (*Chem. Soc. J.* [2] v. 1) also concludes, from a long series of observations carried on at Turquay and at Oxford, that the constituent of the atmosphere which separates iodine from potassium iodide cannot be either nitrous acid or chlorine, inasmuch as it bleaches litmus without previously reddening it, and does not produce turbidity in a solution of silver nitrate. On the other hand, he found that the action of light may introduce a serious error in ozonometry, inasmuch as mere exposure to direct sunshine colours paper dipped in iodised starch or in manganous sulphate, in the same manner as ozone, and even diffused daylight perceptibly strengthens the coloration produced by ozone. Hence for exact determinations of the strength of the ozone reaction the sensitive papers should be exposed to the air in a dark vessel. Observations made on numerous species of plants, with attention to this circumstance, have shown that the green parts of plants, when exposed to light, give out, in addition

to ordinary oxygen, small quantities of active oxygen, and consequently that vegetation must be regarded as one of the most productive sources of atmospheric ozone.

A. Cossa (*Zeitschr. anal. Chem.* vi. 24) recommends that, for the exact estimation of ozone, the air should be passed first through potash-ley (to absorb nitrous acid, &c.), then through a solution of potassium iodide, and the separated iodine determined volumetrically.

Bérigny a. Sallérin (*Compt. rend.* lxx. 982) propose to determine the time during which ozonoscopic paper must be exposed to the air, in order that when subsequently moistened it may acquire a normal colour (the fourth tone of the first violet in Chevreul's circle of colours). For this purpose they cause the paper to be rolled on a cylinder by clockwork, so that for each division the time of exposure may be known. This mode of observation is designated as *chronozometry*.

Variations in the Amount of Atmospheric Ozone.—From observations made by Houzeau (*Compt. rend.* lx. 788) at Rouen in the years 1861 to 1864, it appears that the greatest number of days per month on which the air exhibited indications of ozone fell in the months of May and June; in the later summer months and in autumn the presence of ozone was less frequent, and in winter it attained its minimum, increasing again in March. The quadrennial average of days on which ozone was perceptible was 22 days from January to March, 56 from April to June, 37 from July to September, and 19 from October to December. A. Bérigny (*Compt. rend.* lx. 903), from a nine years' course of observations made at Versailles from 1856 to 1864, came to a general conclusion which agrees to a considerable extent with that of Houzeau. Bérigny observed the absolute maximum to occur in May, the absolute minimum in November and February. All the separate (monthly) maxima were observed to coincide with storms occurring in the neighbourhood or in a perfectly determinate direction; the minima, most frequently at least, with more distant storms (see also Houzeau, *Compt. rend.* lxii. 426). M. Böckel (*Ann. Ch. Phys.* [4] vi. 235) also concludes, from observations continued for eleven years at Strasbourg, that the air is richer in ozone in spring than during the rest of the year. He finds that the month of May is the richest in ozone, while October and November are the poorest. In the first six months of the year, and from October to December, the proportion of ozone in the air is smaller in the evening than in the morning, whereas the opposite relation is observed in July, August, and September. The maxima of ozone occur especially in the first five and the last two months of the year; the minima in the first two and the last three. Many years are exceptionally rich in ozone. Böckel further directs attention to certain relations between the mean height of the barometer and the mean amount of ozone in the air in particular months; within certain limits these two magnitudes appear to be inversely proportional one to the other.

ATOMIC VOLUME. *Specific Volume.*—H. Kopp showed some years ago that the atomic volume of a compound depends, not merely on its molecular weight, but also on its constitution as represented by the rational formula (i. 448). An additional example of this relation is afforded by the isomeric bodies, aldehyde, $\begin{matrix} C^2H^4O \\ H \end{matrix}$, and ethylene oxide, $(C^2H^4)^2O$. According to the previously established atomic volumes of oxygen, in its intra-radicle and extra-radicle position, these two bodies should have different atomic volumes, and consequently different specific gravities. The calculated atomic volume of aldehyde for 0° is 54.3; that of ethylene oxide 50.6, assuming that these two bodies undergo equal contractions for equal decrements of temperature from their boiling points. Consequently the calculated sp. gr. of aldehyde (quotient of atomic weight by atomic volume) is $\frac{44}{54.3} = 0.810$; that of ethylene oxide $\frac{44}{50.6} = 0.870$. Now from actual determinations by Wurtz, it appears that the sp. gr. of aldehyde at 0° is 0.807; that of ethylene oxide 0.895–0.898 (Kopp, *Ann. Ch. Pharm.* cxxviii. 193).

The researches of Marignac have shown that isomorphism may exist between compounds containing equal numbers of atoms of elements not of equal atomicity or combining capacity (p. 237), as for example in $CuTiF_6$ and $CuWO_2F_6$ (iv. 786; v. 902). Such isomorphous compounds thus related have been further shown by Kopp (*Ann. Ch. Pharm.* cxxv. 371; *Jahresb.* 1863, p. 3) to be at least approximately equal in their atomic volumes, as in the following instances:

		Atomic weight	Spec. gravity	Spec. volume
{ Copper glance	CuCuS	158.8	5.71	27.8
{ Argentiferous copper glance	CuAgS	203.4	6.26	32.5
{ Potassium perchlorate	KClO ⁴	138.6	2.54	54.6
{ Potassium permanganat ⁴	KMnO ⁴	158.1	2.71	58.3
{ Potassium nitrate	KNO ³	101.1	2.11	47.9
{ Barium carbonate	BaCO ³	197.0	4.30	45.8
{ Sodium carbonate	NaNO ³	85.0	2.24	37.9
{ Calcite	CaCO ³	100.0	2.72	36.8

In some cases, however, as in anorthite and other complicated minerals, in which the alkali-metals appear to be isomorphously replaced by calcium, such replacement takes place, not in atomic, but in equivalent proportions, e.g. 39 pts. potassium by 20, not by 40 pts. of calcium.

A certain relation between the atomic volumes of similarly constituted compounds and their volatility has been pointed out by J. Persoz (*Compt. rend.* ix. 1126; *Jahresb.* 1865, p. 33). In compounds derivable from one another by substitution, the boiling point becomes lower as the atomic volume increases, the highest boiling points corresponding for the most part to the greatest densities. Thus the atomic volume of chlorine-compounds is greater than that of the (less volatile) oxides; that of the mercaptans is greater than that of the (less volatile) alcohols; the atomic volume of ethyl alcohol at the boiling point is to that of mercaptan as 14 to 17; that of amyl alcohol to that of amyl mercaptan as 39 to 56.

As the molecules of bodies in the state of gas or vapour occupy for the most part equal volumes, it follows that the molecular equations which represent double decompositions between bodies capable of assuming the gaseous state must also be volume-equations; that is to say, in any such reaction the sum of the molecular volumes of the acting bodies must be equal to the sum of the volumes of the products in the state of gas or vapour. The existence of a similar relation in the double decompositions of liquid and solid bodies has been pointed out by Mendelejeff (*Jahresb.* 1858, p. 29) and by Semenoff (*ibid.* 1865, p. 30). Thus:

Formation of Barium Nitrate.

	2NO ² H + BaH ² O ²	Sum	(NO ²) ² Ba + 2H ² O	Sum
Mol. weight	126	171	261.18	26
Sp. gr. . .	1.552*	4.495	3.161	1
Mol. vol. .	81.184	38.042	82.616	36
		119.226		119.626

Formation of Hydro-potassic Sulphate.

	SO ² H ² + KHO	Sum	SO ² KH + H ² O	Sum

		79.663		80.875

Formation of Ethyl Acetate.

	C ² H ³ O + C ² H ³ O ²	Sum	C ² H ³ (C ² H ³)O ² + H ² O	Sum
Mol. weight	46	60	88	18
Sp. gr. . .	0.809†	1.06	0.90	1
Mol. vol. .	57.5	56.5	97.8	18
		114.0		115.8

H. L. Buff (*Ann. Ch. Pharm. Suppl.* iv. 129; *Jahresb.* 1866, p. 17) has carefully determined the specific gravities of a number of compounds into which the elements carbon, sulphur, and phosphorus may be supposed to enter with different atomicities or equivalent values. He finds that in saturated carbon-compounds, like propyl iodide, C³H⁷I, the atomic volume calculated according to Kopp's method (i. 445) agrees very nearly with the quotient obtained by dividing the molecular weight of the compound with its sp. gr. at the boiling point (calculated from the observed sp. gr. according to the known rate of expansion); but in unsaturated compounds—or such as, if regarded as saturated, may be supposed to contain bivalent carbon—like dichlorethylene, carbon dichloride, amylene, &c., the atomic volume calculated by Kopp's method differs from the quotient of the molecular weight by the sp. gr. (observed atomic volume) by quantities too great to be attributed to errors of observation; thus:

* At 15°.

† At 0°.

Substance	Formula	Atomic volume at the boiling point		Difference	Atoms of bivalent carbon
		Observed	Calc.		
Dichlorethylene . .	$\text{C}^2\text{H}^2\text{Cl}^2$	79.9	78.6	+ 1.3	1
Carbon dichloride .	C^2Cl^4	115.4	113.2	+ 2.2	1
Ethyl cinnamate . .	$\text{C}^{11}\text{H}^{12}\text{O}^2$	211.3	207.0	+ 4.3	1
Amylene	C^6H^{10}	111.24 - 112.47	110.0	+ 1.24 - 2.47	1
Diallyl	C^6H^{10}	126.7 - 127.0	121.0	+ 5.7 - 6.0	2
Valerylene	C^6H^8	103.27 - 104.88	99.0	+ 4.27 - 5.48	2

Hence Buff concludes that the atomic volume of bivalent carbon is greater than that of quadrivalent carbon.

Further, from the molecular volume of carbon bisulphide, CS_2 , he calculates the atomic volume of sulphur within the radicle as 27.8 to 28.8; that of quadrivalent sulphur (in sulphurous acid) = 22.6, and that of sexvalent sulphur (in sulphuric anhydride) = 12, both for the intra-radicle position. The atomic volume of trivalent phosphorus he estimates at 25, that of quinquivalent phosphorus at 22. These results are regarded by Buff as leading to the conclusion that the chemical affinity of matter is in some way dependent upon the space which it occupies; and the density of a compound increases with the number of units of affinity with which its component elements enter into combination.

F. W. Clarke has directed attention to the relations between the atomic volumes of the elementary bodies in the liquid and solid states, showing that the atomic volumes of the elements in each equivalent group are in some cases exactly, in others approximately multiples of the lowest number in each group. In the group of the alkali-metals, for example, we have.

	Li	Na	K	Rb
Specific gravities	0.589	0.972	0.865	1.52
Atomic weights	7	23	39.1	85.4
Atomic volumes	11.9	23.7	45.1	56.2

Here the atomic volumes are very nearly in the numbers 1 : 2 ; 4 : 5 (*Sill. Am. J.* [2] xlvii. 180, 308; *Zeitschr. f. Chem.* [2] v. 292, 359). The same paper contains observations on the relations between the atomic volumes of homologous and analogous compounds in the liquid state.

For Tchernak's speculations respecting atomic volumes, see *Ann. Ch. Pharm.* cxii. 129; cxiv. 25; *Jahresb.* 1859, p. 21; *Wien. Akad. Ber.* xli. 67; *Jahresb.* 1860 p. 20. For those of Groshans: *Ann. Ch. Pharm.* cxvi. 221; *N. Arch. ph. nat.* xvii. 5; xxiii. 73; *Jahresb.* 1860, p. 18; 1863, p. 31; 1865, p. 27. Of Kremers: *Pogg. Ann.* cxxii. 245.

ATOMICITY. This term is used to denote the equivalent value or combining capacity of an element, and, as explained in the article CLASSIFICATION (i. 1008), it is measured by the number of atoms of hydrogen or other monatomic or univalent element with which the element in question can combine.

Chlorine, which unites with only 1 atom of hydrogen, is monatomic, monadic, or univalent.

Oxygen, which combines with 2 atoms of hydrogen, is diatomic, dyadic, or bivalent.

Nitrogen, which combines with 3 atoms of hydrogen, is triatomic, triadic, or trivalent.

Carbon, which combines with 4 atoms of hydrogen, is tetratomic, tetradic, or quadrivalent.

When an element does not unite with hydrogen, as is the case with many of the metals, its atomicity may be measured by the number of atoms of chlorine, bromine, or iodine with which it can combine, since the atomicity of these elements is equal to that of hydrogen, and they may be substituted for it atom for atom; also by the number of univalent or monatomic radicles, such as CH^3 , C^2H^3 , OH , &c., that it can unite with, as in the case of lead, which is regarded as tetratomic because it forms with ethyl the compound $\text{Pb}(\text{C}^2\text{H}^3)^4$.

But the atomicity of an element cannot be estimated by the number of diatomic or polyatomic atoms that it may take up, for this number is indefinite. In fact, a diatomic element, like oxygen, may attach itself to another element or group of elements

by one of its combining units, leaving the other free; and to this again another diatomic or other polyatomic element may be attached, and so on indefinitely. For example, we have the series of compounds

Moreover, we know that in by far the greater number of cases, polyatomic elements can unite with monatomic elements in more than one proportion; tin, for example, forms the chlorides SnCl_2 , SnCl_4 ; antimony, the chlorides SbCl_3 , SbCl_5 .

Hence it is evident that the atomicity or combining capacity of elements is in most cases a variable quantity; and a comparison of all known cases of combining proportion shows that the atomicity or equivalent value of any given element in its several compounds always varies by two units, and that the elements may be divided in this respect into two classes, one of odd, the other of even equivalence, the former distinguished as perissads, the latter as artiads; e.g.,

Perissads: N, P, As, Sb, Au.

Artiads: O, S, Se, Te, Ba, Ca, Mg, Sn, Mo, W, &c.

In all cases of varying combining capacity, it has been usual to regard the highest value as representing the true atomicity of the element: thus tin, which forms the chlorides SnCl_2 and SnCl_4 , is regarded as a tetrad; phosphorus, which forms the chlorides PCl_3 and PCl_5 , as a pentad; nitrogen, which in the ammonium salts, NH_4Cl for example, unites with 5 monatomic atoms, also as a pentad.

In all these cases, the compounds in which the polyatomic element exhibits a degree of combining capacity below the maximum are unsaturated compounds, which, though capable of existing in the free state, are nevertheless ready to take up an additional number of atoms and pass to the saturated state, when placed under circumstances favourable to such combination. Thus stannous chloride, SnCl_2 , readily takes up 2 at. Cl, and passes into stannic chloride, SnCl_4 ; in like manner PCl_3 is easily converted into PCl_5 or PCl_3O .

On the other hand, the least saturated compounds of such series are often in one respect more stable than the more saturated compounds. In the pentachloride of phosphorus, for example, the last two atoms of chlorine are less strongly attached to the phosphorus than the other three, so that the compound, under the influence of reducing agents, or even of heat, easily gives up these two atoms of chlorine, and passes to the trichloride; so likewise stannic chloride is reduced to stannous chloride; and in the ammoniacal salts, sal-ammoniac, NH_4Cl , for example, it is easy to remove HCl from the molecule (by the action of potash or other bases), and set free ammonia, NH_3 ; but to dissolve the union between the atom of nitrogen and the three atoms of hydrogen requires the exertion of a much greater amount of chemical force.

Hence it has been supposed that nitrogen and phosphorus are really triatomic elements, that is to say, incapable of uniting with more than 3 atoms of hydrogen or other monatomic elements, but that the compound thus formed can take up two other atoms as a molecule; that in sal-ammoniac, for example, the 4 at. H and 1 at. Cl are not all united directly to the nitrogen, but that the molecule NH_3 unites bodily with the molecule HCl, the union between them being, not atomic, but molecular, like that by which water of crystallisation is attached to a salt, or the molecular constituents of double chlorides are united together, as in $\text{AgCl} \cdot \text{KCl}$; $\text{PtCl}_4 \cdot 2\text{KCl}$, &c. This view receives some support from the fact that sal-ammoniac, NH_4Cl , exhibits an anomalous vapour-density, splitting up at high temperatures into NH_3 and HCl, and therefore exhibiting a condensation, not to two, but to four volumes. For a like reason, phosphorus pentachloride is supposed to be a compound of the saturated molecule PCl_3 with a molecule of chlorine, Cl_2 ; SbCl_5 as a compound of SbCl_3 with Cl_2 ; and iodine trichloride, ICl_3 , a compound of ICl with Cl_2 .

But this mode of viewing the constitution of such bodies is scarcely tenable. It is indeed impossible to regard phosphorus pentachloride, PCl_5 , as consisting of two molecules, when its analogues PCl_3O and PCl_3S certainly consist of one only, these compounds exhibiting in the state of vapour the normal condensation to two volumes. Again, sal-ammoniac, NH_4Cl , which is isomorphous with potassium chloride, KCl, and, like the latter, unites to form a crystalline compound with platonic chloride, auric chloride, &c., must, like potassium chloride, be regarded as consisting, not of two molecules, but only of one. Lastly, if iodine trichloride were a compound of ICl and Cl_2 , the last two atoms of chlorine ought to be easily separated from the third. But this is not the case. On the contrary, when this trichloride is treated with silver

acetate, the three chlorine-atoms are removed at once as silver chloride, and Schützenberger's iodine-triacetate is formed :

This reaction is a complete case of double decomposition, and shows that the compound ICI^3 forms one complete molecule, not two.

From all these facts we must conclude that there is no such thing as *absolute* atomicity or combining capacity, but that the combining capacity of any elementary atom depends upon the other atoms with which it comes in contact, or generally on the circumstances under which it is placed. Thus iodine is monatomic in the compounds IH , IAG , ICI , triatomic in ICI^3 ; phosphorus is triatomic in PCI^3 and PH^3 , pentatomic in PCI^5 ; nitrogen is triatomic in NH^3 , pentatomic in NH^4Cl and the other ammonium salts. Nitrogen indeed forms compounds in which it is at once triatomic and pentatomic, viz. in ammonium cyanate :

In nearly all cases the combining capacity of an element in its several compounds varies, as already observed, by two units: thus iodine, gold, and thallium are monads and triads; phosphorus and its congeners are triads and pentads; silicon, titanium, selenium, tellurium, and tin are dyads and tetrads; sulphur and chromium are dyads, tetrads, and hexads. There is no well-established case of an element acting as a perissad in some cases, and as an artiad in others, excepting perhaps nitrogen, which in combination with oxygen exhibits the series

Now in the first, third, and fifth of these compounds the atomicity of nitrogen follows the general law, but in the second and fourth this element appears as an artiad. It might be brought under the general law by doubling the formulae, in which case the nitrogen would appear as a triad, the two oxides then being represented by the formulæ

and this change would moreover bring the formulæ into accordance with the law of even numbers; but the density of the dioxide, which is a permanent uncondensable gas, shows that the simpler formula NO is in accordance with the general law of two-volume condensation. As to the tetroxide, it appears, from the determination of its vapour-density by Playfair and Wanklyn (iv. 76), to be capable of existing in the two polymeric modifications NO^2 and N^2O^4 . Altogether the combining capacity of nitrogen exhibits peculiarities which are not yet satisfactorily explained.

The variation of combining capacity in an element by two or multiples of two is itself a phenomenon which has not yet received a perfectly satisfactory explanation. The point to be explained is, not that an element capable of taking up 6 atoms of chlorine, for example, should sometimes content itself with 3 atoms, and nevertheless form a compound possessed of considerable stability: for it is quite intelligible that an unsaturated compound, like PCI^3 , may appear perfectly stable and quiescent until it is brought under particular conditions favourable to the saturation of its still uncombined units of affinity; indeed, were it not for the existence of such unsaturated atoms and molecules, there could for the most part be no such thing as direct chemical combination, since saturated molecules cannot take up new elements except by substitution.

But it does not appear from this why the variation of atomicity should always take place by pairs of units. Frankland endeavours to account for this circumstance by supposing that in an atom of any polyatomic element the points of attachment by which the atom unites itself to other atoms are capable of neutralising one another more or less completely, like contiguous electric or magnetic poles of opposite names. Granting this, we may suppose that when 3 poles in the atom of a pentatomic element, phosphorus for example, have been neutralised by combination with 3 atoms of a monatomic element, such as chlorine, the remaining two may still be free, but in opposite polar (? electrical) states, so that the molecule PCI^3 may appear perfectly

neutral and stable. But now let a molecule of chlorine, ClCl ,

having its two component atoms in opposite polar states, approach this molecule. The two atoms will then place themselves so that the opposite poles of the chlorine and the phosphorus may come opposite to one another, and then combination will take place, the trichloride being converted into the pentachloride. In like manner we may suppose that the atom of any polyatomic element, tin for example, may contain two such pairs of opposite poles, and that when brought in contact with chlorine it may take up, first one molecule of that element in the manner just described, and then another, a pair of its poles being brought into activity at each step. This mode of viewing the process may afford some explanation of the fact that change of atomicity in elements almost always takes place by pairs of units.

The same hypothesis may account for the circumstance that a molecule of a perissad element always contains an even number, generally a pair of atoms, the molecule of hydrogen, for example, consisting of H_2 , that of nitrogen of N_2 , &c.; for as the opposite poles of such an atom neutralise one another in pairs, there must always be one left uncombined, and neutralisable by union with a pole of opposite name belonging to another atom. Artiad elements, on the other hand, may also unite in this manner—the molecule of oxygen, for example, being supposed to consist of two atoms, O_2 ; but since each of their poles may be neutralised by a pole of opposite name, they may also exist in the free state as single atoms; in fact, the vapour-densities of mercury, cadmium, and zinc show that the atoms of these elements in the free state exist singly and not in pairs.

Further, it is necessary to remark that saturation is not necessarily perfect, even when all the combining capacities of the elements in a molecule appear to be satisfied. There are indeed but few compounds that appear perfectly saturated, and therefore incapable of combining directly with any other atoms or molecules. The paraffins $\text{C}_n\text{H}_{2n+2}$ exhibit this character, being incapable of direct combination, and being modified only by substitution; but platonic chloride, PtCl_4 , which is also generally regarded as a saturated molecule, cannot be so in the same degree as the compound CH_4 or CCl_4 , inasmuch as it can form definite crystalline compounds with various other metallic chlorides. In such double chlorides, indeed, the combination is commonly said to be molecular, rather than atomic; between the molecules as wholes, rather than between the individual atoms; but molecules could scarcely exhibit any tendency to combine if the combining tendencies or opposite polarities of their component atoms were completely neutralised. At all events, the state of a perfectly neutral molecule, like CH_4 , must be different from that of one which, like PtCl_4 , still exhibits a tendency to take up additional elements and form definite compounds therewith. The same must be the case with all salts and other compounds which can take up water of crystallisation. Their union with this water is attended with evolution of heat, just like combination between atoms; in such molecules, therefore, the combining tendencies of the component atoms cannot be supposed to be perfectly neutralised.

In some cases, however, combination between two saturated compounds may take place in consequence of a different arrangement of the atoms, and a difference in the manner in which they are linked together; thus carbon dioxide, $\text{O}=\text{C}=\text{O}$, and lime, $\text{Ca}=\text{O}$, are both saturated compounds; nevertheless they can combine directly under certain circumstances and form calcium carbonate:

In like manner, sulphuric oxide, SO_2 , and baryta, BaO , unite at high temperatures to form barium sulphate:

But this kind of combination can take place only when both molecules consist wholly of polyatomic elements. In the case of combination between chlorides, on the contrary, such as platonic chloride and hydrogen chloride,

there are no uncombined units of affinity to lay hold of. It is conceivable, however, that the polarities of this atom of platinum may be neutralised by the opposite polarities of the chlorine-atoms so far as not to be further excited by the comparatively feeble polarities of the two atoms composing another chlorine molecule,

$\begin{matrix} + & - \\ \text{Cl} & \text{Cl} \end{matrix}$, but may yet be roused into action by the stronger polarities of such a

molecule as potassium chloride, $\begin{matrix} + & - \\ \text{K} & \text{Cl} \end{matrix}$, and in this manner combination may take place between the two molecules.

Allusion has already been made to the power of polyatomic elements to accumulate in compounds. Two diatomic elements, for example, may unite together so as to completely neutralise all their units of affinity, as in the compounds $\text{Ba}=\text{O}$; $\text{Pb}=\text{S}$. But they may also unite so as each to leave a unity of atomicity free; in such cases other elements may enter the combination to satisfy the uncombined units; as in the following examples:

In these examples we see that a chain of any number of oxygen-atoms, united together by one unit of atomicity belonging to each, must always leave an uncombined unit at each end, which may be neutralised or satisfied by a monatomic atom, such as hydrogen or chlorine. A chain of diatomic or other polyatomic atoms thus connected together, and having uncombined units at each end, is called an open chain. It is possible, however, that the atoms of the extremities may unite between themselves by their uncombined units, and thus form a closed chain; thus:

The equivalent or combining value of any group of atoms must evidently depend partly upon the atomicity of the individual elements, partly on the manner in which they are linked together: thus the group C^2H^4 may be saturated or bivalent, according as the two carbon-atoms are grouped by one or by two of their units of affinity

Any given group of atoms will evidently exhibit its maximum atomicity or combining capacity, or will have the greatest possible number of combining units free, when all the polyatomic atoms are linked together by one unit of affinity only. In such a case it has been shown in the article CLASSIFICATION (i. 1013) that in a group of n polyatomic atoms, A'' , A''' , A^{iv} . . . , thus united, the maximum atomicity is represented by the formula

$$\text{A}'' + \text{A}''' + \text{A}^{iv} \dots - 2(n - 1).$$

A very important case of this law is that of a number of carbon-atoms united together, as in marsh gas and its homologues; thus:

in which the group of n tetrad atoms exhibits an atomicity denoted by $4n - 2(n - 1) = 2n + 2$. A group of two carbon-atoms will therefore take up 6 atoms of

hydrogen; a group of three carbon-atoms will take up 8 hydrogen-atoms, and so forth, each hydrocarbon of the series differing from the preceding by CH_2 .

When any number of hydrogen-atoms in a compound is replaced by an equal number of atoms of chlorine or other monatomic element, or by an equivalent number of multivalent atoms, or univalent and multivalent atoms combined, it is clear that the combining capacity of the group will remain the same as before. Chloroform, CHCl_3 , for example, derived from marsh gas by substitution of Cl^1 for H^1 , is a saturated compound like marsh gas itself; so likewise is aldehyde, $\text{C}^2\text{H}^4\text{O}$, derived from ethane, C^2H_6 , by substitution of O^2 for H_2 ; but dichlorethylene, $\text{C}^2\text{H}_2\text{Cl}_2$, is bivalent, like ethylene, C^2H_4 , itself.

Suppose now an atom of hydrogen in any group to be replaced by oxygen, as when the compound is subjected to the action of oxidising agents. In this case the diatomic oxygen which enters the group attaches itself thereto by one of its units of affinity, leaving the other free, and capable therefore of retaining in the group the hydrogen which it has displaced. The final result is the replacement of an atom of hydrogen by the univalent group or radicle, hydroxyl, OH : thus in propane or propyl hydride, C^3H_8 , we may replace H by OH, yielding propyl alcohol, $\text{C}^3\text{H}_7(\text{OH})$; a second similar substitution produces propylene alcohol, or propylic glycol, $\text{C}^3\text{H}_6(\text{OH})_2$; and a third produces propenyl alcohol or glycerin, $\text{C}^3\text{H}_5(\text{OH})_3$:

The result of these substitutions of OH for H is evidently an addition of one atom of oxygen to the molecule at each successive step.

In like manner, nitrogen (trivalent) taking the place of an atom of hydrogen may bring with it two other hydrogen-atoms to complete the saturation, as in the derivation of ethylamine, $\text{C}^2\text{H}_5\text{N}$, and ethylene-diamine, $\text{C}^2\text{H}_4\text{N}_2$, from ethane, C^2H_6 :

The result is the addition of NH to the molecule at each step.

Quinivalent nitrogen substituted for hydrogen brings with it 4 atoms of hydrogen, as in the formation of ammonium-salts from their respective acids, the result being equivalent to the addition of NH^5 at each successive step.

Instead of 2 or 4 at. hydrogen, nitrogen, accordingly as it enters a molecule in its trivalent or quinivalent capacity, may bring with it 1 or 2 atoms of oxygen, the result being the replacement of the hydrogen by nitrosyl, NO, in the one case, and of nitril, NO^2 , in the other: e.g.,

Carbon, which is tetratomic, entering in like manner into a molecule, takes with it 3 atoms of hydrogen, and thereby increases the molecule by the addition of CH^3 at each successive step, the result being, as is well known, the formation of homologous series: thus in the series of alcohols $\text{C}^n\text{H}^{2n+2}\text{O}$:

Sulphur, regarded as sexvalent, may take with it into combination the quinivalent group $\text{O}^+\text{O}^-(\text{OH})$, the result being the substitution of the univalent radicle SO^+H for H, or the addition of SO^+ to the original molecule. The compound thus formed is usually a sulpho-acid, as sulphacetic acid, $\text{C}^+\text{H}^+\text{O}^+\text{SO}^+$, from acetic acid:

Classification of Elementary Bodies according to their Atomicities.

This subject has been discussed in the article CLASSIFICATION, by Prof. G. C. Foster, and in that on METALS, ATOMIC WEIGHTS AND CLASSIFICATION OF, by Dr. Odling; but a few additional observations are required to bring it into accordance with the results of recent researches. A table of the elementary bodies classified according to the views of their atomicities or combining capacities, now most generally received, will be found at the end of this article. It must be distinctly understood, however, that the atomicities there assigned to the several elements are by no means absolute, but only such as these elements exhibit in their more important compounds.

1. *Monads.*—The atomicity of hydrogen, as exhibited in the single compound which it forms with chlorine, is assumed as the standard of atomicity, equivalent value, or combining capacity. Estimated by this standard, silver appears to be always univalent; but the other elements usually classed as monads, though certainly univalent in most of their compounds, nevertheless appear to be also capable of exhibiting higher equivalent values. Chlorine is univalent in argentic chloride, AgCl ; but in argentous chloride, Ag^2Cl , or rather Ag^+Cl^2 , it appears to be trivalent, the constitutional formula of that compound being

Bromine must also be regarded as trivalent in the corresponding compound Ag^+Br^3 ; and iodine, because it forms a trichloride, ICl^3 . Chlorine and iodine might even be

regarded as septivalent, viz. in perchloric acid, $\text{Cl}^7\text{H}\left\{\begin{array}{c} \text{O}^+ \\ \text{OH}^- \end{array}\right.$, periodic acid, $\text{I}^7\text{H}\left\{\begin{array}{c} \text{O}^+ \\ \text{OH}^- \end{array}\right.$ and the corresponding anhydride, I^7O^+ ; but these oxygen-acids of chlorine and iodine may also be represented by different formulae, in which the oxygen-atoms are linked together, and the chlorine and iodine are univalent (p. 241). Fluorine is most probably a monad, but still there are some reasons for regarding it as a dyad analogous to oxygen (ii. 272). Sodium and the other alkali-metals are univalent in all their compounds; but Wanklyn has lately shown that sodium can also act as a septivalent element. The crystals commonly called sodium and represented by the formula $\text{C}^+\text{H}^+\text{NaO}$, have, according to Wanklyn, a more complex constitution, consisting, when dried at 100° , of

When kept for a long time at 200° , they give off 4 molecules of alcohol, $(\text{C}^2\text{H}^5\text{O})\text{H}$, leaving sodium ethylate or hydrate of ethylene-sodium:

Potassium acts upon alcohol in the same manner as sodium, and will probably be found to yield analogous products.

2. *Dyads*.—The non-metallic elements, oxygen, sulphur, selenium, and tellurium, must be regarded as dyads, if we look only to their hydrogen-compounds; but the three last-mentioned elements form compounds into which they appear to enter as tetrads and hexads; and if argentous oxide be correctly represented by the formula Ag^4O , even oxygen must be regarded as a tetrad.

The chemical relations of the metals now regarded as dyads are fully discussed in Dr. Odling's article above referred to.

3. The *triad* elements are boron, thallium, and gold. Of the trivalence of boron there is no question. Thallium and gold are both univalent and trivalent, the mono-compounds of the former and the tri-compounds of the latter being the most stable. Gold may, however, be regarded as trivalent also in the aurous compounds if

exhibits a very close analogy to the alkali-metals (v. 753).

4. *Tetrads*.—Carbon is quadrivalent in all its compounds, except the monoxide $\text{C}=\text{O}$, in which it is bivalent; but this is an unsaturated compound, ready to take up an additional atom of oxygen or two atoms of chlorine.

Silicon, titanium, and tin are bi- and quadrivalent.

Zirconium forms a tetrachloride, ZrCl^4 , and a dioxide, ZrO^2 , and is indeed quadrivalent in all its compounds.

Aluminium forms but one class of compounds, in which it is apparently trivalent, the chloride being represented by the formula AlCl^3 , the methide and ethide by $\text{Al}(\text{CH}^3)^3$ and $\text{Al}(\text{C}^2\text{H}^5)^3$, and the oxide by Al^2O^3 . This view is in accordance with the vapour-densities of the ethide and methide at high temperatures (iii. 983). On the other hand, the vapour-density of the chloride, as determined by Deville, points to the formula Al^2Cl^6 , and similarly those of the methide and ethide near their boiling points accord more nearly with the double formulæ $\text{Al}^2(\text{CH}^3)^6$ and $\text{Al}^2(\text{C}^2\text{H}^5)^6$ than with the simpler formulæ above given. If these double formulæ are correct, aluminium may be regarded as quadrivalent, its chloride and oxide being represented by the formulæ

This latter view is corroborated by the isomorphism between alumina and ferric oxide and their corresponding salts.

Cerium, uranium, cobalt, and nickel are bivalent and quadrivalent. They all form dichlorides. Of cerium a native trifluoride CeF^3 is known, analogous in composition to the chloride of aluminium. No trichloride of uranium is known; but the oxychloride, $\text{U}^2\text{O}^2\text{Cl}^4$, derived from the trichloride by substitution of O^2 for Cl^1 , is a well-known compound. Cobalt forms a trichloride, Co^3Cl^3 . Of nickel only the dichloride, NiCl^2 , has been obtained; but the sesquioxide, Ni^2O^3 , is known, analogous to cobaltic oxide, and from the close resemblance of nickel to cobalt in all its chemical relations, it evidently belongs to the same class. All the four metals included in this paragraph are also analogous in many respects to iron, manganese, and chromium, and might accordingly be regarded as hexads; but, as no compounds

are actually known in which they appear to be sexvalent, it is best to regard them as tetrads.

Lead is bivalent in the only chloride which it forms, viz. $PbCl^2$, and in its basic oxide, PbO ; quadrivalent in plumbic ethide, $Pb(C^2H^3)^4$, and in the dioxide, PbO^2 .

Platinum, palladium, iridium, and rhodium are bivalent and quadrivalent. Platinum and palladium form dichlorides and tetrachlorides, and corresponding oxides. Iridium forms a dichloride, a tetrachloride, and an intermediate chloride, Ir^2Cl^4 , which may be regarded as analogous in composition to ferric chloride and aluminium chloride, that is as containing quadrivalent iridium. Rhodium forms only a dichloride, $RhCl^2$, and a trichloride, Rh^2Cl^3 . These two metals also form oxides analogous in composition to the chlorides, and yielding corresponding salts with acids, and likewise higher oxides, viz. IrO^3 and RhO^3 .

5. *Pentads*.—Among these elements, nitrogen, phosphorus, arsenic, antimony, and vanadium form one natural group; tantalum and niobium another. The reasons for regarding nitrogen as quinivalent as well as trivalent have already been given (p. 238). Phosphorus and antimony form trichlorides and pentachlorides, with corresponding oxides, oxy-salts, and organo-metallic bodies. Arsenic forms only a trichloride, but its oxygen-compounds, sulphur-compounds, and organo-metallic compounds are analogous to those of phosphorus. Bismuth

forms a trichloride and a dichloride, Bi^2Cl^3 or $BiCl^2$, in both of which it is trivalent; also corresponding organo-metallic compounds and oxides. It also forms a pentoxide, with corresponding salts, whence, and from its analogy with antimony, it is regarded as a pentad. Vanadium was formerly regarded as a hexad; but Roscoe has lately shown that it is a pentad (v. 984). Tantalum and niobium were formerly regarded as tetrads; but the recent experiments of Marignac have shown that they are pentads (iv. 785; v. 602).

6. *Hexads*.—Sulphur, selenium, and tellurium are bivalent in their hydrogen-compounds, quadrivalent in their chlorides, those of selenium and tellurium being definite and stable compounds in the free state, whereas the tetrachloride of sulphur is known only in combination with metallic chlorides (v. 535). In sulphurous triethiodide, $S\left\{\begin{smallmatrix} (C^2H^3)^2 \\ I \end{smallmatrix}\right.$ (v. 881), sulphur is undoubtedly quadrivalent, and in sulphuric

ethylene-diethyl-bromide, $S\left\{\begin{smallmatrix} (C^2H^3)^2 \\ Br^2 \end{smallmatrix}\right.$, it appears to be sexvalent. The same degree of

atomicity is likewise exhibited by sulphur in the sulphates. Sulphuric acid or hydrogen sulphate might indeed be represented by either of the formulæ

in the former of which the sulphur is bivalent, while in the latter it is sexvalent. But the stability of the sulphates is rather in favour of the latter view, inasmuch as compounds in which oxygen is directly united with oxygen, as in the first formula, are usually rather unstable. Moreover, the sulphates are isomorphous with the chromates, and should therefore be represented by similar formulæ; now chromium is undoubtedly a hexad. Selenium and tellurium, which are analogous to sulphur in nearly every respect, and especially in the constitution of their highest oxygen-acids, must in like manner be regarded as hexads.

Chromium forms a hexfluoride, CrF^6 , to which there corresponds the trioxide or chromic anhydride, CrO^3 , with the corresponding salts; potassium monochromate, K^2CrO^4 , for example, may be represented by a formula exactly similar to the second of the two above given for hydrogen sulphate. Chromium also forms the chromous salts, in which it is bivalent, e.g. $CrCl^2$, and the chromic salts, e.g. Cr^2Cl^6 , in which it is quadrivalent. (See CHROMIUM.)

Iron exhibits combining capacities exactly analogous to those of chromium. In the ferrous compounds, as $FeCl^2$, it is bivalent; in the ferric compounds, quadrivalent, ferric chloride being represented, like aluminium chloride, by the formula $FeCl^4$. In the ferrates, supposing their constitution to be well established, iron must be regarded

as sexvalent, the formulæ of those salts being analogous to those of the sulphates and chromates; potassium ferrate, for example, being represented by the formula $\text{Fe}^{\text{VI}}\text{K}^2\text{O}^4$ or $\text{Fe}^{\text{VI}}\text{O}^2(\text{OK})^2$.

Precisely similar observations may be applied to manganese in the manganous and manganic salts, and in the manganates respectively. The manganates are isomorphous with the chromates, which corroborates the supposition that the manganese in these salts is sexvalent. Manganese however forms a class of still more highly oxidised salts, viz. the permanganates, as MnKO^4 or $\text{Mn}^{\text{VII}}\text{O}^2(\text{OK})$, to which there are said also to be a corresponding chloride, MnCl^7 , and fluoride, MnF^7 (iii. 805, 808). This would seem to show that manganese can also be septivalent, a fact not in accordance with the general law that the variation of combining capacity in any element takes place by successive increments of two units. But the so-called heptachloride appears from H. Rose's experiments to be really an oxychloride, MnO^2Cl^2 , analogous to chromic oxychloride; and the so-called heptafluoride has probably a similar composition, the manganese being sexvalent in both compounds. The constitution of the permanganates may also be represented by a formula in which manganese is sexvalent. The potassium salt, for example, may be represented as $\text{Mn}^{\text{VI}}\text{K}^2\text{O}^5$, or

It is true that the permanganates are isomorphous with the perchlorates, in which chlorine must be regarded either as univalent or septivalent; thus for the potassium salt:

But although isomorphous compounds very frequently, and perhaps in most cases, contain polyatomic elements of equal combining capacity, still this rule is not invariable: Marignac, for example, has shown that the fluotantalates and fluoniobates are isomorphous with the fluosilicates, fluotitanates, and fluotannates; and nevertheless tantalum and niobium are pentads, whereas silicon, titanium, and zirconium are tetrads. The balance of evidence is therefore in favour of regarding manganese in the permanganates as a hexad.

Molybdenum forms a hexfluoride known in combination, though not in the free state; also a tetrachloride and dichloride, together with corresponding oxides.

Tungsten forms a hexchloride and tetrachloride, with corresponding oxides.

Ruthenium and osmium form chlorides analogous to those of iridium, e.g. RuCl^3 , Ru^2Cl^6 , and RuCl^4 , also hexchlorides RuCl^6 and OsCl^6 , known however only in combination. The two metals also form oxides analogous to these several chlorides, and likewise higher oxides, viz. RuO^4 and OsO^4 . From this it might be inferred that ruthenium and osmium are octads; but, as already observed, the atomicity of an element cannot safely be inferred from the number of atoms of oxygen or any other polyatomic element with which it may unite.

The following table exhibits a classification of the elementary bodies according to the principles above explained, together with their atomic weights according to the most recent determinations. The atomicity assigned to each element is the highest that it exhibits in its most important and best defined compounds. The elements are further divided by horizontal lines into groups consisting of elements closely related in their chemical characters; and in each of these groups the elements are arranged according to their atomic weights, beginning with the lowest.

TABLE OF THE ELEMENTARY BODIES, WITH THEIR ATOMIC WEIGHTS.

Elementary Bodies	Atomic Weights	Elementary Bodies	Atomic Weights
MONADS:		TETRADES, continued:

ATRACTYLIC ACID. $C^*H^{14}O^{12}.S^*O^*?$? (E. Lefranc, *Bull. Soc. Chim.* [2] xi. 499).—The potassium salt of this acid exists in the root of *Atractylis gummifera*, and

* Thorina = Th.O (see vol. v. p. 786).

† Vanadic oxide = V^*O^* (Roscoe, v. 366).

‡ Niobic oxide = Nb^*O^* (Marignac, iv. 784).

§ Tantallic oxide = Ta^*O^* (Marignac, v. 664).

Lefranc gives the formula $S^*O^*.C^*H^{14}O^{12}.3HO$, which is improbable, on account of the odd number of hydrogen-atoms.

may be extracted therefrom by exhaustion with boiling alcohol of 56 to 75 p. c., from which it crystallises on cooling. By converting it into a lead-salt, and decomposing the latter with hydrogen sulphide, the *hydrogen salt* or *acid* is obtained. It is very soluble in water, inodorous, with a sour, styptic, and bitter taste. Its concentrated solution is easily decomposed by heat. The acid has not been obtained in the solid state.

Atrectylic acid is tribasic, forming salts containing 1, 2, and 3 atoms of metal. They are crystallisable, soluble in water and in weak alcohol, much more soluble at high than at ordinary temperatures.

The *triargentic salt* forms a nacreous mass of microscopic crystals: it is very unstable. The *tribasic salt* crystallises in hexagonal dodecahedrons, and in six-sided prisms with pyramidal summits. The *potassio-calcic salt* $\text{Ca}^2\text{K}^4(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)^2$ is obtained by decomposing the native potassium salt with calcium carbonate, and adding alcohol, as a white granular crystalline precipitate. There are two *potassio-baric salts*, $\text{Ba}^2\text{K}^4(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)^2$ and $\text{Ba}^3\text{K}^3(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)$, obtained by decomposing the preceding salt with barium chloride in different proportions.

Bimetallic Salts.—The native *potassium salt* $\text{K}^2\text{H}^4(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)$ is colourless, inodorous, bitter, and crystallises in prismatic needles. It is levogyrate, with a rotatory power of $5\cdot77^\circ$; at 100° it swells up, blackens, and gives off valeric acid. By calcination it leaves a residue of neutral potassium sulphate amounting to 20 p. c. Its solution is not precipitated by barium-salts till it has been decomposed by an acid, in which case it yields sulphuric acid, valeric acid, glucose, and a resinous matter. Hence atrectylic acid appears to be a conjugated sulpho-acid of complex constitution; it is remarkable as being the first-known example of such an acid existing ready-formed in the vegetable organism. The corresponding *barium salt*, $\text{Ba}^2\text{H}^4(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)$, crystallises in very light silky tufts. The *zinc salt* $\text{Zn}^2\text{H}^4(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)$ resembles it. The *diargentic salt* is white, nacreous, and very unstable.

The *monometallic atrectylates* are prepared by means of the salt $\text{Ba}^2\text{K}^4(\text{C}^{30}\text{H}^{51}\text{O}^{23}\cdot\text{S}^2\text{O}^6)$, this salt being decomposed by a quantity of sulphuric acid just sufficient to precipitate the barium. They cannot be obtained in the solid state, on account of their tendency to decompose into the free acid (hydrogen salt) and a bimetallic salt.

ATROPIC ACID. See the next article.

ATROPINE. According to Gulielmo (*Zeitschr. anal. Chem.* ii. 404), this base, in quantity not exceeding $\frac{1}{20}$ to $\frac{1}{30}$ of a grain, may be detected by the intense odour, resembling that of the flowers of oranges and wild plums, which is evolved on heating it with a few drops of strong sulphuric acid till it turns brown, and then adding a few drops of water. When very carefully sublimed in the manner described under ALKALOIDS (p. 87), it condenses in transparent drops, which if left for 24 hours in contact with hydrochloric acid, are converted into distinct octohedrons (Helwig, *ibid.* iii. 43). With *phosphomolybdic acid* it forms a yellow precipitate which dissolves in ammonia, forming a blue solution becoming colourless on boiling (J. Trupp, *Jahresb.* 1863, p. 702). It is decomposed by boiling with dilute sulphuric acid and *potassium bichromate*, with formation of benzoic acid; and the solution, which has become green, gives off, when supersaturated with potash, a volatile base smelling like herring-pickle. An odour of benzoic acid is likewise evolved when atropine burns in contact with the air (H. Ludwig, *Arch. Pharm.* [2] cvii. 129).

Atropine sulphate may be obtained in crystals by carefully neutralising a solution of the base in 8 grms. absolute alcohol with a mixture of sulphuric acid (0.6 grms.) and absolute alcohol, and leaving the solution to evaporate. The salt, which crystallises in stellate groups of needles having a mother-of-pearl lustre, is soluble in water and in alcohol, but not in ether or chloroform (Laveau, *J. Pharm.* [3] xlv. 132).

Ethyl-atropine iodide, $\text{C}^{17}\text{H}^{23}\text{NO}^2\text{I}$ or $\text{C}^{17}\text{H}^{18}(\text{C}^2\text{H}^5)\text{NO}^2\text{I}$, is formed, as a crystalline precipitate, on heating an ethereo-alcoholic solution of atropine with ethyl-iodide over the water-bath. The corresponding *chloride*, obtained by treating the iodide with silver-chloride, forms with platonic chloride the double salt $2\text{C}^{17}\text{H}^{23}\text{NO}^2\text{Cl}^1\cdot\text{PtCl}^4$, which crystallises in orange-coloured laminae. The iodide treated with silver oxide yields an easily soluble, uncrystallisable base, which, by renewed treatment with ethyl-iodide, is converted into an iodine-compound, appearing, from the analysis of the corresponding platinum salt, to consist of hydriodide of tropine (v. 896), resulting from a further decomposition (Lossen).

Acids produced by decomposition of Atropine.

According to Kraut (v. 896), atropine is resolved by the action of baryta-water at 58° , or of hydrochloric acid, into tropine and atropic acid:

According to Lossen (*Ann. Ch. Pharm.* cxxxviii. 230), atropine is resolved, either by baryta-water or by hydrochloric acid, into tropine and tropic acid, $\text{C}^8\text{H}^{10}\text{O}^3$, containing 1 mol. H_2O more than atropic acid:

and the tropic acid, by the further action of these reagents, is converted, with elimination of water, into two isomeric acids, which he designates as a tropic and an atropic acids. These acids are isolated as follows: Atropine is heated with fuming hydrochloric acid to 120° – 130° for several hours, whereby a semifluid layer is produced containing the acids (and increasing on dilution with water). The dilute liquid contains, besides tropine hydrochloride, nothing but tropic acid, which may be extracted by ether. The semifluid mixture treated with dilute sodium carbonate yields a solution from which, by saturation with hydrochloric acid, isatropic acid, nearly insoluble in water, is separated, while tropic acid remains in solution, together with atropic acid, which is present in small quantity only. Both these acids are extracted from the solution by ether, the ether is evaporated, and the residue is treated with benzol, which dissolves scarcely anything but the atropic acid; the two acids are then purified by recrystallisation from boiling water. The isatropic acid precipitated by hydrochloric acid generally contains also a semifluid acid, easily soluble in alcohol and ether, but not yet further examined (Lossen; see also Kraut, *Ann. Ch. Pharm.* cxlviii. 236).

Tropic Acid, $\text{C}^8\text{H}^{10}\text{O}^3$, separates from hot saturated aqueous solutions in slender prismatic crystals grouped in hemispherical cauliflower-like masses; it is soluble in alcohol, in ether, and in 40 pts. of water at 14.5° ; has a slightly sour taste, melts at 117° – 118° , and does not volatilise without decomposition. The calcium salt $\text{C}^8\text{H}^{10}\text{CaO}^3 \cdot 4\text{H}_2\text{O}$ crystallises in the form described by Kraut for calcium atropate (*infra*). According to recent observations by Kraut (*loc. cit.*), this salt crystallises in rhomboïdal plates of $100^\circ 39'$, with 4 mols. of water; it may also be obtained anhydrous in needles. It does not diminish sensibly in weight when heated to 200° for two or three hours in an atmosphere of hydrogen, but when exposed to the air at 100° its composition slowly approaches that of the atropate. At 220° it decomposes, giving off oily drops having the odour of bitter almonds, and leaving carbonate, atropate, and isatropate of calcium. The silver salt $\text{C}^8\text{H}^7\text{AgO}^3$, obtained by precipitation, crystallises from hot water and decomposes at 110° – 120° (Lossen).

Atropic Acid, $\text{C}^8\text{H}^{10}\text{O}^3$, isomeric with cinnamic acid, is produced by heating tropic acid with concentrated baryta-water to 130° for several hours (Lossen). For Kraut's method of preparing it directly from atropine, see v. 895. This acid crystallises from aqueous solution in needles having the odour of benzoic acid, and from alcohol in monoclinic prisms exhibiting the combination $\infty P \cdot [\infty P\infty] \cdot \infty P\infty$. It melts at 106.5° , solidifies from fusion in the crystalline form, and volatilises with an acid, cough-exciting odour, but does not volatilise with vapour of water. It dissolves in 692.5 pts. of water at 19.1° , and its neutral salts do not produce any precipitate in solutions of manganese salts, whereas cinnamic acid melts at 133.4° , dissolves in 3,500 pts. water at 17° , and immediately precipitates manganese salts. Atropic acid heated with potassium bichromate and sulphuric acid forms benzoic acid, and further resembles cinnamic acid in its behaviour to bromine, of which it takes up 2 atoms.

The solution of atropine acid in aqueous ammonia leaves on evaporation an acid residue only partially soluble in water. The potassium salt forms shining laminae soluble in alcohol. The silver salt $\text{C}^8\text{H}^7\text{AgO}^3$ crystallises from hot water in nodules. The calcium salt $\text{C}^8\text{H}^{10}\text{CaO}^3 \cdot 5\text{H}_2\text{O}$ separates by slow evaporation in large monoclinic prisms, having a bright vitreous lustre, and exhibiting the combination $\infty P \cdot [P\infty] \cdot \infty P\infty$, and with the approximately determined angles $\infty P : [P\infty] = 160^\circ$; $\infty P : \infty P\infty = 129^\circ$; $\infty P : \infty P\infty = 77^\circ$ – 78° . The crystals are tabular from predominance of ∞P , and cleave parallel to this face. The salt effloresces slowly in the air, more quickly over oil of vitriol, but does not become perfectly anhydrous till heated to between 190° and 200° , and then quickly takes up about 12 p. c. water from the air. It dissolves in 42 to 44 pts. water at 18° (calcium cinnamate in 608 pts.). There appear also to be calcium-salts of atropic acid which contain smaller quantities of water and give it up more easily (Kraut). Lossen describes a salt, $\text{C}^8\text{H}^{10}\text{CaO}^3 \cdot 2\text{H}_2\text{O}$, which crystallises imperfectly in needles.

Atropic acid is resolved by oxidation with potassium dichromate and sulphuric acid into benzoic acid and carbon dioxide, with a trace of formic acid. When 2 grms. of it are fused with 40 grms. potassium hydrate till a brisk evolution of gas takes place, a small quantity of a solid acid is produced resembling benzoic acid; but if the fusion

be interrupted as soon as a bright-burning gas begins to escape, the products formed are formic and alphetoluic acids. Atropic acid, heated to 137° for six hours with hydrochloric acid of sp. gr. 1.18, forms an amorphous chlorinated acid, together with an acid which is precipitated from its alkaline solution by mineral acids, dissolves in ether and in benzol, and is converted by prolonged boiling with water into isatropic acid. Possibly an additive product of atropic acid with hydrochloric acid is formed in the first instance. Atropic acid is converted by sodium-amalgam into an acid, $C^9H^{10}O^2$, which is different from homotoluic acid, forms a very soluble calcium salt, and a silver salt, $C^9H^8AgO^2$, crystallising from boiling water in scales. From these facts Kraut infers that atropic acid has the constitution represented by the formula $C^7H.CH(C^6H^4).COOH$, containing a bivalent carbon-atom (*Zeitschr. f. Chem.* [2] v. 147).

Isatropic Acid, $C^9H^8O^2$, is produced, as above mentioned, by the action of baryta-water on tropic acid; also by heating the latter for several hours to 140° with strong hydrochloric acid. It differs considerably in its properties both from atropic and from cinnamic acid. It is nearly insoluble in cold water, dissolves but slightly in boiling water and in ether, and is still less soluble in alcohol than atropic acid. It suffers no loss of weight at 120° , and does not melt till heated to about 200° , whereas atropic acid melts at about 106° and sublimes at a slightly higher temperature. When precipitated from its alcoholic solution by water, it gradually forms microscopic thin rhombic laminae.

Base obtained from Atropine.—Commercial atropine does not dissolve completely in boiling baryta-water, but separates oily drops, which on cooling form a resinous mass, consisting of a base, $C^{10}H^{14}NO$, the chloroplatinate of which crystallises from boiling water in small yellow needles (Kraut, *Ann. Ch. Pharm.* cxlviii. 236).

ATROSIN. A black substance contained in small quantity, according to F. Hübschmann (*Chem. Centr.* 1863, p. 864), in the alcoholic extract of the root of deadly nightshade, from which it is precipitated by ammonia. It is insoluble in water, alcohol, and ether, but dissolves in aqueous acids, and is precipitated therefrom as a black powder by ammonia. Hübschmann supposes that this substance in the pure state forms the deep black of the ripe deadly nightshade berries, and in combination with an acid, the red colour of the juice.

AUERBACHITE. This name is given by R. Hermann (*J. pr. Chem.* lxxiii. 209) to a zirconium silicate occurring in the silicious slate in the Circle of Mariupel, Government of Jekaterinoslaw. It forms small quadrate octohedrons, having the angle P : P in the lateral edges = $86\frac{1}{2}^{\circ}$ – 87° ; in the terminal edges = 121° . Colour brownish grey. Sp. gr. = 4.06. Hardness = 6.5 (Hermann), 7.5 (Kokscharow, *Jahresb.* 1860, p. 756). It gave by analysis 42.91 p. c. SiO_2 , 55.18 ZrO_2 , 0.93 FeO , and 0.95 loss by ignition (= 99.97), whence it appears to consist of $2ZrO_2.3SiO_2$, and to contain one-half more silica than zircon. It likewise differs from zircon, with which it is isomorphous, by its greater hardness and density.

AUGITE. On the composition of augite and amphibole (hornblende), see G. Tchernak (*Deut. Chem. Gesells. Berlin.* 1869, p. 384; *Zeitschr. f. Chem.* [2] v. 633).

AURICHALCITE. A copper-zinc bloom allied to aurichalcite is described by Risse and Braun (*Jahresb.* 1862, p. 759). It occurs at Guipuzcoa in Spain, in crystallo-radial and fibrous light-blue aggregates imbedded in calamine. Its analysis gave 13.41 p. c. CuO , 55.29 ZnO , 14.08 CO_2 , 10.30 H_2O , and 1.86 residue (= 100.44), leading to the formula $(Cu; Zn)CO_2.2ZnH_2O^2$.

AURINE. A commercial name of rosolic acid (q.v.).

AUROSACETYL OXIDE. See ACETYLENE (p. 36).

AUSTRACAMPHENE.

AUSTRALENE.

AUSTRAPYROLENE.

See TURPENTINE OIL (v. 921, 924, 925).

AUTUNITE. *Uranite, Lime-uranite, Uranium mica, Calcio-uranic Phosphate.*—From analyses by Laugier (*Ann. Ch. Phys.* [3] xxiv. 239) and Pisani (*Compt. rend.* lii. 817; *Jahresb.* 1862, p. 1030), this mineral appears to contain 21 p. c. water, instead of 15 p. c. as formerly supposed. According to Pisani, the amount of water is reduced to 15 p. c. when the mineral is dried at 70° , but remains unaltered when it is kept at ordinary temperatures, even for months. In the mineral from Autun, Pisani found:

P_2O_5	U_2O_5	CaO	H_2O	Sum
13.4	56.47	5.60	20.10	3.20 = 98.67
14.0	59.0	5.8	21.2	— = 100.0

These numbers lead to the formula $\text{CaO} \cdot 2\text{U}^{\text{O}^2} \cdot \text{P}^{\text{O}^4} \cdot 12\text{aq.}$ or $\text{Ca}^*(\text{U}^{\text{O}^2})_2\text{P}^{\text{O}^4} \cdot 12\text{aq.}$ Accordingly, autunite is not analogous in composition to chalcocite or cupric-uranic phosphate, which contains only 8 molecules of water (iv. 585). Moreover, Descloizeaux has shown that the two minerals are dissimilar in crystalline form, chalcocite being dimetric, whereas autunite is trimetric. In small crystals from Cornwall he found the form to be derivable from a rhombic prism of $90^\circ 43'$, and exhibiting the combination $\text{oP} : \text{P}\infty : \text{P}\infty : \frac{1}{2}\text{P}$, with the angles $\text{oP} : \text{P}\infty = 109^\circ 19'$; $\text{oP} : \frac{1}{2}\text{P} = 116^\circ 14'$ (*Ann. Min.* [5] xiv. 330; *Jahresb.* 1858, p. 724).

AVORNIN. This name is given by Kubly (*Zeitschr. f. Chem.* 1867, p. 26) to a glucoside which he has obtained (though not pure) from the bark of *Rhamnus frangula*, as an amorphous, easily fusible, brown or black mass, giving by analysis numbers agreeing with the formula $\text{C}^{18}\text{H}^{10}\text{O}^8$, and separable by acids into sugar, crystallisable, aurora-red avornic acid, $\text{C}^{11}\text{H}^8\text{O}^4$, and an amorphous resin. According to Faust (*Zeitschr. f. Chem.* [2] v. 18), avornin and avornic acid are identical with frangulin and frangulic acid respectively.

AXIN. A fat obtained in Mexico by boiling a species of coccus. (See ADDITIONS, vol. v. p. 1087.)

AZADIRACHTA INDICA. The almonds of this plant yield 41.5 p. c. of a yellow oil having a bitter taste, an alliacious odour, sp. gr. 0.921, and solidifying at $+7^\circ$. By saponification it yields 35 p. c. of fatty acids melting at 30° , and 65 p. c. melting at 44° .

AZALIN. One of the varieties of aniline red.

AZELAIC ACID. $\text{C}^8\text{H}^{10}\text{O}^4$.—This acid agrees in composition and most of its properties with anchoic or lepagylic acid, but differs from it in its melting point, which is 8° or 10° lower (iii. 572). According to Overbeck (*Ann. Ch. Pharm.* xli. 39; *Jahresb.* 1866, p. 332), it is produced, together with azelaic aldehyde, $\text{C}^8\text{H}^{10}\text{O}^3$, and stearoxylic acid, $\text{C}^{18}\text{H}^{32}\text{O}^4$, by the action of fuming nitric acid on stearoleic acid (q.v.). The azelaic acid and aldehyde remain in the alcoholic mother-liquor left after the first crystallisation of the stearoxylic acid. This liquid after some time deposits an oil which has a peculiar ethereal odour, and after distillation with water is nearly colourless, mobile, and insoluble in water. It is not saponified by alkalis, and in alcoholic solution forms with ammoniacal silver nitrate a precipitate which turns black when heated. It is not altered by nitric acid, but in contact with bromine and water it is gradually converted into azelaic acid. It exhibits the composition of azelaic aldehyde.

AZELAIC ALDEHYDE. See the last article.

AZO-AMIDOCHRYSAMMIC ACID. See CHRYSAMMIC ACID.

AZO-AMIDODRACYLIC ACID. See DRACYLIC ACID, under BENZOIC ACID.

AZO-ANISIC ACID. See ANISIC ACID (p. 173).

AZOBENZENE. See BENZENE.

AZOBENZOIC ACID. See BENZOIC ACID.

AZO-COMPOUNDS. The constitution, general properties, and modes of formation of these compounds are described under AROMATIC SERIES (p. 208).

AZOCOMHYDRINE. $\text{C}^7\text{H}^{14}\text{N}^2\text{O}^4$. See vol. ii. ADDENDA (p. 964).

AZOCYMELE. See CYMELE-DERIVATIVES, and BENZENE, HOMOLOGUES OF.

AZODINAPHTHYL-DIAMINE. See NAPHTHYLAMINES.

AZODIOXINDOL. See ISATIN.

AZODIPHENYL-DIAMINE. Syn. with DIAZOAMIDOBENZENE (iv. 459).

AZODRACYLIC ACID. See DRACYLIC ACID, under BENZOIC ACID.

AZOPHENYLAMINE. Syn. with DIAZOBENZENE (iv. 430).

AZOROSANILINE. $\text{C}^{10}\text{H}^{10}\text{N}^2 = \text{C}^{10}(\text{H}^{10}\text{N}^2)\text{N}^2$ (Caro a. Wanklyn, *Chem. Soc. J.* [2] iv. 324).—A base related to rosaniline in the same manner as azophenylamine (diazobenzene) to aniline, and produced in like manner by the action of nitrous acid on a salt of rosaniline:

It resembles azophenylamine in yielding explosive salts, and when boiled with hydrochloric acid, it is converted into rosolic acid, which is related to rosaniline in the same manner as phenol to aniline:

- AZOTOLUENE.** See TOLUENE-DERIVATIVES, under BENZENE, HOMOLOGUES OF.
- AZOKINDOL.** See ISATIN.
- AZOKYBENZENE.** See BENZENE.
- AZOXYBENZOIC ACID.** See BENZOIC ACID.
- AZOXYLENE.** See XYLENE-DERIVATIVES, under BENZENE, HOMOLOGUES OF.
- AZOTOLUENE and AZOXYTOLUENE.** See TOLUENE-DERIVATIVES, under BENZENE, HOMOLOGUES OF.
- AZULENE or CÆRULEIN.** A deep blue substance contained in many essentials oils (iv. 185).
- AZULIN or AZURIN.** A blue colouring matter obtained by boiling *péonine* stable (iv. 324) with aniline.
- AZYMIC.** A term applied by Pasteur to those infusoria which act as ferments only in presence of air, those which act independently of the air being called *zymic*.

B

BALATA. A substance resembling caoutchouc and gutta-percha, obtained from the dried milky juice of the Bully-tree of Guiana (*Sapota Muellertii*) (Sporling, *Zeitschr. f. Chem.* [2] v. 480).

BALSAMS. See COCAIRA and PERU BALSAM.

BARANILINE. This name is applied by Reimann (*Dingl. pol. J.* clxxxv. 49; *Jahresh.* 1867, p. 960) to the aniline oil prepared from crude benzol boiling between 100° and 150°, that which is obtained from benzol boiling below 100° being called *euphaniline*. According to Reimann, the best yield of aniline red is obtained from a mixture of 3 pts. euphaniline and 1 pt. baraniline, or approximately, 3 pts. aniline to 1 pt. toluidine.

BARBITURIC ACID. See URIC ACID, DERIVATIVES OF (v. 962).

BARAMMONIUM. A compound of barium and ammonium, described under SODAMMONIUM (v. 320).

BARIUM. Crookes (*Chem. News*, vi. 194) prepares metallic barium as follows: A saturated solution of the chloride is heated to 93° with sodium-amalgam; the supernatant liquid is decanted from the amalgam thereby produced; and this amalgam is again boiled with the barium solution, then freed from salts by kneading under water, and from excess of mercury by pressure in a cloth. The very compact crystalline amalgam thus produced is placed in a bent tube under petroleum, and this liquid, together with the mercury, is removed by distillation, the heat being ultimately raised to redness. The metallic barium which remains tarnishes quickly on exposure to the air, and is gradually oxidised to pulverulent baryta; when scratched under petroleum, it exhibits metallic lustre. In water it gradually sinks and oxidises, with violent disengagement of hydrogen. In an alcohol flame it burns with red-green colour.

Barium Alcoholate, $Ba(C_2H_5O)_2$, separates on boiling an alcoholic solution of baryta. It can only be dried in an atmosphere of perfectly dry hydrogen gas at 100°. In contact with the liquid in which it has been formed, it redissolves on cooling, yielding a solution more concentrated than the original. A solution thus formed contained 2.188 grms. barium oxide in 10 cub. cent., and had a sp. gr. of 1.031 (Berthelot, *Bull. Soc. Chim.* [2] viii. 289).

Barium Alloys. When an alloy of sodium with lead, tin, bismuth, or antimony (not containing more than a third of its weight of sodium) is introduced into a crucible in which barium chloride is fused at a strong red heat (the quantity of the barium chloride being more than equivalent to the sodium contained in the alloy), the heat continued for a few seconds longer, and the crucible then removed from the fire, a crystalline alloy of barium and the heavy metal is produced containing only a trace of sodium. An alloy thus prepared with sodium bismuthide and barium chloride contained 28 p. c. barium. Such alloys may also be prepared without the use of reduced sodium, by heating an intimate mixture of sodium carbonate, charcoal,

barium chloride, and finely divided tin, &c., as long as vapours of sodium continue to escape. The same methods serve for the preparation of alloys of tin, antimony, &c., with strontium and calcium. The alloys of the earth-metals thus obtained are not decomposed by strong heating in a crucible lined with charcoal; they oxidise quickly in the air, and if they contain more than 5 p. c. of the earth-metal, decompose water with facility, the other metal then remaining unattacked, in the form of a black powder; those which contain antimony give off gaseous hydrogen antimonide (Caron, *Compt. rend.* xlviii. 440; *Jahresb.* 1859, p. 129).

A crystalline alloy of barium and aluminium is obtained by heating baryta with aluminium and a small quantity of barium chloride. This alloy, which contains 23 or 24 p. c. barium, is somewhat darker-coloured than aluminium, and exhibits a yellow reflex on some of its faces; it decomposes water quickly at ordinary temperatures, forming a solution which does not exhibit any alkaline reaction, probably because the baryta and alumina unite to form an aluminate (Beketoff, *Bull. Soc. Chim.* 11 mars 1859).

A platinum wire plunged into fused barium chloride, and attached to the negative pole of a battery, the current of which is passing through the chloride, becomes covered with a yellow brittle alloy of barium and platinum, which slowly decomposes water, leaving platinum in the form of a fine powder (Matthiessen, *Chem. Soc. J.* viii. 294).

Caron (*Compt. rend.* i. 547) obtained an alloy of barium and zinc by melting zinc with barium chloride and sodium.

Barium Bromide. The hydrated bromide $\text{BaBr}^2 \cdot 2\text{H}_2\text{O}$ crystallises, according to Hanell (*Jahresb.* 1859 p. 132), in rhombic combinations of a prism of $106^\circ 8'$ and $73^\circ 52'$, having the acute edges truncated, and terminated at both ends by several pyramids and brachydomes. Rammsberg (*Pogg. Ann.* cxxii. 616; *Jahresb.* 1864, p. 189) refers the crystals to a primary form in which the axes $a : b : c = 0.3758 : 1 : 0.4348$ (Hanell's prism of $106^\circ 8'$ and $73^\circ 52'$ then becoming ∞P^2). He observed combinations of $P : 3P^3 : \infty P^2 : P\infty : 3P\infty : P\infty : \infty P\infty$. Angle $P : P$ (brach.) = $148^\circ 16'$; $P : P$ (naer.) = $86^\circ 36'$; $P : P$ (basal.) = $102^\circ 2'$. The hemimorphous and partial development of the crystals gives them a monoclinic character; and in fact G. Werther (*J. pr. Chem.* xci. 167) supposed them to belong to the monoclinic system.

The specific gravity of anhydrous barium bromide is 4.23; of the hydrated salt, 3.690 (H. Schiff, *Jahresb.* 1858, p. 11).

The specific gravities (referred to water at 19.5° as unity) of solutions of barium bromide of various strengths have been determined by Kremers (*Jahresb.* 1857, p. 67) with the following results:

BaBr^2 in 100 pts. water .	17.81	38.83	60.92	81.97	104.68
Sp gr. of solution .	1.1440	1.3005	1.4507	1.5816	1.7115

Barium Chloride. Sp. gr. of the anhydrous chloride $\text{BaCl}^2 = 3.82$; of the hydrated chloride, $\text{BaCl}^2 \cdot 2\text{H}_2\text{O} = 3.052$ (Schiff, *loc. cit.*); 3.081 (Buignet, *Jahresb.* 1861, p. 16).

Specific Gravities of Aqueous Solutions of Barium Chloride.

Kremers *		Gerlach †		Schiff ‡	
Percentage of BaCl^2	Sp. gr. (water at $19.5^\circ = 1$)	Percentage of BaCl^2	Specific gravity at 16°	Percentage of $\text{BaCl}^2 \cdot 2\text{H}_2\text{O}$	Specific gravity at $21^\circ 5^\circ$
8.88	1.0760	5	1.0458	3.50	1.0261
18.24	1.1521	10	1.0951	7.00	1.0531

Respecting the solubility of barium chloride in aqueous alcohol of various strengths, see ETHYL ALCOHOL.

* *Pogg. Ann.* xcix. 62; *Jahresb.* 1857, p. 67.

† *Spec. Gewichte der gebräuchlichsten Salzlösungen bei verschiedenen Concentrationsgraden.* Freiberg, 1859. *Jahresb.* 1859, p. 43.

‡ *Ann. Ch. Pharm.* cvii. 293; *Jahresb.* 1858, p. 38.

Barium Iodide. BaI^2 .—Liebig prepares this salt by drenching 1 pt. of finely divided amorphous phosphorus in a porcelain dish with 40 pts. of warm water, gradually adding 20 pts. of dry iodine, and bringing it into contact with the phosphorus by trituration with a pestle. As soon as the originally dark brown liquid has become colourless (a change which may be accelerated by warming in the water-bath) it is to be decanted from the slight residue of phosphorus, and saturated with barium carbonate; baryta-water then added sufficient to produce a slight alkaline reaction; the liquid filtered from the separated barium phosphate; and the solution of barium iodide evaporated, any slight excess of baryta that it may contain being separated by absorption of carbonic acid during the evaporation (*Ann. Ch. Pharm.* cxxi. 222), G. Werther (*J. pr. Chem.* xci. 331) obtained this compound as a bye-product in the preparation of barium tetrathionate (v. 641), in rather large, well-defined crystals containing $\text{BaI}^2 \cdot 2\text{H}^2\text{O}$, and isomorphous with the bromide; they are very deliquescent, and quickly turn red-brown in contact with the air. Werther did not obtain the heptahydrated crystals described by Croft (i. 504).

According to Kremers (*Jahresb.* 1858, p. 40), 1 pt. of anhydrous barium iodide dissolves in the following quantities of water at the temperatures under-mentioned:

Temperature . . .	0°	19.5°	30°	40°	60°	90°	106°
Quantity of water .	0.59	0.48	0.44	0.43	0.41	0.37	0.35

Solutions of various strengths were found by Kremers to have the specific gravities stated in the following table, referred to that of water at 19.5° as unity;

Quantity of BaI^2 in 100 pts. of water	Specific gravity of solution
27.0	1.2157
53.8	1.4099
85.8	1.6186
115.6	1.7953
146.0	1.9585

Respecting the expansions of solutions of barium iodide of various strengths, see Kremers, *Pogg. Ann.* cxi. 60; *Jahresb.* 1860, p. 47.

Barium Oxides. The *monoxide* or *Anhydrous Baryta*, BaO , may be prepared on the large scale by igniting a mixture of barium carbonate and charcoal in a reverberatory furnace, and directing a stream of oxygen gas on the hearth towards the end of the reaction; the remaining charcoal is thereby burnt, but in consequence of the high temperature the carbon dioxide produced is not absorbed by the baryta (atmospheric air cannot be substituted for pure oxygen in the process). The baryta thus obtained is said to be pure, with the exception of a small amount of alkali (Tessié du Mothay, *Bull. Soc. Chim.* [2] viii. 454). Rivière ignites barium sulphate with $\frac{1}{4}$ of its weight of pounded coal; decomposes the barium sulphide by means of the carbonic acid gas produced in the reduction; and finally converts the precipitated barium carbonate into oxide by ignition with $\frac{1}{10}$ of its weight of coal; but, according to Scheurer-Kestner, the process does not yield very good results (*Bull. Soc. industr. de Mulhouse*, xxxvi. 446; *Jahresb.* 1867, p. 908).

Dioxide or Peroxide. BaO^2 .—The dioxide prepared by passing oxygen over heated baryta, or by igniting baryta with potassium chlorate (i. 506), always contains a certain proportion of the monoxide. To obtain it pure, Brodie (*Proc. Roy. Soc.* xii. 655) converts the crude peroxide produced by either of the methods just mentioned into a hydrate by trituration with water; then gradually supersaturates it with dilute hydrochloric acid; mixes the filtered solution, first with a slight excess of baryta-water, and then (after quickly filtering off the precipitate of alumina and ferric oxide through linen) with more baryta-water, whereby the hydrated dioxide is thrown down in shining laminae. It is insoluble in water, and when pressed between paper and dried under the air-pump, gives off its water and leaves the anhydrous dioxide, in the form of a white perfectly stable powder resembling magnesia.

Barium dioxide is decomposed by the sulphates of the alkali-metals, yielding barium sulphate and a hydrate of the alkali-metal, together with rapidly diminishing quantities of hydrogen dioxide; with alkaline carbonates in slight excess, the hydrogen dioxide produced is somewhat more stable (Weltzien, *Jahresb.* 1866, p. 110). With ethylsulphuric acid, it yields ethyl oxide and ethylene gas (Baudrimont, *Compt. rend.* lxii. 829).

The chlorides and oxides of oxygenated organic radicles are converted by barium dioxide into the corresponding peroxides (Brodie). See vol. iv. p. 309.

BATHVILLITE. A substance of organic origin, occurring in the coal-measures of the neighbourhood of Bathville (bordering on the Torbane Hill district) in brown brittle lumps of sp. gr. 1.010. It is infusible and does not yield anything to benzol. Moderately dilute nitric acid has no action upon it, but strong sulphuric acid, with aid of heat, chars it completely. Heated in a platinum crucible, it emits a fatty odour, gives off gases which burn with a smoky flame, and leaves a pure white ash. Its analysis gave

C	H	N, O, S, &c.	Ash
58.89	8.56	7.23	25.32 = 100

or, calculated on the substance free from ash, C 78.86, H 11.46. The difference from 100 being reckoned as oxygen, the composition answers to the formula $C^{30}H^{10}O^2$ (C. Gr. Williams, *Chem. News*, vii. 153).

BAUXITE. This name was originally applied by Berthier (*Ann. Min.* [5] vi. 531) to a ferruginous aluminic hydrate, containing 55.4 p. c. alumina and 44.5 ferric oxide, occurring in roundish masses in the crystalline limestone of Baux, near Arles, in France. This mineral fused with alkalis gives traces of vanadic acid (H. Deville, *Ann. Ch. Phys.* [3] lxi. 309).

Analyses of bauxite and allied minerals have been made by M. v. Lill (*Jahresb.* 1866, p. 923), Schnitzer (*Dingl. pol. J.* clxxxiv. 329; *Jahresb.* xx. 982), and H. Deville (*Ann. Ch. Phys.* [3] lxi. 321, 324).

BAYLDONITE. A hydrated arsenate of lead and copper from Cornwall, occurring in small warty concretions, of grass-green or blackish-green colour, slightly conchoidal fracture, and more or less distinct resinous lustre. Hardness = 4.5. Sp. gr. = 5.35. Analysis gave 30.13 p. c. PbO , 30.88 CuO , 31.76 As_2O_3 , 4.58 H_2O , with 2.65 ferric oxide and loss, leading to the formula $PbO.3CuO.As_2O_3.2H_2O$ or $PbCu_2(AsO_4)_2 \cdot H_2O$ (Church, *Chem. Soc. J.* [2] iii. 265).

BEAN. The bean from which Dr. Stenhouse obtained bases (apparently of the pyridine series) by destructive distillation (*Phil. Mag.* [3] xxxv. 534) was the kidney-bean (*Phaseolus vulgaris*), not the common field-bean (*Faba vulgaris*) as originally stated (*Communication from Dr. Stenhouse*).

BEAUMONTITE. Descloizeaux (*Ann. Min.* [5] xi. 261) concludes from the optical properties of this mineral that it is identical with heulandite (stilbite). See *STILBITE* (v. 433).

BEHIRINE or **BEEBERINE.** According to J. Trupp (*Jahresb.* 1863, p. 702), this alkaloid gives with phosphomolybdic acid a yellow precipitate, which dissolves in ammonia, forming a blue solution which becomes colourless on boiling.

According to Walz (*N. Jahrb. Pharm.* xiv. 15; *Jahresb.* 1860, p. 548), buxine, the alkaloid obtained from the leaves and other parts of *Buxus sempervirens*, is identical with bebirine, the analysis of the alkaloid itself, and of its hydrochloride, platinohydrochloride, and mercuriochloride, leading to the formula of bebirine $C^{20}H^{21}NO^3$. The alkaloid dissolves in 6,000 pts. of cold water, forming a feeble alkaline solution, in 1,800 pts. of boiling water, in 2 to 3 pts. alcohol of sp. 0.85, in 5.2 pts. of anhydrous alcohol, and in 13 pts. of pure ether, the alcoholic and ethereal solutions being strongly alkaline. It remains in the amorphous state when its solutions are evaporated, and all its salts are uncrystallisable.

According to Flückiger (*Zeitschr. f. Chem.* [2] vi. 251), purisine obtained by Winckler from a cinchona-bark, and pelosine from the root- and stem-bark of *Cissampelos Pereira* and *Batryopsis platyphylla* are likewise identical with bebirine. This alkaloid is especially distinguished by the readiness with which it is precipitated from solution in hydrochloric acid by potassium nitrate, ammonium chloride, and potassium iodide.

BECKITE. For Church's observations on this mineral, see *Phil. Mag.* [4] xxiii. 95.

BEUCISIC ACID. A crystallisable acid contained, together with gum, resin, and tannin, in the red juice of *Myristica bicukhya* (Th. Peckolt, *Chem. Centr.* 1861, p. 726).

BEER. A large number of analyses, recently made, show that in the various classes of malt-liquor sold in London there is a variation in the amount of alcoholic contents from 3.37 to 8.41 per cent. of absolute alcohol by weight, these two extremes corresponding to .98 and 2.18 fluid ounces of absolute alcohol in the pint of beer. The amount of extract varies from 2.16 to 18.32 per cent. by weight, or from .73 to 2.77 ounces per pint of beer, as will be seen from the accompanying table.

Kind of malt liquor	Specific gravity	Percentage of			Original gravity of wort	Malt per barrel	Contents per pint		
		Alcohol	Extract	Acetic acid			Alcohol fl. oz.	Extract oza.	Acid gra.
Burton ale (Allsopp's) . . .	1040.38	8.25	13.32	.32	1121.63	4.50	2.18	2.77	29.12
Bass's barley wine	1032.31	8.41	11.75	.23	1114.78	4.25	2.18	2.42	20.77
Edinburgh ale . . .	1006.63	4.41	3.58	.19	1048.38	1.77	1.12	.72	16.73
Guinness's stout . .	1015.51	6.81	6.17	.24	1078.06	2.88	1.74	1.25	21.32
Truman, Hanbury, & Co.'s porter	1013.16	4.02	5.12	.24	1051.33	1.90	1.03	1.01	21.27
Whitbread's porter	1014.04	4.28	5.15	.18	1054.11	2.00	1.09	1.03	15.97
Hoare's porter . . .	1012.99	4.18	5.04	.18	1052.42	1.94	1.06	1.03	15.96
Perry's ale	1006.48	3.87	3.65	.14	1045.82	1.69	0.98	0.73	7.97

The relative proportions of alcohol and extract also differ according to the class of malt-liquor, and independently of the actual strength measured by the quantity of malt per barrel used in brewing. Thus, for instance, pale ale, as a rule, contains less extract relatively to the alcohol than old or mild ale. This difference is chiefly due to the way in which the fermentation is conducted, and to its being carried further in the brewing of pale ale than it is in other cases.

In comparing the results of analysis, with the object of judging as to the quality of beer, some considerable allowance must be made for those differences in the character of beer which are not clearly expressed by the amount either of alcohol or of extract, nor even by the proportion of malt used in brewing, as indicated by the estimated original gravity. In this respect, the system of brewing adopted in particular cases may be of far greater influence in determining the quality and character of beer than the mere amounts of alcohol and of extract that it contains; but, subject to this influence, the amount of malt indicated by the estimated original gravity of beer, as having been used in the brewing, may be regarded as the best approximative test of quality. It must, however, be borne in mind that sugar is now largely used in brewing as a substitute for malt, and that there are no means of ascertaining by analysis when this is the case.

The relative proportions of alcohol and extract in beer will also have some influence on its fitness in a medical point of view for certain persons; and in some instances thin dry beer that has had the fermentation carried so far as to reduce the amount of extract to a minimum, may be very preferable to beer containing a larger amount of extract. In this respect, some samples of the Prestonpans beer are remarkable for the small proportion of extract they contain.

In regard to the nutritive value of beer, over and above the stimulant and tonic actions due to the alcohol and to the bitter principle of the hop, it is worth notice that a pint of pale ale contains from $\frac{1}{2}$ an ounce to 1 ounce of solid extract, while mild and old ale contain from $1\frac{1}{10}$ to $2\frac{1}{2}$ ounces in the pint.

The amount of free acid in British beer appears to be uniformly larger than in the Viennese and Bavarian beer recently introduced here, and sometimes it is very much larger. This free acid is represented in the tables as acetic acid; but there is reason to believe that beer probably contains lactic acid or other fixed acids, together with a substance analogous to glucic acid, which, according to Graham, Hofmann, and Redwood, appears to be produced in the fermentation of beer-wort, as practised in this country.

There appear to be great differences in the quality of beer sold by publicans at a given price. Thus, for instance, the variation in the pale ale sold at fourpence per pint is from 4.08 to 7.10 per cent. of alcohol, and from 3.22 to 7.53 per cent. of extract; in the mild ale sold at twopence per pint it is from 4.43 to 5.62 per cent. alcohol, and from 5.01 to 5.56 per cent. of extract; and in old ale sold at fourpence per pint it is from 6.20 to 8.31 per cent. of alcohol, and from 4.56 to 6.2 per cent. of extract. These differences represent respectively 1.58, .27 and .49 bushels of malt per barrel of the beer.

From the great alcoholic strength of some kinds of old ale, they partake more of the nature of wine than of beer, in the usual sense of this term. They are, in fact, quite equal in that respect to most of the cheaper wine imported from the Continent,

while, in flavour and general character, old ale, such as that brewed at Burton-on-Trent and in Scotland, is far superior to any wine of the kind referred to, which can be sold here at a price even double that of the best old ale. This kind of ale, however, is but rarely sold by publicans. B. II. P.

BENOLIC ACID. $C^{22}H^{16}O^2$ (Haussknecht, *Ann. Ch. Pharm.* cxliii. 40).—An acid produced by the abstraction of the elements of hydrogen bromide from bromide of erucic acid, $C^{22}H^{42}O^2Br^2$. When this latter compound is enclosed in a sealed tube together with 4 or 5 mol. of potassium hydrate in alcoholic solution, and heated to 145° for seven or eight hours, the product, after cooling, dissolved in water, and hydrochloric acid added, benolic acid separates, and may be obtained by recrystallisation from alcohol in tufts of white needles. It melts at 57.5° , becomes electric when rubbed, dissolves easily in ether and in absolute alcohol, less easily in cold aqueous alcohol, and is insoluble in water. It does not take up hydrogen when heated with sodium-amalgam.

The benolates of the alkali-metals are soluble in water, the rest insoluble. The *potassium* and *sodium salts* form nodular crystals; the *ammonium salt* separates from dilute alcoholic solution in colourless laminae, which soon give off ammonia and become opaque. The *silver salt* $C^{22}H^{16}AgO^2$ is insoluble in water and in alcohol. The *barium salt* $Ba(C^{22}H^{16}O^2)^2$, obtained by precipitating barium chloride with the acid, is insoluble in water, alcohol, and ether. The *strontium* and *calcium salts* resemble it. The *magnesium salt* is precipitated by the acid from an alcoholic solution of magnesium acetate, and separates from boiling alcohol in crystals containing $Mg(C^{22}H^{16}O^2)^2 \cdot 3H^2O$. It is efflorescent, and melts at 130° with loss of its crystallisation-water.

As erucic acid, which belongs to the acrylic series, is bivalent, benolic acid, which is derived from it by abstraction of H^2 , must be quadrivalent. Accordingly it forms a dibromide and a tetrabromide.

The dibromide, $C^{22}H^{14}Br^2O^2$, is produced, with slight evolution of hydrobromic acid, when rather more than 1 mol. of bromine is gradually added to 1 mol. of the benolic acid. It forms shining white laminae, melting between 46° and 47° , heavier than water, easily soluble in alcohol and ether. Heated for several hours with alcoholic potash in a sealed tube to 150° (not in the cold), it gives up bromine and appears to be chiefly reconverted into benolic acid; an acid containing less hydrogen does not appear to be formed.

The tetrabromide, $C^{22}H^{12}Br^4O^2$, is formed, with violent hissing and copious evolution of hydrobromic acid, when benolic acid is added by small portions to excess of bromine, and separates as a fused, afterwards solidifying mass, which may be purified by solution in soda-ley, precipitation with hydrochloric acid, and crystallisation from alcohol. It forms white shining laminae, melting at 77° to 78° . It is decomposed by alcoholic potash, but without yielding any definite products. Sodium-amalgam at the boiling heat slowly withdraws the whole of the bromine, forming an acid melting at 33° , probably erucic acid.

Dioxybenolic Acid, $C^{22}H^{14}O^4$, is produced, together with another solid acid (brassylic acid) and a liquid oil (brassylic aldehyde), when red fuming nitric acid is added by drops to melting benolic acid; and if the semisolid product of the oxidation be carefully washed with water and then dissolved in hot absolute alcohol, the dioxybenolic acid crystallises out for the most part on cooling, while the other solid acid and the oil remain in solution, and separate out after some time only. Dioxybenolic acid is obtained by repeated crystallisation in small yellowish scales; it melts at 90° – 91° , and solidifies again in the crystalline state. It is insoluble in water, less soluble in alcohol than benolic acid, not further attacked by nitric acid. It is monobasic. The dioxybenolates of the alkali-metals separate from alcoholic solution in crystalline crusts; those of the alkaline earth-metals are insoluble in water and in alcohol. The *silver salt* $C^{22}H^{12}AgO^4$ is a white precipitate not much affected by light.

BENZAMIDE. According to Petersen (*Ann. Ch. Pharm.* cv. 277), benzamide is formed on distilling a mixture of sodium benzoate and sal-ammoniac; according to J. Head, on the contrary (*Jahresb.* 1858, p. 314), no benzamide is formed under these circumstances, but a sublimate of benzoic acid is obtained, with evolution of ammonia; probably thus:

The crystals of benzamide obtained by melting it, and decanting the still fluid from the partially solidified portion, are tabular rhombic combinations, $\infty P_2 \cdot \infty P \cdot \infty P$, having the axes $a : b : c$ in the ratio 0.9338 : 1 : 0.227, and
Sup. 8

the angle $\infty P : \infty P$ (macr.) = $89^{\circ} 4'$; $P\infty : P\infty$ in the same = $153^{\circ} 56'$. Cleavage perfect parallel to $\infty P\infty$ (G. vom Rath, *Pogg. Ann.* cx. 107).

Sulphuric anhydride converts benzamide into a brownish-yellow mass smelling of benzonitrile, and containing (together with unaltered benzamide) ammonia and sulphobenzoic acid, the benzamide being probably first resolved into ammonia, benzonitrile, and benzoic acid, which latter is then converted into sulphobenzoic acid. *Sulphuric chlorhydrate*, SO^2HCl , heated with benzamide, yields benzoic chloride, benzonitrile, benzoic acid, and probably also sulphobenzoic acid (Engelhardt, *Jahresb.* 1864, p. 350).

Benzamide boiled with *bromine* and water is converted into *salt-ammoniac* and bromobenzoic acid:

The bromobenzoic acid thus produced appeared to be a mixture of two isomeric acids, inasmuch as on recrystallisation the melting point rose from 149° to nearly 200° (W. Brauns, *Arch. Pharm.* [2] cxvi. 214).

Benzamide gently heated with *phosphoric sulphide*, P^2S^3 , yields a distillate of benzonitrile, and a residue probably consisting of cyaphenine mixed with phosphoric anhydride (L. Henry, *Zeitschr. f. Chem.* [2] v. 446).

Metachlorobenzamide, C^6H^4ClNO , is formed by triturating metachlorobenzoyl chloride (salyl chloride) with ammonium carbonate (Gerhardt & Drion; see i. 540); also by the action of ammonia on ethyl metachlorobenzoate. It crystallises in very beautiful nacreous needles, soluble in alcohol and ether, very slightly soluble in boiling water, melting at 139° , and sublimable without decomposition (Kekulé, *Ann. Ch. Pharm.* cxvii. 456).

NITROBENZAMIDE, $C^6H^4(NO^2)NO$, is most easily obtained from the product of the action of phosphorus pentachloride on nitrobenzoic acid (after removal of the oxychloride at about 130°) by dropping this product into strong aqueous ammonia. It melts at 140° to 142° , and is converted, by treatment with ammonium sulphide, into amidobenzamide, $C^6H^4(NH^2)NO$ or oxybenzodiamide, $N^2(C^6H^4O)^2H$, isomeric with phenyl-carbamide. This compound separates from solution in crystals containing $C^6H^5N^2O \cdot H^2O$, which melt and give off their water at 75° (Beilstein, *Ann. Ch. Pharm.* xxxii. 137). Compare Chancel's statements, under OXYBENZODIAMIDE (iv. 204).

Paranitrobenzamide (nitrodracylamide), prepared similarly to (ortho-) nitrobenzamide, is less soluble in water, and melts at 197° to 198° . By ammonium sulphide it is converted into para-amidobenzamide (amidodracylamide), which forms large light yellow crystals, $2C^6H^5N^2O \cdot H^2O$, much less soluble in water than (ortho-) amidobenzamide, and melting at 178° to 179° with loss of 3.2 p. c. water. By boiling with potash, it is resolved into ammonia and para-amidobenzoic (amidodracylic) acid (Beilstein, *loc. cit.*).

THIOBENZAMIDE, C^6H^5NS , is converted by iodine into the compound $C^6H^5N^2S_3$, which crystallises from boiling alcohol in long colourless needles; melts at 90° ; sublimes without decomposition at a higher temperature; is decomposed by boiling with alcoholic soda, the sulphur being separated as sodium hyposulphite; not altered by boiling with hydrochloric, nitric, or dilute sulphuric acid; but converted by boiling with moderately strong sulphuric acid into a base, $C^6H^5N^2S$, which melts at 71° and forms crystallisable salts. Chlorine, bromine, and dilute nitric acid act upon thio-benzamide in the first instance in the same manner as iodine, but their action has a tendency to go further, giving rise to substitution-products (Hofmann, *Deut. Chem. Ges. Berlin.* 1869, 646; *Zeitschr. f. Chem.* [2] vi. 208).

DIAZOBENZAMIDE, $C^6H^5N^2O = N \begin{Bmatrix} C^6H^5N^2O \\ H^2 \end{Bmatrix}$.—The nitrate of this amide, $C^6H^5N^2O \cdot NHO^2$, is described in vol. iv. p. 295.

The nitrates of the isomeric compounds diazodracylamide and diazosallylamide are produced in like manner by the action of nitrous acid on amidodracylamide and amidosallylamide in ethereal solution.

DIAZOBENZIMIDE, $C^6H^5N^2O^2 = N \begin{Bmatrix} C^6H^5N^2O^2 \\ H \end{Bmatrix}$, is produced by the action of aqueous ammonia on the perbromide of diazobenzoic acid:

It crystallises in almost white thin laminae, which dissolve easily in alcohol and ether, less easily in boiling water, scarcely at all in cold water, melting at 160° , and decomposing with slight detonation. It forms well-defined salts; the silver salt is a white amorphous precipitate.

Isomeric compounds are formed by the action of ammonia on the perbromides of diazodracrylic and diazosallylic acid. *Diazodracylimide* likewise crystallises in laminae, but melts at 185°. *Diazosallylimide* is moderately soluble in boiling water, and crystallises therefrom in long needles which melt at 145° and sublime at 100° (Griess, *Zeitschr. f. Chem.* [2] iii. 164).

DIBENZAMIDE OF DIBENZOYLAMIDE, $C^{14}H^{11}NO^2 = N(C^6H^5O)^2H$, is produced, together with benzamide, by the action of potassamide on benzoyl chloride dissolved in anhydrous ether (iv. 695):

The mass of colourless crystals thereby produced is freed from ether by distillation, and rapidly washed with cold water to remove potassium chloride: the residue, on recrystallisation from boiling water, separates into more soluble benzamide and less soluble dibenzamide. Dibenzamide crystallises in rhombic combinations of a pyramid with a secondary prism, soluble in 800 pts. of water at 15°, and melting at 138°. Its reactions are similar to those of benzamide (Beilstein a. Landolt, *Ann. Ch. Pharm.* cx. 1). According to G. vom Rath (*Pogg. Ann.* cx. 107), the crystals exhibit the combination $P \infty P_2$, with the axes $a : b : c$ in the ratio 0.9305 : 1 : 1.0690; and angle $P : P$ (brach.) = $109^\circ 50'$; $P : P$ (macr.) = $103^\circ 46'$; $\infty P_2 : \infty P_2$ (macr.) = $123^\circ 30'$. Cleavage perfect parallel to $\infty P \infty$.

BENZANILIDE and **DIBENZANILIDE**. See **PHENYL-BENZAMIDES** (iv. 476).

BENZANILIDYL CHLORIDE. This name was given by Gerhardt (*Ann. Ch. Phys.* [3] liii. 307) to a compound obtained by the action of phosphorus pentachloride, assisted by a gentle heat, on benzanilide (iv. 476). A brisk reaction takes place; hydrochloric acid is evolved; phosphoric oxychloride distils over; and the small quantity of that compound remaining in the liquid product may be removed by adding a small piece of phosphorus, whereby it is converted into phosphorous chloride, PCl_3 , which is easily driven off by a gentle heat. Benzanilidyl chloride, $\text{N}(\text{C}^6\text{H}_5)^2(\text{C}^6\text{H}_4)\text{Cl}$, then remains in the form of a viscid mass, which colours flame green, fumes in the air, is decomposed by water and aqueous alcohol, with formation of benzanilide, dissolves without decomposition in ether, and is resolved by heat into benzonitrile, NC^6H_5 , and phenyl chloride, $\text{C}^6\text{H}_5\text{Cl}$. Heated with excess of *aniline*, it gives off hydrochloric acid and forms a solid mass, consisting of a diamide, $\text{C}^6\text{H}_5\text{N}^2$ or $\text{N}(\text{C}^6\text{H}_5)^2(\text{C}^6\text{H}_4)^2\text{H}$. If, on the other hand, the chloride is in excess, the resulting thick mass, treated with boiling alcoholic potash, gives off the odour of phenol and forms an alkaline solution containing salicylic acid:

Benzanilidyl chloride is violently attacked by dry ammonium carbonate, and the solid product, after being washed with water, yields to boiling alcohol a solution from which benzanilidylamide crystallises in brownish-yellow radiate nodules, which are but slowly attacked by alcoholic potash solution, even at the boiling heat.

BENZENE or BENZOL. C_6H_6 . *Formation*.—1. From other hydrocarbons. a. Acetylene, heated in a bent glass tube over mercury to the softening point of the glass, is converted into a number of polymeric hydrocarbons, among which is benzene, forming about half the entire liquid product: $3C_2H_2 = C_6H_6$. Benzene may therefore be regarded as triacetylene (Berthelot). See ACETYLENE (p. 32).—b. Toluene, C_7H_8 , passed through a red-hot porcelain tube yields a liquid distillate containing a considerable quantity of benzene, together with naphthalene:

7. Xylene, C^8H^{10} , and Cumene, C^9H^{12} (from coal-tar), similarly treated, yield benzene, together with some of its homologues and other hydrocarbons.—8. Cinnamene or styrol, C^9H^8 , passed through a red-hot tube is partly resolved into benzene and acetylene, ($C^2H^2 + C^3H^2$). The same hydrocarbon heated in a sealed tube filled with hydrogen is resolved into benzene and ethylene:

e. Diphenyl, $C^{12}H^{10}$, heated in a tube filled with hydrogen is partly converted into benzene and chrysene, $C^{12}H^{12}$, the latter probably resulting from polymerisation of previously formed phenylene, C^6H^4 :

* The term benzene will be used to denote the pure hydrocarbon C_6H_6 ; and benzol for the commercial product, containing also the higher homologues of benzene.

6. A mixture of diphenyl-vapour and ethylene passed through a red-hot tube is partly resolved into benzene and cinnamene:

7. A mixture of chrysene-vapour and ethylene yields, under the same circumstances, benzene and anthracene, with a small quantity of naphthalene:

8. Ethylene and anthracene also yield benzene and naphthalene:

9. Chrysene heated with hydrogen yields benzene and diphenyl:

2. From Menhaden oil (obtained from *Alosa Menhaden*, a kind of herring), which is resolved by the dry distillation of its lime-soap into benzene and its homologues, together with a number of hydrocarbons of the marsh-gas series (Warren and Storer, *Zeitschr. f. Chem.* [2] iv. 229).

3. From chlorobenzol, C^6H^5Cl , and from benzoic trichloride, $C^6H^5Cl^3 = C^6H^5(CCl^2)$, by heating with soda-lime (Limpricht, *Ann. Ch. Pharm.* cxxxix. 303; *Jahresb.* 1866, 593, 595):

and

4. From diazobenzene, by heating its nitrate or sulphate with alcohol, or the latter with alcoholic potash, aldehyde and other products being formed at the same time (Griess; *vide* iv. 432):

5. From bromobenzoic acid by distillation with lime (A. Riche, *Jahresb.* 1861, p. 616).

6. From cinnamic acid by distillation with a large excess of lime or baryta (D. Howard, *Chem. Soc. J.* xiii. 135).—7. From trimelic acid, $C^6H^4O^6$, by heating strongly with excess of lime: $C^6H^4O^6 = C^6H^6 + 3CO^2$ (Fittig a. Furtenbach, *Zeitschr. f. Chem.* [2] iv. 4).

Purification of Commercial Benzol.—When 1 vol. rectified coal-tar naptha, containing about 50 p. c. benzene, is mixed with 6 vol. strong sulphuric acid previously diluted with 1 vol. water, and the mixture is heated in a still, the hydrocarbons of higher boiling point dissolve for the most part in the acid, while the benzene remains unattacked. If lumps of pumice-stone are moistened with the acid, its action becomes more decided (Church, *Phil. Mag.* [4] xxi. 176).

E. Kopp (*Moniteur scientifique*, vi. 329) recommends for the purification of benzol, for conversion into nitrobenzol, aniline, &c., to cool it in Carré's refrigerator to -15° , press the resulting crystalline mass quickly, fuse it, and again subject it to the same treatment.

Berthelot (*Bull. Soc. Chim.* [2] vi. 289) enumerates the following properties of benzene as readily available for its separation from mixtures of hydrocarbons of which it forms only a small fraction: α . Its unalterability when heated in sealed tubes to 200° – 400° (cinnamene, terebenthene, &c., pass under these circumstances into polymeric modifications of high boiling point).— β . Indifference towards iodine, saturated solutions of hydriodic and hydrochloric acids, and concentrated sulphuric acid, and its comparative indifference towards bromine.

Density.—Louguinine (*Ann. Ch. Phys.* [4] xi. 465) has given the following table of the densities and volumes of benzene at various temperatures:

Temperatures	Densities	Volumes	Temperatures	Densities	Volumes
0°	0.8995	1.0000	45°	0.8512	1.0567
5	0.8939	1.0063	50	0.8468	1.0622
10	0.8887	1.0122	55	0.8402	1.0706
15	0.8833	1.0183	60	0.8349	1.0774
20	0.8780	1.0245	65	0.8293	1.0846
25	0.8726	1.0308	70	0.8238	1.0919
30	0.8673	1.0371	75	0.8181	1.0995
35	0.8620	1.0435	80	0.8129	1.1066
40	0.8567	1.0500			

Decompositions.—1. Benzene may be heated in a close vessel to 200°, 300°, or 400° without alteration; but when passed through a porcelain tube heated to bright redness, it is partly decomposed, yielding hydrogen gas containing a little acetylene, and a liquid product separable by fractional distillation into: (1) Diphenyl, $C^{12}H^{10} = 2(C^6H^4 - H^2)$, distilling between 250° and 300°.—(2) Chrysene, $C^{14}H^{12} = 3C^6H^4 - 3H^2$, distilling above 360°.—(3) Benzerythrene, which distills at a dull red heat and solidifies into an orange-red resin of the consistence of colophony.—(4) A substance called by Berthelot bitumene, which remains in the retort at a dull red heat, as a blackish liquid, solidifying as it cools; it dissolves slightly in ether, forming a fluorescent liquid, which leaves on evaporation a film having a metallic lustre (Berthelot, *Bull. Soc. Chim.* [2] vi. 272, 279; *Jahresh.* 1866, p. 541).

2. Benzene heated in a glass tube over mercury with acetylene absorbs it, forming: (1) A small quantity of cinnamene, $C^8H^8 = C^6H^4 + C^2H^2$.—(2) A solid hydrocarbon, which, after the excess of benzene has been evaporated, remains in the form of slender needles, volatilising with difficulty.—(3) Tarry products.

3. A mixture of benzene and ethylene passed through a red-hot tube yields: (1) Cinnamene in considerable quantity at a red heat, and as chief product at a white heat.—(2) Naphthalene, the chief product at a red heat.—(3) Acenaphthene (p. 3), formed chiefly at a white heat.—(4) Anthracene mixed with a liquid hydrocarbon. The formation of cinnamene, naphthalene, and anthracene is represented by the equations

Cinnamene.

Naphthalene.

Naphthalene.

4. Benzene and marsh gas do not act on one another under the same conditions as benzene and ethylene; but when they are brought together in the nascent state, as when a mixture of benzoate and acetate of sodium is subjected to dry distillation, they react so as to form toluene or methyl-benzene:

5. A mixture of benzene and cinnamene vapour passed through a red-hot tube yields anthracene, together with small quantities of naphthalene and a hydrocarbon resembling diphenyl:

Cinnamene. Benzene. Anthracene.

6. Benzene vapour and naphthalene vapour at a white heat yield anthracene:

(Berthelot, *Bull. Soc. Chim.* [2] vii. 113, 274; *Jahresh.* 1866, p. 544).

7. Benzene oxidised by a mixture of manganese dioxide and sulphuric acid, is converted into formic, carbonic, benzoic, and phthalic acids (Carius, *Zeitschr. f. Chem.* iv. 505):

Benzene.

Formic acid.

Benzoic acid.

and

Benzoic acid.

Formic acid.

Phthalic acid.

It is not attacked by potassium dichromate and sulphuric acid even after prolonged boiling (Church, *Phil. Mag.* [4] xxi. 176).

8. When 100 to 120 drops of benzene are taken into the stomach of men or dogs, the urine is found to contain phenol (Schultzen a. Naunyn, *Chem. Centr.* 1867, p. 705).—9. Benzene treated with potassium chlorate and nitric acid (sp. gr. 1.4) gives off a large quantity of gas, and yields a brownish oil which decomposes on distillation

yielding the compound $C^7H^5 \cdot NO_2 \cdot Cl$ or $C^7H^5 \cdot NO_2$, a volatile liquid smelling of bitter almond oil.—10. Heated for some time with sulphuric acid or potassium dichromate, benzene yields phenyl iodide, $C^6H^5 \cdot I$, together with a substance (H. Peltzer, *Ann. Ch. Pharm.* cxvi. 1868) which is benzene

in sealed tubes with *sulphuric chloride*, SO^2Cl^2 , is completely decomposed, yielding monochlorobenzene, hydrochloric acid, and sulphurous oxide:

(Dubois, *Zeitschr. f. Chem.* [2] ii. 705).

With *sulphuric chlorhydrate*, $\text{SO}^2.\text{HO}.\text{Cl}$, benzene yields sulphobenzide, together with smaller quantities of sulphobenzoic acid and sulphobenzoic chloride:

(Knapp, *Zeitschr. f. Chem.* [2] v. 41).

12. Benzene is not attacked by *alkalis* or by phosphorus pentachloride.—13. According to Lauth (*Bull. Soc. Chim.* [2] iv. 3), *sodium* attacks it with evolution of hydrogen and formation of a solid substance which encrusts the excess of sodium; but according to Berthelot, pure benzene is not attacked by sodium.

14. Benzene in the state of vapour unites with *carbonyl chloride*, forming benzoyl chloride (Harnitz-Harnitzky, *Ann. Ch. Pharm.* cxi. 192):

According to Berthelot, however (*Deut. Chem. Gesellsch.* 1869, p. 288; *Zeitschr. f. Chem.* [2] v. 480), pure carbonyl chloride does not act upon benzene (or upon ethylene or acetylene) either at ordinary or at higher temperatures; and when benzene is treated with ordinary phosgene gas (a mixture of carbonyl chloride with free chlorine), no benzoyl chloride is produced, the only action which takes place being due to the free chlorine.

On the other hand, Schützenberger finds (*Zeitschr. f. Chem.* [2] v. 631) that when benzene is acted upon by a mixture of sulphuric anhydride and carbon tetrachloride, which yields carbonyl chloride, ($2\text{SO}^3 + \text{CCl}^4 = \text{S}^2\text{O}^3\text{Cl}^2 + \text{COCl}^2$), and the product is heated with water, a considerable quantity of benzoic acid is obtained, together with hydrochloric acid, sulphobenzide, and benzene-sulphuric acid.

15. Benzene unites directly with 3 molecules of *hypochlorous acid*, forming the trichlorhydrin of phenose, $\left(\text{C}^6\text{H}^5\right)_3\text{O}^2\text{Cl}^3$ (Carius, *Ann. Ch. Pharm.* cxxvi. 323). See PHENOSE.

16. Benzene agitated with *aqueous chlorous acid* is converted into trichlorophenomalic acid, $\text{C}^6\text{H}^3\text{Cl}^3\text{O}^4$:

monochlorobenzene and dichloroquinone being formed at the same time (Carius, *Ann. Ch. Pharm.* cxlii. 129; *Jahresb.* 1866, p. 559). These last two products are formed in larger quantity when gaseous *chlorous anhydride* is made to act on dry benzene, $4\text{C}^6\text{H}^6 + 3\text{Cl}^2\text{O}^3 = 2\text{C}^6\text{H}^5\text{Cl} + 2\text{C}^6\text{H}^3\text{Cl}^2\text{O}^3 + 5\text{H}^2\text{O}$ (Carius, *Ann. Ch. Pharm.* cxliii. 315; *Bull. Soc. Chim.* [2] x. 49).

17. The method given by Hofmann (i. 542) for detecting the presence of benzene in a mixture of volatile oils has been modified as follows by Berthelot (*Bull. Soc. Chim.* [2] vi. 292), with the view of increasing its delicacy. A few drops of the liquid to be tested are mixed in a cooled tube with 4 times their volume of *fuming nitric acid*, and the mixture, after being briskly agitated and left to itself for a quarter of an hour, is mixed with ten times its bulk of water, which throws down drops of nitrobenzene. The whole is then agitated with an equal volume of common ether, which takes up the whole of the nitrobenzene. The ethereal solution is decanted, filtered, and rapidly distilled in a small retort to expel the ether. The drop of nitrobenzene remaining in the retort is then treated with 1 to 2 cubic centimetres of acetic acid and a particle of iron-filings, and distilled over a very small flame. As soon as the liquid in the retort is nearly evaporated, 2 or 3 cub. cent. of water are added, the distillation is repeated, and the distillates are mixed together. The liquid thus obtained is ready to be tested for aniline with chloride of lime. Sometimes, however, the presence of *nitrobenzene* interferes with the reaction. In that case a small piece of slaked lime is added, and the filtered liquid is placed in a porcelain capsule and treated with a dilute

aqueous solution of chloride of lime. By proceeding in this manner benzene may be detected in a cubic centimetre of a mixture containing not more than 2 per cent. of it.

18. With *chlorine* and *bromine*, benzene forms additive or substitution-products, according to the circumstances of the reaction. In sunshine additive compounds for the most part are obtained; but in diffused daylight only substitution-products are formed. Respecting the constitution of the additive compounds, see AROMATIC SERIES (p. 196).

BROMINATED DERIVATIVES OF BENZENE.

The *hexbromide* $C^6H^0Br^6$, produced by the action of bromine on benzene in sunshine, is described in vol. i. p. 543, under the name of *hydrobromate of tribromobenzene*, $C^3H^3Br^3 \cdot 3HBr$.

Monobromobenzene, C^6H^5Br . Described at vol. i. p. 542, and iv. 414.—Griess has shown that it is produced in the decomposition of diazobenzene platinobromide by caustic soda, according to the equation $2(C^6H^5N^2 \cdot HBr) \cdot PtBr^4 = 2C^6H^5Br + Pt + 2Br^2 + 2N^2$; also by heating diazobenzene-perbromide with sodium carbonate, or by warming its alcoholic solution, $C^6H^5N^2 \cdot HBr^2 = C^6H^5Br + N^2 + Br^2$ (see iv. 331). Heated for several days with *ethyl chlorocarbonate* and *sodium amalgam*, it yields ethyl benzoate (Wurtz, *Zeitschr. f. Chem.* [2] iv. 385):

Dibromobenzene, $C^6H^4Br^2$ (i. 543; iv. 414), may be obtained, together with the tetrabrominated compound, by distilling monobromophenol with phosphorus pentabromide: $C^6H^5BrO + PBr^5 = C^6H^4Br^2 + HBr + POBr^3$ (A. Mayer, *Ann. Ch. Pharm.* cxxxvii. 210). According to Friedel (*Bull. Soc. Chim.* [2] xi. 38), the crystals (obtained by Couper) are oblique rhomboidal prisms, isomorphous with those of dichlorobenzene. F. Riese (*Berlin. Chem. Gesellsch.* 1869, p. 60) in preparing ordinary (α) dibromobenzene, obtained a small quantity of a liquid modification (β). This modification solidifies below 0° , melts at -1° , and boils without decomposition at 214° , whereas α -dibromobenzene melts at 89° , and boils at 219° . By solution in fuming nitric acid and precipitation with water, a β -nitrodibromobenzene is obtained, which forms needles melting at 58° (α -nitrodibromobenzene melts at 84°). Sodium acts slowly on α -dibromobenzene, producing brominated compounds, diphenyl, and a hydrocarbon boiling above 360° but below the boiling point of sulphur.

Tribromobenzene, $C^6H^3Br^3$, is obtained: (α) By treating the hexbromide $C^6H^0Br^6$ with boiling alcoholic potash (i. 543).—(β) By treating dibromobenzene with bromine.—(γ) By the action of phosphorus pentabromide on dibromophenol (Mayer). It crystallises in tufts of white shining needles; sublimes at about 50° in highly lustrous needles; melts at 44° , and distils between 266° and 280° , the greater part passing over at 275° . It is soluble in alcohol and ether. By strong nitric acid it is converted into mononitro-tribromobenzene, and by a hot mixture of nitric and sulphuric acids into dinitro-tribromobenzene (Mayer).

Tetrabromobenzene, $C^6H^2Br^4$, exists in two modifications, one of which, obtained by heating the preceding compound with bromine, has been already described (iv. 415); it melts at 160° (Riche a. Bérard); at 137° – 140° (Kekulé, *Ann. Ch. Pharm.* cxxxvii. 72). The other modification is obtained by the action of phosphorus pentabromide on tribromophenol. It forms shining needles melting at 96° (Körner); at 98° (Mayer); and, like the preceding, yields a crystallised nitro-derivative.

Pentabromobenzene, C^6HBr^5 , is produced in small quantity, together with tetrabromobenzene, by heating nitrobenzene or dinitrobenzene with bromine to 250° . It crystallises in silky needles fusible and volatile without decomposition; its melting point is above 240° . Nearly soluble in cold, slightly soluble in boiling alcohol; dissolves easily in benzene or in a mixture of benzene and alcohol.

CHLORINATED DERIVATIVES OF BENZENE.

I. Additive Compounds.

Benzene Hexchloride, $C^6H^0Cl^6$, described at p. 543, vol. i., as *hydrochlorate of trichlorobenzene*, is produced by the action of chlorine in sunshine, under the influence of the direct solar rays. According to Berthelot, the formation of this crystalline body affords a test of the purity of the benzene, as with impurities the crystals are not produced. According to Lesimple (*Bull. Soc. Chim.* [2] 1869, p. 186),

the compound is easily obtained by passing chlorine into the vapour of benzene [in sunshine?].

Chlorides of Chlorinated Benzenes. These compounds are produced by the action of chlorine in sunshine on monochlorobenzene and on sulphobenzide.

a. When monochlorobenzene is introduced into a flask of colourless glass filled with dry chlorine and exposed to the sun's rays, the flask becomes hot and filled with white vapours, and the chlorine is rapidly absorbed. If the chlorobenzene is in excess, the gas disappears completely, and a thick oil is produced; but if the chlorine is in excess, hydrochloric acid is formed, and a crystalline body makes its appearance, together with the oil. In the former case the product consists of a mixture of the four compounds

in the latter, of these same compounds, together with others formed from them by replacement of 1 at. hydrogen with chlorine, namely, $\text{C}^6(\text{H}^4\text{Cl})\text{Cl}.\text{Cl}^2$, &c. The oil drained from the crystals is partly decomposed by distillation into hydrochloric acid and chlorinated benzenes: e.g. $\text{C}^6\text{H}^4\text{Cl}.\text{Cl}^2$ into HCl and $\text{C}^6\text{H}^4\text{Cl}^2$. The same decomposition is completely effected by heating with alcoholic potash. The resulting alcoholic solution mixed with water deposits a heavy oil mixed with crystals; and on washing this oil with water, drying it, and submitting it to repeated fractional distillation, there are obtained (besides a large quantity of unattacked monochlorobenzene passing over at 140°): dichlorobenzene, distilling at about 175° ; trichlorobenzene, at 210° ; tetrachlorobenzene, at 245° ; pentachlorobenzene, at 275° ; and at a higher temperature a mixture of the latter with hexachlorobenzene (Jungfleisch, *Bull. Soc. Chim.* [2] ix. 346; *Zeitschr. f. Chem.* [2] iv. 484).

The crystals obtained as above described when the chlorine is in excess consist chiefly of dichlorobenzene hexachloride, $\text{C}^6\text{H}^4\text{Cl}^6 = \text{C}^6\text{H}^4\text{Cl}^2.\text{Cl}^4$; and by separating them from the oily product, washing them with cold alcohol, and recrystallising several times from chloroform, this compound is obtained in colourless, well-defined, oblique rhomboidal prisms. Heated with alcoholic potash, it yields potassium chloride and pentachlorobenzene, melting at 74° , and identical with that which is produced by direct substitution (p. 266).

β . When sulphobenzide is exposed to the action of dry chlorine in sunshine, a thick yellowish oil is formed, and by prolonged action, also a crystalline body, which covers the sides of the retort and receiver. The oil is a mixture of chlorinated compounds, containing a portion of the crystalline compound in solution, and when decomposed by alcoholic potash yields a mixture of chlorinated benzenes, chiefly $\text{C}^6\text{H}^4\text{Cl}^2$ and $\text{C}^6\text{H}^3\text{Cl}^3$. The crystalline body, after separation from the oil by filtration through asbestos, washing with ether, pressing, and recrystallisation from boiling absolute alcohol, forms small quadratic prisms, having a vitreous lustre, melting between 255° and 257° , sublimable without decomposition, insoluble in water, slightly soluble in cold alcohol and ether, very soluble in hot alcohol. Alcoholic potash decomposes them, with formation of potassium chloride. The analysis of these crystals leads to the formula $\text{C}^6\text{H}^4\text{Cl}^2$, which is that of monochlorobenzene-hexachloride, $\text{C}^6\text{H}^4\text{Cl}.\text{Cl}^5$ (Otto a. Ostrop, *Ann. Ch. Pharm.* cxli. 105; *Jahresb.* 1866, p. 573). Jungfleisch, on the other hand, regards them as identical with dichlorobenzene hexachloride, $\text{C}^6\text{H}^4\text{Cl}^2.\text{Cl}^4$, and this view has been confirmed by subsequent experiments of Otto (*Zeitschr. f. Chem.* [2] vi. 36). When heated with potash they are converted into pentachlorobenzene, melting at 85° : $\text{C}^6\text{H}^4\text{Cl}^2.\text{Cl}^4 = 3\text{HCl} + \text{C}^6\text{HCl}^5$ (Otto).

II. Substitution-products. Chlorobenzenes.

There are two general methods of preparing these compounds: **a.** By passing chlorine into benzene containing iodine (Hugo Müller, iv. 414; Jungfleisch, *Ann. Ch. Phys.* [4] xv. 186-329; *Jahresb.* 1867, pp. 342-355).— **β .** By heating the additive compounds above described with alcoholic potash (Jungfleisch, *Ann. Ch. Phys.* [4] xv. 291; *Jahresb.* 1867, p. 355). The monochlorinated compound is the same, whether obtained by the one or the other process; but, according to Jungfleisch, the di-, tri-, tetra-, and pentachlorobenzenes obtained by the second process are not identical, but only isomeric, with those obtained by direct substitution. The existence of two isomeric modifications of the di-, tri-, and tetra-chlorinated compounds is easily explained on Kekulé's view of the constitution of benzene, by the different relative positions of the chlorine-atoms; they are, in fact, susceptible of three such modifications; but the existence of two pentachlorobenzenes, if established, requires that theory to be modified in the manner suggested by Städelé. (See AROMATIC SERIES, p. 194.)

Lesimple (*Zeitschr. f. Chem.* [2] iv. 235) recommends dry antimony trichloride as the best vehicle of chlorine for the preparation of these compounds; it dissolves easily in benzene with aid of heat, and may afterwards be completely removed by hydrochloric acid.

Monochlorobenzene. C^6H^5Cl .—1. In preparing this compound by passing chlorine into benzene containing iodine (iv. 414), Jungfleisch finds it advantageous to distil the liquid from time to time, in order to withdraw the portion boiling above 130° from the further action of the chlorine. The crude chlorobenzene (also containing iodobenzene) is purified by alternate agitation with potassium hydrate and exposure for several days to sunshine, and finally by fractional distillation.—2. The same compound is obtained by the action of phosphorus pentachloride on phenol (iv. 414); see also Glutz (*Ann. Ch. Pharm.* cxliii. 181; *Jahresb.* 1867, p. 607).—3. Together with chloride of sulphobenzene, by the action of chlorine in diffused daylight at 120° – 130° , or of phosphorus pentachloride, on sulphobenzide (Otto, *Ann. Ch. Pharm.* cxxvi. 154; Otto & Ostrop, *ibid.* cxli. 93):

When chlorine acts on sulphobenzide in direct sunshine, part of the chlorobenzene produced takes up 2 at. chlorine, forming the crystalline compound above described.—

4. By heating diazobenzene-platinichloride with sodium carbonate (Griess, iv. 432).—5. By the action of chlorous anhydride on benzene (Carius, p. 262).

Monochlorobenzene (prepared by 1) boils at 138° , is indifferent to alcoholic potash, and is not attacked by zinc or tin, even at 140° ; with an alloy of tin and sodium it yields a white pulverulent body, soluble in alcohol, and converted by nitric acid into nitrobenzene and stannic oxide (Jungfleisch). According to Sokoloff (*Jahresb.* 1865, p. 517; 1866, p. 551), the action of phosphorus pentachloride on phenol yields a compound (phenyl chloride) differing in its properties from the monochlorobenzene obtained by the action of iodine chloride on benzene; thus phenyl chloride has a sp. gr. of 1.1199 at 0° and 1.092 at 30° , and boils at 136° (bar. at 0.767 met.), whereas chlorobenzene has a sp. gr. of 1.499 at 0° and 1.1188 at 30° , and boils at 132.5° . Moreover, nitric acid acts more rapidly on the former than on the latter, though the products of the reaction are the same in both cases. These differences are, however, not of sufficient magnitude to warrant the conclusion that the monochlorobenzenes produced by the two processes are merely isomeric and not identical.

Monochlorobenzene treated with *sulphuric anhydride* is converted into dichlorosulphobenzide and sulphochlorobenzic acid:

(Otto, *Ann. Ch. Pharm.* cxlv. 28).

By the gradual action of a mixture of *manganese dioxide* and *dilute sulphuric acid*, chlorobenzene is converted into parachlorobenzic acid, in the same manner as benzene into benzoic acid (p. 261):

(Carius, *Zeitschr. f. Chem.* [2] iv. 505; C. Müller, *ibid.* v. 137).

Dichlorobenzene. $C^6H^4Cl^2$ (H. Müller, *Zeitschr. f. Chem.* 1864, p. 401; Jungfleisch, *loc. cit.*).—This compound is prepared by passing chlorine into a solution of iodine in benzene, till the liquid partly solidifies in the crystalline state on cooling, and again subjecting the liquid drained from the crystals to the action of chlorine. The crystals are washed with a cold-saturated alcoholic solution of dichlorobenzene, then decolorised by washing with alkaline water, and finally crystallised from alcohol or ether. It forms, especially after very slow evaporation of the ethereal solution, large right rhombic prisms, which melt at 53° and boil at 171° (Jungfleisch); 172° (Müller). According to Müller, it sublimes in closed vessels, even at ordinary temperatures, in large four-sided prisms. Sp. gr. 1.46 at 20° . Insoluble in water, easily soluble in alcohol and ether, not decomposed by sulphuric acid or alcoholic potash. With fuming nitric acid it forms two nitro-compounds, one of which forms distinct crystals. In ethereal solution it is decomposed by sodium or sodium-amalgam, without evolution of gas. The dichlorobenzene which Griess obtained by

composition of the platinum salt of diazochlorobenzene (iv. 415) appears to be identical with that just described. Another modification, melting below 0° , and stilling at 176° , is formed, together with other products, by the action of alcoholic potash on the oily product of the action of chlorine on monochlorobenzene in sunshine, apparently by abstraction of HCl from the compound $\text{C}^6\text{H}^5\text{Cl} \cdot \text{Cl}^2$ (Jungfleisch).

Trichlorobenzene, $\text{C}^6\text{H}^3\text{Cl}^3$. is known in two modifications, one being that which Mitscherlich obtained (i. 543) by decomposing the compound $\text{C}^6\text{H}^5\text{Cl}^2$ with alcoholic potash. According to Jungfleisch, the same modification is formed by the action of chlorine on benzene, and may be separated from the other products of this action by submitting the liquid drained from the crystals of dichlorobenzene to fractional distillation, collecting the portion which boils above 215° , and freeing it from the more easily crystallisable products by cooling. The trichlorobenzene thus obtained melts at 16° or 17° , and boils at 206° , whereas Mitscherlich's product remained liquid below 0° and boiled at 210° . Nevertheless, Jungfleisch regards his product as identical with Mitscherlich's, since the nitro-compounds obtained from the two are identical in every respect; he attributes the different physical properties of Mitscherlich's compound to impurities, inasmuch as, in the action of potash on the compound $\text{C}^6\text{H}^5\text{Cl}^2$, other compounds, especially chlorinated phenols, are simultaneously produced. The same modification of trichlorobenzene is found among the products obtained by decomposing with alcoholic potash the oily product of the action of chlorine on monochlorobenzene, together with another, which is crystalline at ordinary temperatures, and melts at 60° (Jungfleisch).

Tetrachlorobenzene. $\text{C}^6\text{H}^2\text{Cl}^4$.—Of this compound also two modifications are known, both crystalline at ordinary temperatures. One of them is obtained by the action of chlorine on benzene containing iodine, and separates on cooling from the fraction of the distillate boiling above 220° . For purification it is washed with potash, crystallised from alcohol, subjected to fractional distillation, to free it from the pentachlorinated compound, and finally recrystallised. It forms long, white, silky crystals, melting at 139° , and boiling without decomposition at 240° . Insoluble in water, easily soluble in hot alcohol and in ether, not decomposed by sulphuric acid, but convertible by fuming nitric acid into a crystalline nitro-compound (Jungfleisch). This modification is also obtained, as a secondary product, in the preparation of trichlorobenzyl trichloride, $\text{C}^6\text{H}^2\text{Cl}^3 \cdot \text{CCl}^3$, from trichlorotoluene, $\text{C}^6\text{H}^3\text{Cl}^3 \cdot \text{CH}^3$ (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 529). The other modification is obtained in considerable quantity by the action of alcoholic potash on the oil obtained by the action of chlorine on monochlorobenzene (p. 264); it passes over nearly pure between 245° and 250° , and is easily rendered quite pure by a few recrystallisations from alcohol (Jungfleisch). The same modification is obtained (together with other chlorobenzenes) by the action of alcoholic potash on the yellow oil which is formed, together with hexachloride of monochlorobenzene (p. 263), by the action of chlorine on sulphobenzide. The tetrachlorobenzene is contained in the portion of the product which on fractional distillation passes over between 250° and 260° (Otto a. Östrop). This modification crystallises in long, colourless nacreous needles; melts at 35° ; boils at 253° ; dissolves easily in boiling, less easily in cold alcohol; is soluble also in ether, benzene, chloroform, and carbon bisulphide. Antimonic chloride converts it into hexachlorobenzene (Jungfleisch).

Pentachlorobenzene, C^6HCl^5 , is contained in that portion of the liquid produced by the action of iodine chloride on benzene, which distils at about 275° ; it crystallises easily in stellate groups of needles, melting at 74° , and boiling at 272° (Jungfleisch). The same compound, in two modifications, constitutes that portion of the product of the action of alcoholic potash on the oil obtained by treating monochlorobenzene with chlorine (p. 263), which passes over at about 270° , and in larger quantity than any of the other distillates. The crystalline mass thus obtained may be separated into the two modifications of pentachlorobenzene by fusing it and treating it with boiling alcohol, which dissolves the modification above described, and leaves the other in the form of powder. The first modification may be obtained perfectly pure by recrystallisation from alcohol, and the second from a mixture of alcohol and benzene. The latter crystallises in very slender silky crystals, nearly insoluble in alcohol and in ether, soluble in benzene and in chloroform. The crystals melt at 175° , if brought directly into a bath heated to this temperature, but after solidification they do not fuse below 198° ; they melt also at nearly the same temperature if the heat of the bath be slowly raised (Jungfleisch, *Jahresb.* 1868, p. 357). The same modification is found among the products of the action of alcoholic potash on the oil obtained by treating sulphobenzide with chlorine (Otto a. Östrop; see further, Otto, *Monatsh.* 1871, p. 35). See p. 264, also AROMATIC SERIES (p. 194).

According to Beilstein a. Kuhlberg (*Zeitschr. f. Chem.* [2] v. 529), the first modification is likewise obtained, in an impure state, by passing chlorine into tetrachlorobenzyl chloride, $C^4HCl^4.CH^2Cl$, at the boiling heat. Both modifications are converted by antimonie chloride into hexachlorobenzene.

Hexachlorobenzene, C^6Cl^6 , is obtained: 1. By pouring benzene on antimonie chloride and passing chlorine into the liquid as long as it is absorbed. The antimony chloride is then removed by hydrochloric acid, and the hexachlorobenzene is purified by crystallisation or sublimation (H. Müller, *Zeitschr. Ch. Pharm.* 1864, p. 40).—2. It is present in small quantity amongst the highest products of the action of alcoholic potash on the oil resulting from the action of chlorine on monochlorobenzene (Jungfleisch, p. 263).—3. By the action of phosphorus pentachloride on tetrachloroquinone, tetrachlorhydroquinone, and trichloroquinone:

Tetrachloroquinone.

Tetrachlorhydroquinone.

Trichloroquinone.

also, together with pentachlorobenzene, by the action of phosphorus pentachloride on trichlorhydroquinone (C. Graebe, *Ann. Ch. Pharm.* cxlvi. 1; *Jahresb.* 1867, p. 651).—

4. According to Beilstein a. Kuhlberg (*Zeitschr. f. Chem.* [2] v. 183), it is the ultimate product of the action of antimonie chloride, $SbCl^3$, on all chlorotoluenes and chloroxylones. It crystallises in fine silky prismatic needles of a dazzling whiteness; melts at 220° ; begins to sublime at a lower temperature; is insoluble in water, slightly soluble in cold alcohol, easily in boiling alcohol, ether, and benzene; is with difficulty attacked by potash, not at all by nitric acid (Müller). It is identical with Julin's chloride of carbon produced by the decomposition of chloroform vapour at a bright red heat. According to Berthelot a. Jungfleisch (*Zeitschr. f. Chem.* [2] iv. 666), hexachlorobenzene melts at 226° and boils at 326° (corr.); Julin's chloride of carbon melts at 226° and boils at 331° (corr.). Both dissolve to very nearly the same extent in carbon bisulphide at corresponding temperatures. Moreover, the vapour-density of the compound prepared from chloroform was found by Bassett (*Chem. Soc. J.* [2] v. 243) to be 10.06, and the density calculated for the formula C^6Cl^6 is 9.87.

IODOBENZENES.

Mono-iodobenzene, C^6H^5I , originally obtained by the action of iodine and phosphorus on phenol (Scruggam, iv. 415), is likewise produced: a. In the decomposition of iodine-benzoate, or in the action of iodine chloride on sodium benzoate (Schützenberger, *Compt. rend.* lii. 963). See BENZOATES.—b. By heating benzene for some time with iodic acid, or with potassium iodate and sulphuric acid (Peltzer, *Ann. Ch. Pharm.* cxxxv. 194).—c. By the action of hydriodic acid on diazobenzene: $C^6H^5N^2 + HI = C^6H^5I + N^2$ (Griess).—d. By the action of iodine and iodic acid on benzene. A mixture of 20 grms. benzene, 15 grms. iodine, and 10 grms. iodic acid is heated in sealed tubes to 200° – 240° , the tubes being opened from time to time to give vent to carbon dioxide resulting from a secondary action. The product is distilled, either immediately or after washing with water and alkali, the mono-iodobenzene then passing over between 180° and 190° , while di-, and sometimes also tri-iodobenzene remains behind (Kekulé, *Ann. Ch. Pharm.* cxxvii. 157).

Mono-iodobenzene, when purified by repeated rectification, is a colourless liquid, insoluble in water, smelling like benzene and phenol. It does not solidify at -18° ; boils at 185° ; has a sp. gr. of 1.69 (Schützenberger) 1.833 at 15° (Kekulé). By sodium-amalgam and water it is easily reconverted into benzene, also by aqueous hydriodic acid at 250° . It is not decomposed by solid potassium hydrate, or by the alcoholic solution of potash or ammonia (Kekulé).

Di-iodobenzene, $C^6H^4I^2$, is likewise produced in the decomposition of iodine-benzoate by heat (Schützenberger), and by the action of iodine and iodic acid on mono-iodobenzene (or the crude product of its preparation). On distilling the washed product, liquid mono-iodobenzene passes over first, while the following crystallisable portion contains di- and tri-iodobenzene (the former greatly predominating) which may be separated, though with difficulty, by crystallisation from alcohol (Kekulé).

Di-iodobenzene forms white nacreous laminae resembling naphthalene, melting at 122° (Sch.), at 127° (K.), boiling at 250° (Sch.), at 277° (corr. 285°) (Kekulé), and subliming at comparatively low temperatures.

Tri-iodobenzene, $C^6H^3I^3$, forms small needles, melting at 76° and subliming without decomposition (Kekulé).

NITROBENZENES.

Mononitrobenzene. $C^6H^5(NO^2)$.—Schiff (*Ann. Ch. Pharm.* cxiv. 201) has found this compound amongst the products of the action of strong nitric acid on turpentine-oil. These products evaporated at a gentle heat, mixed with sand and distilled, yield a strongly acid watery liquid, and a brown oil containing nitrobenzene.

Nitrobenzene is prepared on the large scale, for the manufacture of aniline, by treating benzene, either with a mixture of sodium nitrate and sulphuric acid, or with a mixture of ordinary nitric acid of sp. gr. 1.3 and strong sulphuric acid. The apparatus used consists of large cast-iron pots provided with stirrers. (See Perkin's 'Lectures on Aniline Colours,' *Journal of the Society of Arts.*)

Reactions.—Nitrobenzene is converted, by oxidation with potassium dichromate and sulphuric acid, into nitrophenic acid, $C^6H^4(NO^2)O^2$ (Church, iv. 388).

Most of the reagents employed for the reduction of nitrobenzene to aniline are mentioned under PHENYLAMINE (iv. 420). The reduction may also be effected by heating with carbon bisulphide to 160° (Schlagdenhauffen, *J. Pharm.* [3] xxxiv. 175); by heating it to 104° with hydriodic acid of sp. gr. 1.44 (E. J. Mills, *Jahresb.* 1864, p. 625); and by means of tin and hydrochloric acid, operating, however, only with small quantities, as the reaction is very violent (Scheurer-Kestner, *Rép. Chim.* app. iv. 121).

Heated in sealed tubes with hydrobromic acid to 185° – 190° , nitrobenzene yields mono- and di-bromaniline. The reduction takes place in the same way as with hydriodic acid, viz.,

the difference in the products arising merely from the circumstance that bromine exerts a substituting action upon aniline salts, whereas iodine does not (H. Baumhauer, *Zeitschr. f. Chem.* [2] v. 198). With hydrochloric acid in like manner to 245° it yields dichloraniline, with a small quantity of aniline (Baumhauer, *ibid.* vi. 8).

With iron-filings and hydrochloric acid nitrobenzene yields a red colouring matter called erythrobenzin (F. Laurent a. J. Castlehaz, *Jahresb.* 1862, p. 693).

Nitrobenzene in alcoholic solution is reduced by sodium-amalgam to azoxybenzene, $C^{12}H^{10}N^2O$, or, if the sodium-amalgam is in excess, into azobenzene, $C^{12}H^{10}N^2$, which by further action is converted into hydrazobenzene, $C^{12}H^{12}N^2$. Exactly the same reactions are produced by zinc-dust in presence of a small quantity of potash or soda (Alexeyeff, *Bull. Soc. Chim.* [2] i. 324; *Zeitschr. f. Chem.* [3] iii. 33).

Nitrobenzene dissolved in dilute alcohol and boiled with 3 mol. ammonium sulphite is converted into disulphanilic acid, $C^6H^4NS^2O^6$ (Carius, *Jahresb.* 1861, p. 634):

Di-nitrobenzene, $C^6H^4(NO^2)^2$, is reduced by iron and acetic acid to phenylenediamine, $C^6H^4N^2$ (Hofmann, *Proc. Roy. Soc.* xi. 518). A mixture of dinitrobenzene (1 mol.) and metallic tin (6 at.) dissolves rapidly in strong hydrochloric acid, forming a liquid which on evaporation deposits a double salt of phenylene-diamine hydrochloride with stannous chloride, $C^6H^4N^2 \cdot 2HCl \cdot 2SnCl^2$, in needles having a silky lustre (H. Gerdemann, *Jahresb.* 1866, p. 412).

In the reduction of nitro-compounds by tin and hydrochloric acid, it is to be observed: (1) that the reaction does not necessarily stop at the formation of stannous chloride, but may proceed to the formation of stannic chloride, inasmuch as many nitro-compounds are reduced by stannous chloride (nitrobenzene, for example, with violence); and (2) that the result depends also upon the nature of the solvent and the solubility therein of the nitro-compound and of any possible intermediate product of reduction. Thus when di-nitrobenzene is treated with tin and aqueous hydrochloric acid, in which it is insoluble, whereas the intermediate product of reduction (paranitraniline) is soluble, then even if the nitro-compound is in excess, the final product, paraphenylenediamine, is formed, chiefly or exclusively, together with stannic chloride, and the excess of dinitrobenzene remains unattacked, because the soluble intermediate product formed in the first instance is exposed to the full action of the reducing agent. But if an alcoholic solution of dinitrobenzene is used, and the tin added in the quantity required for the formation of stannic chloride, then on passing hydrochloric acid gas into the liquid, only paranitraniline is produced (Kekulé, *Zeitschr. f. Chem.* [2] ii. 695).

Nitrobromobenzenes. The compounds $C^6H^4(NO^2)Br$ and $C^6H^3(NO^2)^2Br$ have been already described (iv. 416).

Dinitrobromobenzene, $C^6H^3(NO^2)^2Br$, produced by heating monobromobenzene with a mixture of fuming nitric acid and sulphuric acid, crystallises in large yellow

transparent prisms, melting at 72° , soluble in boiling alcohol (Kekulé, *Ann. Ch. Pharm.* cxxvii. 129).

Nitrotribromobenzene, $C^6H^3(NO^2)Br^3$, obtained by treating tribromobenzene with fuming nitric acid, precipitating with water, and crystallising from hot alcohol, forms long yellow needles, sparingly soluble in cold, easily soluble in hot alcohol, also in ether, benzene, and carbon bisulphide (A. Mayer, *Ann. Ch. Pharm.* cxxvii. 219).

Dinitrotribromobenzene, $C^6H(NO^2)^2Br^3$, is produced (together with a little bromopierin) by heating the preceding compound with a mixture of fuming sulphuric and nitric acids. It dissolves easily in hot alcohol, ether, benzene, and carbon bisulphide, and crystallises from the latter in yellowish scales melting at 125° (Mayer, *loc. cit.*).

Nitrotetrabromobenzene, $C^6H(NO^2)Br^4$, produced by the action of fuming nitric acid on tetrabromobenzene, is white, crystalline, melts at 88° , sublimes in flocks, and dissolves sparingly in cold, more freely in hot alcohol and ether (Riche a. Bérard; Mayer).

Nitrochlorobenzenes. **Nitrochlorobenzene**, $C^6H^5(NO^2)Cl$, has been already described (i. 416) as a crystalline body produced by treating monochlorobenzene with fuming nitric acid. According to Sokoloff (*Jahresb.* 1866, p. 651) and Lesimple (*Zeitschr. f. Chem.* [2] iv. 225), an oily modification of the compound is formed at the same time.

Nitrodichlorobenzene, $C^6H^4(NO^2)Cl^2$, produced by treating dichlorobenzene with fuming nitric acid, crystallises from alcohol in thin plates, insoluble in water, slightly soluble in cold alcohol, more freely in ether, benzene, and hot alcohol. Melts at 55° , distils without decomposition when strongly heated, and smells like cinnamon. An oily modification appears to be formed simultaneously with this crystalline body (Lesimple, *Zeitschr. f. Chem.* [2] iv. 226; see also Jungfleisch, *Bull. Soc. Chim.* [2] iv. 241).

Nitrotrichlorobenzene, $C^6H^3(NO^2)Cl^3$, produced by the action of fuming nitric acid at the boiling heat on trichlorobenzene, crystallises in colourless needles melting below 100° . It boils without decomposition at 273.5° , is insoluble in water, slightly soluble in cold alcohol, freely in boiling alcohol, ether, and benzene. Treated in alcoholic solution with zinc and hydrochloric acid, it is converted into trichloraniline (Lesimple, *Bull. Soc. Chim.* [2] vi. 161).

Nitrotetrachlorobenzene, $C^6H(NO^2)Cl^4$, is a crystallisable compound, formed by heating tetrachlorobenzene with fuming nitric acid (Jungfleisch), or by repeated treatment with a mixture of fuming nitric and sulphuric acids, and even then with difficulty. Crystallises from hot alcohol in needles, absolutely insoluble in water, and very sparingly soluble in most alcoholic solvents. Melts at 75° – 78° , solidifies at 62° , and distils at about 300° (Lesimple).*

Nitro-iodobenzene, $C^6H^5(NO^2)I$, is known in two modifications: the one, produced by the action of iodine monochloride on sodium nitrobenzoate, is a yellow liquid having a distinct odour of bitter almonds, and boiling at about 290° (Schützenberger a. Sengenwald, *Rép. Chim. pur.* 1862, p. 144). The other, produced by the action of fuming nitric acid on mono-iodobenzene, crystallises in beautiful pale yellow needles, melting at 171° , and subliming without decomposition (Kekulé, *Ann. Ch. Pharm.* cxxvii. 129).

COMPOUNDS FORMED BY REDUCTION OF THE NITROBENZENES.

Respecting amidobenzene, $C^6H^5(NH^2)$, diamidobenzene, $C^6H^4(NH^2)^2$, and their derivatives, see PHENYLAMINES and PHENYLENE-DIAMINES (iv. 419–484); also the same articles and ANILINE in this volume.

The diazobenzenes and diazo-amidobenzenes are described under AZO-PHENYLAMINES and AZODIPHENYL-DIAMINES (iv. 430, 459).

Azobenzene. $C^{12}H^{10}N^2$.—This compound is formed by the action of sodium-amalgam on an alcoholic solution of nitrobenzene acidulated with acetic acid (Werigo, *Ann. Ch. Pharm.* cxxv. 176). According to Alexejeff (*Zeitschr. f. Chem.* [2] iii. 33), the product of this reaction is azoxybenzene or azobenzene, accordingly as the nitrobenzene or the sodium-amalgam is in excess; in the latter cases the azobenzene is converted, by prolonged action of the sodium-amalgam, into hydrazobenzene, $C^{12}H^{12}N^2$. Exactly the same effects are produced by zinc-dust, with addition of a small quantity of potash or soda (Alexejeff, *Zeitschr. f. Chem.* [2] iv. 497).

* Further details on the nitrochlorobenzenes, according to the latest investigation of Jungfleisch, will be given under X.

Azobenzene is also produced, together with azoxybenzene and hydrazobenzene, by oxidation of aniline with solution of potassium permanganate. Manganic oxide is thereby separated, carrying down with it the greater part of the azo-compounds produced. The precipitate washed with cold water yields, on distillation in the water-bath, red drops of azobenzene which solidify on cooling. The azobenzene may also be extracted from the precipitate by hot alcohol; the mother-liquor, from the first crystallisation of the azobenzene, often yields lighter-coloured needles of azoxybenzene; and on distilling the crude product, quadratic laminæ were once observed, which exhibited the reactions of hydrazobenzene. The formation of azobenzene from aniline is represented by the equation

(E. Glaser, *Ann. Ch. Pharm.* cxlii. 364). Respecting the constitution of these bodies, and their relation to nitrobenzene and aniline, see AROMATIC SERIES (pp. 208-210).

In the action of reducing agents on azobenzene, the latter is in the first instance converted into hydrazobenzene, afterwards into the isomeric and more stable compound benzidine (Hofmann, *Proc. Roy. Soc.* xii. 576).

A mixture of 1 mol. azobenzene with 2 mols. *aniline hydrochloride* heated to 170°-230° in closed vessels, yields a blue and a violet colouring matter. 1 mol. azobenzene and 1 mol. *toluidine hydrochloride* yield, in like manner, violet and blue substances, together with a small quantity of a product having a fine ruby colour (Städeler, *J. pr. Chem.* xvi. 65; *Jahresh.* 1865, p. 409).

Azobenzene unites directly with 2 at. *bromine*, forming the compound $\text{C}^{12}\text{H}^{10}\text{N}^2\text{Br}^2$, which is slightly soluble in alcohol and ether, and crystallises in golden-yellow needles melting at 205°, and subliming in large iridescent needles. This compound is isomeric with dibromobenzidine. It dissolves in hot strong sulphuric acid, and is converted by fuming nitric acid into the compound $\text{C}^{12}\text{H}^8(\text{NO}^2)\text{N}^2\text{Br}^2$ melting at 150° (Werigo, *Ann. Ch. Pharm.* cxxxv. 176).

Azobenzene heated with strong *hydrobromic acid* is converted into a white crystalline body, forming with water a solution from which sodium hydrate throws down an oil, quickly solidifying in the crystalline form (Werigo, *Zeitschr. f. Chem.* [2] iv. 210).

Azobenzene-sulphuric acid, $\text{C}^{12}\text{H}^{10}\text{N}^2\text{SO}^2$, is produced by heating azobenzene with fuming sulphuric acid to 150°. It forms yellow crystals or red scales, and yields crystallisable salts. The silver salt contains $\text{C}^{12}\text{H}^8\text{AgN}^2\text{SO}^2$ (Griess, *Ann. Ch. Pharm.* cxviii. 89).

AMIDAZOBENZENE OR AMIDODIPHENYLIMIDE. $\text{C}^{12}\text{H}^{11}\text{N}^2 = \text{C}^{12}\text{H}^8(\text{NH}^2)\text{N}^2$ (Martius a. Griess, *Zeitschr. f. Chem.* [2] i. 132; G. A. Schmidt, *ibid.* v. 417).—Produced: 1. By oxidation of aniline:

a. When nitrous acid gas is passed into a gently warmed solution of aniline in 3 pts. alcohol,* till the liquid acquires a deep red colour, and moderately strong hydrochloric acid is then added in excess, a thick brown-red pulp is produced, from which, after it has been freed by pressure from the mother-liquor and washed with weak spirit, hot water extracts hydrochloride of amidazobenzene, and from this the base may be precipitated by ammonia.—β. It may also be prepared by heating a mixture of 1 pt. aniline nitrate, 3 pts. sodium stannate, and 10 pts. water to 100°, gradually adding soda-ley till a sample is coloured deep-red by hydrochloric acid, then supersaturating in the cold with hydrochloric acid, digesting the separated red-brown resin with soda-ley, dissolving it in hot water containing hydrochloric acid, and precipitating with ammonia (Martius a. Griess).

2. Amidazobenzene is produced, together with amidazoxybenzene, by reduction of mononitro-azoxybenzene. The reaction appears to take place as shown by the equation†:

1 pt. of this nitro-compound is heated to boiling with 10 pts. of strong alcohol, and gradually mixed, while the boiling is continued, with a concentrated alcoholic solution of ammonium sulphide, in small portions (2-3 c.c.), each being added only after the odour of the former portion has disappeared, and the process continued till all the nitroazoxybenzene is dissolved, and a sample taken out of the liquid no longer crystallises on cooling. (If the ammonium sulphide were added more quickly, a further

* In a cold solution the only product is diazoamidobenzene (iv. 456).

reduction would take place, resulting in the formation of aniline and paraphenylene-diamine.) The liquid decanted from the separated sulphur, freed from the greater part of the alcohol by distillation, and mixed with water, deposits a yellow lamino-crystalline mixture of amidazobenzene and amidazoxybenzene, which may be separated by the different solubilities of their hydrochlorides in dilute alcohol. The crude product drenched with weak spirit and excess of hydrochloric acid, yields a red-brown crystalline pulp, the greater part of which remains undissolved when heated to the boiling point. The whole filtered at the boiling heat yields a dark-red filtrate, which on cooling first deposits a small quantity of amidazobenzene hydrochloride in characteristic steel-blue needles; and if the solution be again filtered at the boiling heat, the filtrate yields almost pure amidazoxybenzene hydrochloride in rose-coloured laminar crystals. The united residues on the filters, repeatedly boiled with weak spirit containing hydrochloric acid, then crystallised from acidulated spirit of 60 p. c., or from very dilute aqueous hydrochloric acid, yield pure amidazobenzene hydrochloride in laminae or needles having a dark violet-blue colour and metallic lustre. They are decomposed even by pure water, more readily by ammonia, yielding the free base (Schmidt).

3. By the action of aniline and its salts—most readily with the hydrochloride—on the isomeric compound diazo-amidobenzene, a small quantity of the aniline salt sufficing, as already explained under AROMATIC SERIES (p. 209), for the conversion of a large quantity of diazo-amidobenzene. Hence this transformation takes place to a certain extent in the preparation and in all the decompositions of diazo-amidobenzene, inasmuch as in these reactions aniline is always set free. Amidazobenzene is also found amongst the products of the action of bromine on aniline (Kekulé, *Zeitschr. f. Chem.* [2] i. 687, 689; *Jahresb.* 1866, pp. 429, 467).

Properties and Reactions.—Amidazobenzene is but very slightly soluble in water, even at the boiling heat; it dissolves more freely in ether and in hot alcohol, and crystallises from the latter in yellow rhombic needles or prisms of about $49^{\circ} 20'$, having their acute lateral edges perpendicularly truncated by broad faces. It melts at 130° (Martius & Griess), at 127.4° (Schmidt),* solidifies at 120° and distils without decomposition at a temperature above the boiling point of mercury.

Amidazobenzene heated with tin and hydrochloric acid is resolved into aniline and paraphenylene-diamine:

It is nearly related to diphenine or diamidazobenzene, $C^{12}H^{10}(NH^2)^2N^2$, and, like that compound, yields with manganese dioxide and sulphuric acid a large quantity of quinone, and with aniline-nitrate a blue colouring matter.

With acids amidazobenzene forms well-defined salts, most of which crystallise easily; they are decomposed by water, and their slightly acid solutions have a fine cochineal-red colour. It is a mono-acid base, its hydrochloride being $C^6H^4N^2 \cdot HCl$; the platinumchloride, a red-brown crystalline precipitate, $2(C^6H^4N^2 \cdot HCl)PtCl_4$; the sulphate $(C^6H^4N^2)^2 \cdot H_2SO_4$, &c. The alcoholic solution of the base mixed with silver nitrate yields the compound $(C^6H^4N^2)^2 \cdot AgHO$, which crystallises in golden-yellow laminae.

Wool and silk are coloured deep lemon-yellow by slightly acid solutions of amidazobenzene; the picrate dyes wool a fine cochineal red; but the colours are very fugitive. The oxalate of amidazobenzene constitutes aniline yellow (p. 169).

The alcoholic solution of the base kept in contact for some time, at ordinary temperatures, with ethyl iodide yields a crystalline hydriodide of ethyl-amidazobenzene, $C^6H^{11}(C^2H^5)^2N^2 \cdot HI$.

HYDRAZOBENZENE. $C^6H^4N^2$ (Hofmann, *Proc. Roy. Soc.* xii. 176).—This neutral body, isomeric with benzidine (which is basic), is the first product of hydrogen sulphide and other reducing agents on azobenzene, being in some cases subsequently converted into benzidine. It is prepared by passing a stream of hydrogen sulphide into a solution of azobenzene in alcoholic ammonia, whereupon the yellowish-red liquid quickly loses its colour, and on adding water hydrazobenzene is thrown down as a crystalline precipitate, which may be purified by two or three crystallisations from alcohol (Hofmann). According to Glaser, it is sometimes found amongst the products of the oxidation of aniline by potassium permanganate.

Hydrazobenzene crystallises in well-defined laminae, slightly soluble in water, moderately soluble in alcohol and ether. It is not dissolved by acetic acid, but the stronger acids, such as hydrochloric and sulphuric, convert it into benzidine, and then

* Schmidt found the same melting point with amidazobenzene prepared by the method of Martius & Griess.

dissolve it. It melts at 131° (benzidine at 118°), and is resolved by distillation into azobenzene and aniline: $2C^{12}H^{12}N^2 = C^{12}H^{10}N^2 + 2C^6H^5N$. Hydrazobenzene is also reconverted into azobenzene by oxidising agents, as nitrous acid, chlorine, bromine, iodine, potassium chromate, and potassium permanganate. The same transformation takes place when hydrazobenzene is simply moistened with alcohol, and exposed to the air. Benzidine does not undergo this change (Hofmann).

Azobenzene-sulphuric acid treated with hydrogen sulphide yields a sulpho-acid of hydrazobenzene (Griess).

Azoxybenzene. $C^{12}H^{10}N^2O$.—Formed by the action of sodium-amalgam, not in excess, and of ammonium sulphide, on nitrobenzene in alcoholic solution, and, together with azobenzene, by oxidation of aniline with potassium permanganate (p. 269). *Preparation* (i. 479).—By prolonged action of reducing agents it is converted into hydrazobenzene. Dichlorazoxybenzene treated in like manner is converted into dichlorhydrazobenzene (Alexejeff).

Azoxybenzene heated with strong hydrobromic acid to 250° in sealed tubes dissolves in it and forms dibromaniline, according to the equation

Other products are formed at the same time, but in very small quantity, when a considerable excess of hydrobromic acid is present (Sendzink, *Zeitschr. f. Chem.* [2] vi. 266).

Amidazoxybenzene. $C^{12}H^{11}N^3O = C^{12}H^9(NH^2)^2N^3O$ (G. A. Schmidt, *Zeitschr. f. Chem.* [2] v. 419).—Produced, together with amidazobenzene, by the action of ammonium sulphide on nitro-azoxybenzene in alcoholic solution. The crude hydrochloride of amidazoxybenzene, crystallising, as above mentioned (p. 270), in rose-coloured laminae, cannot be freed by recrystallisation from obstinately adhering traces of amidazobenzene hydrochloride; but it is easily purified by dissolving it in the smallest possible quantity of hot water acidulated with hydrochloric acid, and agitating it for a few seconds with a little granulated tin till it is decolorised. The solution quickly decanted from the excess of tin (to prevent further reduction) deposits on cooling pure amidazoxybenzene hydrochloride in colourless silvery laminae. From this salt the base may be separated by ammonia, and after one or two crystallisations from weak spirit, it is easily obtained in large tabular brittle crystals of a somewhat paler yellow colour than amidazobenzene. It is nearly insoluble in cold water, slightly soluble in boiling water, easily in strong alcohol, ether, and benzene. It melts at 138.5° , and begins to decompose at about 200° , giving off nitrogen gas, yielding a brown oily distillate containing water, aniline, and amidazobenzene, and leaving a small quantity of loose spongy charcoal. It does not appear to be converted into amidazobenzene by the action of reducing agents: ammonium sulphide does not act upon it, and by tin and hydrochloric acid it is reduced to aniline and paraphenylenediamine.

The salts of amidazoxybenzene are colourless, well crystallised, and mostly sparingly soluble, especially the sulphate. The hydrochloride, $C^{12}H^{11}N^3O \cdot HCl$, crystallises in silvery laminae; gives off hydrochloric acid when heated, even at 100° ; and, like the corresponding amidazobenzene salt, is decomposed by water, with yellow coloration. It dissolves sparingly in cold, very dilute hydrochloric acid, much more easily at the boiling heat, still more easily in acidulated alcohol. Its solution gives with *platinic chloride* a yellow indistinctly crystalline precipitate of the platino-chloride $2(C^{12}H^{11}N^3O \cdot HCl) \cdot PtCl_4$, slightly soluble in water and in alcohol. *Silver nitrate* added to the alcoholic solution of the base forms a precipitate consisting of long, slender, straw-yellow needles.

Trinitro-azoxybenzene. $C^{12}H^7(NO_2)^3N^2O$ (G. A. Schmidt, *Zeitschr. f. Chem.* [2] v. 421).—Produced by treating azoxybenzene with a mixture of strong nitric and sulphuric acids (with nitric acid alone only the two modifications of mononitro-azoxybenzene are formed: i. 479). 20 grms. of azoxybenzene are heated in a flask with a mixture of 200 grms. nitric acid (sp. gr. 1.50) and 100 grms. sulphuric acid (sp. gr. 1.80). It then dissolves, with considerable rise of temperature, but without emission of red fumes, and the solution, if immediately poured into water, yields a light yellow crystalline mass, caked together by a resinous substance. To remove the latter, the mass is triturated with a little water, washed on a filter, dried, and repeatedly exhausted with ether, till it no longer colours that liquid yellow (Schmidt). It is also formed by the action of strong nitric acid at the boiling heat on azobenzene, another body, probably trinitrazobenzene, being formed at the same time (Petrieff, *ibid.* vi. 264).

Trinitrazoxybenzene thus prepared is an indistinctly crystalline yellow powder, very

much resembling the mononitrated compound in appearance. It is insoluble in water, dissolves very sparingly in alcohol and ether, easily in benzene, but is best crystallised from nitric acid (sp. gr. 1.38), in which it dissolves somewhat freely at the boiling heat, and separates on cooling in needle-shaped crystals recognisable by the naked eye, and looking in the mass very much like flowers of sulphur. It melts at 152° , solidifies in the crystalline form at 140° , and detonates with some violence at a stronger heat, leaving a small quantity of charcoal. When carefully heated above its melting point it does not crystallise again on cooling, but solidifies to a transparent yellow glass, which if again heated nearly to its melting point suddenly becomes crystalline: the formula of this glassy substance is $C^6H^4N^2O^7$.

The resinous substance dissolved by the ether, and forming about a sixth of the crude product, probably contains *dinitro-azoxybenzene*, or bodies isomeric therewith.

SULPHO DERIVATIVES OF BENZENE.

Benzene-sulphamide or **Sulphobenzolamide**, $C^6H^5NSO^2 = C^6H^5 \cdot SO^2(NH^2)$, was obtained by Stenhouse by heating ammonium benzene-sulphate to 200° (v. 489). Otto a. Ostrop (*Jahresb.* 1866, p. 570) prepare it by the action of ammonium on benzene-sulphobromide. It is also formed, together with phenyl bisulphide, by the action of hot concentrated aqueous ammonia on bromophenylsulphide (Otto, *Jahresb.* 1867, p. 629):

It is nearly insoluble in cold, more soluble in hot ammoniacal water, dissolves easily in alcohol and ether, and crystallises in large nacreous laminae, melting at 149° .

When 1 mol. benzene-sulphamide is heated with about 2 mol. potassium hydrate, a violent reaction takes place near the melting point of the amide, the mass becoming fluid, but soon giving off water and solidifying again. The product dissolves easily in water, and acids added to the solution throw down the unaltered amide. Probably the potassium replaces part of the typic hydrogen in the amide with simultaneous formation of H^2O , and a compound is formed which dissolves easily in water. If the product after solidification be heated to 250° – 300° , it solidifies again, and the amide is resolved into sulphurous anhydride and phenol:

(Lindow a. Otto, *Zeitschr. f. Chem.* [2] iv. 39).

Chlorobenzene-sulphamide or **Sulphochlorobenzolamide**, $C^6H^4ClNSO^2$, is formed by treating chlorobenzene-sulphochloride with alcoholic ammonia, and crystallises from hot water (after the sal-ammoniac has been removed by cold water) in small needles, or by slow evaporation in large four-sided rhombic prisms. Dissolves easily in hot water, ether, and alcohol, and melts at 143° – 144° (Otto a. Brummer). When heated with potassium hydrate it appears to react like benzene-sulphamide, and on adding hydrochloric acid to the solution of the product, sulphurous anhydride is evolved, and a resinous body is separated which crystallises from alcohol, but no chlorophenol appears to be formed (Lindow a. Otto).

Benzene-sulphuric or **Sulphobenzolic acid**, $C^6H^5SO^3 = C^6H^5 \cdot SO^3H$.—This acid, described in vol. v. p. 564 as *Phenyl-sulphurous acid*, is produced by oxidation of benzene-sulphurous acid, $C^6H^5SO^2$, either slowly by exposure to the air, or more quickly, together with nitrobenzene-sulphuric acid, by the action of nitric acid (Otto a. Ostrop, *Ann. Ch. Pharm.* cxii. 365). Also, together with phenyl-oxy-sulphide by heating benzene-sulphurous acid with water to 130° :

(Otto, *Ann. Ch. Pharm.* cxlv. 317). The sodium-salt of this acid, $C^6H^5NaSO^3$, yields by dry distillation, carbon dioxide, sulphur dioxide, and phenyl sulphide (Stenhouse, *Proc. Roy. Soc.* xiv. 351). The potassium salt heated with alkaline carbonates yields a small quantity of benzoic acid. Larger quantities of the latter are obtained by heating the benzene-sulphate with potassium cyanide, whereby phenyl-cyanide or benzonitrile, $C^6H^5 \cdot CN$, is formed, and heating the latter with potash (Merz, *Zeitschr. f. Chem.* [2] v. 33).

Benzene-sulphuric or **Sulphobenzolic chloride**, $C^6H^5SO^2Cl$, described in vol. v. p. 564 as *Phenylsulphurous chloride*, is also produced by passing chlorine into
S_{up}. T

water in which benzene-sulphurous acid is suspended (Otto); 3 mol. sulphobenzol-chloride and 4 mol. potassium cyanide form a solution from which water throws down a resinous precipitate yielding to alcohol a not inconsiderable quantity of phenyl bisulphide, $(C^6H^5)_2S^2$ (Lindow a. Otto, *Zeitschr. f. Chem.* [2] iv. 40).

Chlorobenzene-sulphuric bromide, $C^6H^5ClSO^2Br$, is produced by the action of bromine on chlorobenzene-sulphurous acid (p. 275) suspended in water, and remains, on evaporating the ethereal solution, as an oil which solidifies to a crystalline mass. It melts at 52° to 53° , and is resolved by alkalis into metallic bromide and chlorobenzene-sulphite (Otto, *Jahresb.* 1867, p. 630).

Chlorobenzene-sulphuric chloride, $C^6H^5ClSO^2Cl$, is formed, together with phosphorus oxychloride, by triturating 1 mol. dry sodium sulphochlorobenzolate with 1 mol. phosphorus pentachloride, remaining undissolved when the product is treated with water. It crystallises from ether (free from alcohol) in well-defined four-sided rhombic tables, or prisms resembling those of sulphotoluol-chloride, melting at 50° – 51° , insoluble in water, but easily soluble in ether and in benzene. On dissolving it in alcohol, ethylic sulphochlorobenzolate is formed, which separates as a heavy, non-distillable oil. Heated with alkalis or baryta-water, it is resolved into metallic chloride and sulphochlorobenzolate. With fuming nitric acid, after prolonged action, it forms nitrochlorobenzene-sulphuric acid (Otto a. Brummer, *Jahresb.* 1867, p. 632).

Bromobenzene-sulphuric acid, $C^6H^5BrSO^2H$, is produced by dissolving bromobenzene in fuming sulphuric acid (Couper, *Compt. rend.* xlii. 230). When separated from its lead-salt by hydrogen sulphide, it forms a radio-crystalline deliquescent mass, melting at 88° . It is specially distinguished by the crystallising power and beauty of its salts. The *lead salt* $(C^6H^5BrSO^2)^2Pb$ forms very characteristic, large, hemispherical aggregates, having almost the aspect of fungi; not very soluble in cold water. The *potassium salt* $C^6H^5BrSO^2K$ crystallises from water in well-developed, flat, rhombic crystals, very soluble in water. The potassium salt fused with caustic potash yields resorcin: consequently bromobenzene-sulphuric acid belongs to the para-series (1:4) (A. Ross Garrick, *Zeitschr. f. Chem.* [2] v. 549).

Isobromobenzene-sulphuric acid, $C^6H^5BrSO^2H$, is produced by the action of bromine on sulphobenzolic acid. The action does not take place in the cold, and is slow even at 100° ; to complete it, the two substances must be heated together for several days in a sealed tube. The product is to be mixed with water, and evaporated over the water-bath till all the hydrobromic acid has evaporated, then neutralised with lead carbonate, and the resulting lead salt purified by repeated crystallisation. From this salt the acid and the other salts are prepared. All the salts of this acid are totally different from those of the preceding acid. The acid itself may be obtained in the solid state, by leaving its concentrated solution to stand for some time, but it is so deliquescent that its melting point cannot be determined. The *lead salt* $(C^6H^5BrSO^2)^2Pb + 3H^2O$ forms white granular crystals, more soluble in water than the lead salt of the preceding acid. The *potassium salt* $C^6H^5BrSO^2K + H^2O$ is extremely soluble in water, and crystallises in small stellate groups. The salt fused with potassium-hydrate appears to yield hydroquinone, showing that the acid belongs to the ortho-series (1:2). Hence it appears that the group SO^2HO introduces the bromine into the same place as the group $COHO$ in benzoic acid (Ross Garrick, *loc. cit.*). According to R. Geuz (*ibid.* 692), the acid prepared by the action of bromine on sulphobenzolic acid appears to yield resorcin as well as hydroquinone when fused with potash.

Chlorobenzene-sulphuric or *Sulphochlorobenzolic acid*, $C^6H^5ClSO^2H$, is produced by heating monochlorobenzene with fuming sulphuric acid. When separated from its lead-salt by hydrogen sulphide and evaporated, it remains as a syrup, which when left over oil of vitriol crystallises in large deliquescent prisms. Its salts are very stable. The sodium salt $C^6H^5ClSO^2Na \cdot H^2O$ forms cubic crystals; the *silver salt* $C^6H^5ClSO^2Ag$, nacreous scales; the *barium salt* $(C^6H^5ClSO^2)^2Ba \cdot 2H^2O$, also nacreous scales; the *lead salt* $(C^6H^5ClSO^2)^2Pb \cdot 5H^2O$, a laminar mass; the *copper salt* $(C^6H^5ClSO^2)^2Cu \cdot 5H^2O$, greenish needles (Glutz, *Ann. Ch. Pharm.* cxliii. 181; Otto a. Brummer, *ibid.* 100).

Sodium-amalgam converts the acid into benzene-sulphuric acid, identical with that formed from benzene and sulphuric acid. The chlorinated acid is not acted upon by zinc and sulphuric acid, or by boiling potash-ley. In concentrated solution it is oxidised by a mixture of potassium chromate and sulphuric acid, with evolution of chlorine and carbon dioxide. The lead salt yields with nitric acid, nitrochlorobenzene-sulphate and sulphate of lead, together with nitrochlorobenzene, $C^6H^5Cl(NO^2)$, which melts at 75° and solidifies at 65° – 60° (Glutz). The sodium salt triturated with phosphorus pentachloride yields chlorobenzene sulphochloride, $C^6H^5ClSO^2Cl$, together

with phosphorus oxychloride (Otto a. Brummer). The potassium salt fused with a small quantity of potash turns red and probably forms chlorophenol; heated with twice its weight of potassium hydrate, till the red colour almost disappears, it yields resorcin: consequently the acid belongs to the para-series (Oppenheim a. Vogt, *Zeitschr. f. Chem.* [2] v. 722).

Dichlorobenzene-sulphuric or Sulphodichlorobenzosulphic Acid. $C^6H^4Cl^2SO^2H$. SO^2H (Lesimple, *Zeitschr. f. Chem.* [2] iv. 226).—Fuming sulphuric acid does not act on dichlorobenzene at ordinary temperatures, and may therefore be used for the separation of mono- and di-chlorobenzene. But when the latter is strongly heated and occasionally agitated with excess of the fuming acid, it dissolves completely, and the sulpho-acid crystallises out on cooling. An easier method of preparing it is to pass the vapour of sulphuric anhydride into a flask containing dichlorobenzene, dissolve the product in water, and treat the filtered solution as above. The acid, separated from the purified lead-salt by hydrogen sulphide, crystallises from aqueous solution in small colourless rhombic prisms, containing 2 at. water, melting at a temperature above 100° , easily soluble in water, sparingly in ethereal liquids. Its salts crystallise with great facility, dissolve somewhat sparingly in water, are nearly insoluble in alcohol and ether, and bear a temperature of more than 200° without decomposition, but decompose at a red heat, with evolution of sulphurous anhydride:

Potassium salt,	$C^6H^4Cl^2SO^2K.H^2O$,	small prisms and tables.
Sodium "	$C^6H^4Cl^2SO^2Na.H^2O$,	six-sided tables.
Ammonium "	$C^6H^4Cl^2SO^2(NH^4).H^2O$,	needles moderately soluble in water.
Silver "	$C^6H^4Cl^2SO^2Ag$,	greyish-white nacreous pointed needles.
Barium "	$(C^6H^4Cl^2SO^2)^2Ba$,	luminæ.
Magnesium "	$(C^6H^4Cl^2SO^2)^2Mg.6H^2O$,	colourless interlaced needles.
Lead "	$(C^6H^4Cl^2SO^2)^2Pb.3H^2O$,	tufts of needles, or large crystals which on exposure to air give off water and assume a dull appearance like porcelain.

3. Benzene-disulphuric or Disulphobenzosulphic acid, $C^6H^4\begin{matrix} SO^2HO \\ SO^2HO \end{matrix}$ discovered by Buckton and Hofmann, is prepared by heating sulphobenzosulphic acid for two hours with an equal volume of fuming sulphuric acid. The lead salt $C^6H^4(SO^2)^2Pb + 2H^2O$ forms small granular crystals, very soluble in water. The potassium salt $C^6H^4(SO^2K)^2 + 13H^2O$ crystallises in small, but well-defined, shining, transparent crystals, easily soluble in water. Heated to 230° with excess of potassium hydrate, it yields resorcin; consequently, disulphobenzosulphic acid, like sulphobromobenzosulphic acid, belongs to the para-series (1:4). Its potassium salt, distilled with potassium cyanide, yields dicyanobenzene, $C^6H^4(CN)^2$ (Ross Garrick, *loc. cit.*).

Benzene-sulphurous Acid. $C^6H^5.SO^2H$ (Otto a. Ostrop, *Ann. Ch. Pharm.* xlii. 365; Otto, *ibid.* xlv. 317).—This compound, discovered by Kolbe, and described in vol. v. p. 564 as *Phenylsulphurous hydride*, was originally obtained as a zinc-salt by the action of zinc-ethyl on benzene-sulphochloride (phenylsulphurous chloride). Otto and Ostrop find that it may be more easily prepared by treating this chloride with sodium-amalgam:

Perfectly dry benzene-sulphochloride (50–60 grms.) is mixed with several times its volume of pure anhydrous ether in a retort provided with an upright condenser, and sodium-amalgam is added by small portions, till a sample, freed from ether by evaporation, no longer smells of benzene-sulphochloride, and forms a clear solution in water. When the reaction is completed, the ether is evaporated off on the water-bath; the sodium salt is dissolved in the smallest possible quantity of water; the clear decanted solution is mixed with hydrochloric acid; and the separated acid, $C^6H^5SO^2H$, is freed from an adhering oily body by crystallisation from hot deaerated water, as far as possible apart from the air.

Benzene-sulphurous acid thus obtained crystallises in stellate groups of large prisms, exhibiting the properties described by Kolbe (i. 565). Its aqueous solution first reddens litmus and then bleaches it. The crystals melt at 68° – 69° , and decompose when heated above 100° . They deliquesce in the air, taking up oxygen and forming benzene-sulphuric acid, $2C^6H^5SO^2.3H^2O$.

Benzene-sulphurous acid dissolves in moderately concentrated nitric acid, forming benzene-sulphuric and nitrobenzene-sulphuric acids. Fuming nitric acid attacks it strongly, forming a nitro-compound, $C^6H^4N^2SO^2H$, which is precipitated by water, and crystallises from alcohol in hard vitreous rhombohedral crystals, having two of

their diametrically opposite lateral edges truncated; it melts at 98.5° , detonates slightly on platinum foil, is insoluble in water and ether, but easily soluble in alcohol; its constitution has not been exactly determined. The aqueous solution filtered from this compound contains nitrobenzene-sulphuric acid (Otto a. Ostrop).

Benzene-sulphurous acid heated with water to 130° is resolved (analogously to toluene-sulphurous acid, p. 288) into phenyl oxysulphide and benzene-sulphuric acid:

Its potassium salt, heated to 250° – 300° with rather more than 1 mol. potassium hydrate, yields benzene and potassium sulphite:

The acid suspended in water into which a stream of chlorine gas is passed is converted into benzene-sulphochloride (Otto); by bromine, in like manner, into benzene-sulphobromide (Otto a. Ostrop).

Chlorobenzene-sulphurous Acid. $\text{C}^6\text{H}^5\text{Cl} \cdot \text{SO}^2\text{H}$ (Otto a. Brummer, *Ann. Ch. Pharm.* cxliii. 191).—Produced by the action of sodium-amalgam on chlorobenzene-sulphochloride. When separated from the resulting sodium salt and recrystallised from water, with addition of animal charcoal, it forms long four-sided rhombic prisms, which melt at 88° – 90° , dissolve sparingly in cold, easily in hot water, also in alcohol and ether:

Sodium salt, $\text{C}^6\text{H}^5\text{ClSO}^2\text{Na} \cdot 2\text{H}^2\text{O}$, four-sided rhombic tables.

Barium „ $(\text{C}^6\text{H}^5\text{ClSO}^2)^2\text{Ba}$, small needles.

Calcium „ $(\text{C}^6\text{H}^5\text{ClSO}^2)^2\text{Ca}$, „

Lead „ $(\text{C}^6\text{H}^5\text{ClSO}^2)^2\text{Pb}$, crystalline precipitate.

Ethyl Chlorobenzene-sulphite, $\text{C}^6\text{H}^5\text{ClSO}^2(\text{C}^2\text{H}^5)$, produced by heating the acid with alcohol containing hydrochloric acid, is precipitated by water, as an oil which solidifies in the crystalline form, and crystallises from alcohol in small needles melting at 123° . Converted by aqueous chromic acid into chlorobenzene-sulphuric acid, by chlorine-water into chlorobenzene-sulphochloride, and by zinc and sulphuric acid into chlorophenyl sulphhydrate.

Sulphobenzide. $\text{C}^{12}\text{H}^{10}\text{SO}^2$.—Discovered by Mitscherlich, who obtained it by the action of sulphuric anhydride on benzene (v. 486). It is also produced by treating benzene with sulphuric chlorhydrate: $\text{SO}^2(\text{HO})\text{Cl} + 2\text{C}^6\text{H}^6 = \text{C}^{12}\text{H}^{10}\text{SO}^2 + \text{H}^2\text{O} + \text{HCl}$ (Karl Knapp, *Zeitschr. f. Chem.* [2] v. 41). Stenhouse's sulphobenzolene (v. 489), obtained by oxidation of phenyl sulphide, $\text{C}^{12}\text{H}^{10}\text{S}$, and originally regarded as isomeric with sulphobenzide, is really identical therewith, the melting point of sulphobenzide being, according to Knapp, 125° – 126° , which is the same as that of sulphobenzolene. (See also Kekulé a. Szuch, *Bull. Soc. Chim.* [2] viii. 204.)

Sulphobenzide dissolves without alteration in hot dilute sulphuric acid, and crystallises out again on cooling; but the concentrated acid dissolves it with blackening and formation of sulphobenzolic acid: $\text{C}^{12}\text{H}^{10}\text{SO}^2 + \text{SO}^2\text{H}^2 = 2\text{C}^6\text{H}^5\text{SO}^3$. It is not acted upon by alcoholic potash, even at 180° in sealed tubes (Gericke, *Ann. Ch. Pharm.* c. 207).

The results of the action of chlorine on sulphobenzide have been variously stated by different chemists. According to Gericke, an additive compound, $\text{C}^{12}\text{H}^{10}\text{SO}^2 \cdot \text{Cl}^2$, or $\text{Cl}^2 \cdot \text{C}^{12}\text{H}^{10}\text{SO}^2$, is formed, either at ordinary temperatures in diffused daylight, or more quickly in direct sunshine, or when the sulphobenzide is heated to its melting point; and this compound is resolved by rapid heating, or by the action of potash, into hydrochloric acid and dichlorosulphobenzide: $\text{C}^{12}\text{H}^{10}\text{SO}^2\text{Cl}^2 = 2\text{HCl} + \text{C}^{12}\text{H}^{10}\text{Cl}^2\text{SO}^2$. According to Otto a. Ostrop, on the contrary (*Ann. Ch. Pharm.* cxli. 93), chlorine, either dry or moist, exerts no action whatever on sulphobenzide in diffused daylight at ordinary temperatures; but if the sulphobenzide be heated to its melting point, it is resolved by chlorine in diffused daylight into monochlorobenzene and benzene-sulphochloride:

In direct sunshine, according to the same chemists, chlorine acts on sulphobenzide at ordinary temperatures, producing an oily mixture of several chlorinated benzenes, and a crystalline body consisting of monochlorobenzene hexachloride, $\text{C}^6\text{H}^5\text{Cl} \cdot \text{Cl}^6$ (see p. 264). These results have been fully confirmed by the more recent experiments of Otto a. Gruber (*Zeitschr. f. Chem.* [2] iv. 630). Sulphobenzide dissolved in carbon bisulphide, either pure or containing iodine, is not attacked by chlorine either in shade or in sunshine, the action of the chlorine being entirely confined to the solvent.

Neither does sulphobenzide take up chlorine when suspended in water containing iodine, and treated therewith (Otto a. Gruber).

A modification of sulphobenzide called by Stenhouse *parasulphobenzide** is obtained by oxidation of parasulphide of phenyl. It melts at 230°, is soluble in boiling alcohol, from which it crystallises in long white shining needles; insoluble in water, soluble in benzol, ether, and carbon bisulphide; dissolves readily without blackening in warm sulphuric acid, and is precipitated unchanged by water. It dissolves also in hot strong nitric acid and crystallises out on cooling (*Proc. Roy. Soc.* xviii. 543).

Dichlorosulphobenzide, $C^6H^3Cl^2SO^2$, is produced by exposing sulphobenzide, mixed with a few grains of iodine and heated to 100°, to a slow stream of dry chlorine in diffused daylight, till it is wholly converted into a viscid non-crystallising mass. The remainder of the iodine is then expelled by chlorine; the product is washed with warm water containing a little sodium carbonate, then dissolved in ether; and the ethereal solution is evaporated. Dichlorosulphobenzide thus obtained is a thickish, transparent, nearly colourless oil, which becomes mobile when warmed; heavier than water, insoluble therein, easily soluble in ether and in benzol, less soluble in absolute alcohol. It has a faint odour, becoming stronger on warming, and distantly resembling those of chlorobenzol and camphor; distils without decomposition at a temperature above 300°. It is not altered by alcoholic potash or by sodium-amalgam, if the latter be kept in contact with its solution in anhydrous benzene; but in alcoholic solution it is quickly decomposed by sodium-amalgam, yielding products not yet examined (Otto a. Gruber).

A compound isomeric with this liquid dichlorosulphobenzide, and crystallising in beautiful silky inodorous needles melting at 140°–141°, is obtained by the action of sulphuric anhydride on monochlorobenzene (Otto, p. 265).

Representing sulphobenzide by the formula

the crystalline modification of dichlorosulphobenzide may perhaps be represented as $C^6H^3ClSO^2$ or $C^6H^3Cl-S-O-O-C^6H^3Cl$, and the liquid modification produced

by the action of chlorine in presence of iodine on sulphobenzide, as $\left. \begin{array}{l} C^6H^3Cl^2SO^2 \\ C^6H^3 \end{array} \right\}$
 $= C^6H^3Cl^2-S-O-O-C^6H^3$, or as $\left. \begin{array}{l} C^6H^3SO^2 \\ C^6H^3Cl^2 \end{array} \right\} = C^6H^3-S-O-O-C^6H^3Cl^2$. The

reaction of sulphobenzide with chlorine in diffused daylight, at its melting point, whereby it is resolved into monochlorobenzene and sulphobenzolic chloride, justifies the formula assigned to it by Kekulé, viz. $C^6H^3-S-O-O-C^6H^3$: for if the two benzene-residues were symmetrically united with the oxygen, as represented by the formula $C^6H^3-O-S-O-C^6H^3$, the action of chlorine should give rise to sulphonyl chloride and chlorinated derivatives of benzene (Otto a. Gruber, *Ann. Ch. Pharm.* calix. 174).

Nitrosulphobenzide, $C^6H^3(NO^2)SO^2$, is produced by heating sulphobenzide with fuming nitric acid till it is completely dissolved. On adding water, and treating the resulting precipitate with hot alcohol, nitrosulphobenzide dissolves, while dinitrosulphobenzide remains behind; and the hot saturated solution deposits nitrosulphobenzide on cooling, as a honey-yellow unctuous mass which solidifies on cooling. It melts at 90°–92°, decomposes completely at 250°, is but slightly soluble in water either hot or cold, easily soluble in ether. From solution in dilute alcohol, it separates on cooling in soft microscopic crystals. *Dinitrosulphobenzide*, $C^6H^3(NO^2)^2SO^2$, is obtained by prolonged boiling of sulphobenzide with fuming nitric acid, or more quickly by the action of a mixture of fuming nitric and sulphuric acids. It forms small white silky rhombic tables, insoluble in water, slightly soluble in alcohol and ether; melts at 164°; solidifies in a radio-crystalline mass; and sublimates without decomposition below 320° (Gericke, *loc. cit.*).

Amidosulphobenzide, $C^6H^3(NH^2)SO^2$, is produced by the action of ammonium sulphide on nitrosulphobenzide dissolved in alcohol. When purified by solution in hydrochloric acid and precipitation by potash, it forms microscopic prisms, slightly soluble in cold water, easily in hot water and in alcohol. The *hydrochloride*, $C^6H^3(NH^2)SO^2 \cdot HCl$, crystallises in reddish four-sided prisms, easily soluble in water

* As the prefix 'para,' when applied to aromatic bodies, has a peculiar signification not here implied, it would perhaps be better to call this modification *iso*sulphobenzide.

and in alcohol, melting at about 90° . The *platinochloride*, $2[C^{12}H^8(NH^2)SO^2 \cdot HCl] \cdot PtCl^4$, is a yellowish-brown amorphous precipitate soluble in alcohol.

Diamidosulphobenzide, $C^{12}H^8(NH^2)^2SO^2$, is obtained by the action of ammonium sulphide on dinitrosulphobenzide, and is thrown down from its solution in hydrochloric acid by potash, as a yellowish-white precipitate, which soon becomes darker. It dissolves with difficulty in cold, easily in hot water and alcohol, and crystallises in four-sided prisms, easily melting to a brown mass. The *hydrochloride*, $C^{12}H^8(NH^2)^2SO^2 \cdot 2HCl$, crystallises in long reddish rhombic prisms, easily soluble in water and in alcohol, not decomposing at 100° . Its solution forms with *platinic chloride* a brown-red indistinctly crystalline precipitate, consisting of $2[C^{12}H^8(NH^2)SO^2 \cdot 2HCl] \cdot PtCl^4$ (Gericke).

BENZENE, HOMOLOGUES OF. C^8H^6 .—The derivation of these hydrocarbons from benzene, the general methods of producing them synthetically, and the nature of the isomerism existing in the several groups of hydrocarbons and their derivatives, have been discussed in the article AROMATIC SERIES. Those which occur in coal-tar naphtha (C^8H^8 , C^8H^{12} , C^8H^{12}) appear to be methylic derivatives, coal-tar cumene, for example, being trimethyl-benzene, $C^8H^8(CH^3)^3$. Toluene and xylene have been found, together with benzene, among the hydrocarbons produced by subjecting to dry distillation the lime-soap of Menhaden oil (Warren a. Storer, *Zeitschr. f. Chem.* iv. 229).

The specific gravities and expansions of these hydrocarbons have been determined by Louguinine (*Ann. Ch. Phys.* [4] xi. 153; also with remarks by H. Kopp, *Ann. Ch. Pharm. Suppl.* v. 295, 303; *Zeitschr. f. Chem.* [2] iv. 194). The specific gravities at 0° were found to be as follows:

	Sp. gr. at 0°
Benzene, from benzoic acid	0.8995
Toluene, from coal-tar: B. P. 111° – 111.5°	0.8841
Xylene, from coal-tar: B. P. 138° – 139°	0.8770
Cymene, from Roman cumin-oil: B. P. 175° – 176°	0.8703
Cymene, from camphor: * B. P. 174° – 175°	0.8732

Hence it appears that: 1. The densities at 0° of the aromatic hydrocarbons decrease as they ascend in the series from benzene to cymene.—2. The successive differences exhibit a certain regularity, that between benzene and toluene being 0.0154, and that between toluene and xylene 0.0071, or nearly half the preceding. Calling the first difference a , the second will be $\frac{a}{2}$; and if we suppose the same law to hold good throughout the series, the difference of density between xylene and cumene will be $\frac{a}{4}$, and that between cumene and cymene $\frac{a}{8}$. Accordingly the density of cymene should be equal to that of benzene diminished by

$$a + \frac{a}{2} + \frac{a}{4} + \frac{a}{8};$$

that is, by $0.0154 + 0.0077 + 0.0039 + 0.0019 = 0.0289$; this would give for the density of cymene

$$d = 0.8995 - 0.0289 = 0.8706,$$

which is nearly the same as the experimental number 0.8705.

The specific volumes of the five hydrocarbons, that of each at $0^{\circ} = 1$, are calculated by means of the following interpolation formulæ:

$v = 1.0000 + 0.00118t$	$+ 0.000002226t^2$	for Benzene.
$v = 1.0000 + 0.001028t$	$+ 0.000001779t^2$	„ Toluene.
$v = 1.0000 + 0.0009506t$	$+ 0.000001632t^2$	„ Xylene.
$v = 1.0000 + 0.0008952t$	$+ 0.000001277t^2$	„ Cymene from Cumin-oil.
$v = 1.0000 + 0.000898t$	$+ 0.000001311t^2$	„ Cymene from Camphor.

The following table contains the volumes of these five hydrocarbons at different temperatures: I. As calculated from the preceding interpolation formulæ; II. As deduced from the expansion curve constructed according to Louguinine's experiments:

* Cymene from camphor is in all probability identical with that from Roman cumin-oil. Kopp doubts the purity of the hydrocarbons used in Louguinine's experiments, inasmuch as none of them, except the benzene, exhibited constant boiling points.

	Benzene		Toluene		Xylene		Cymene from Rom. Cumin-oil		Cymene from Camphor	
	I.	II.	I.	II.	I.	II.	I.	II.	I.	II.
0	1·0000	1·0000	1·0000	1·0000	1·0000	1·0000	1·0000	1·0000	1·0000	1·0000
10	1·0118	1·0122	1·0104	1·0104	1·0096	1·0094	1·0090	1·0093	1·0090	1·0092
20	1·0241	1·0245	1·0213	1·0214	1·0197	1·0195	1·0184	1·0190	1·0184	1·0186
30	1·0368	1·0371	1·0324	1·0324	1·0300	1·0297	1·0280	1·0285	1·0282	1·0282
40	1·0500	1·0500	1·0439	1·0438	1·0407	1·0403	1·0378	1·0379	1·0380	1·0378
50	1·0636	1·0622	1·0558	1·0554	1·0516	1·0513	1·0480	1·0478	1·0481	1·0478
60	1·0776	1·0774	1·0681	1·0678	1·0629	1·0626	1·0583	1·0583	1·0586	1·0584
70	1·0921	1·0919	1·0807	1·0804	1·0745	1·0739	1·0692	1·0690	1·0693	1·0689
80	1·1070	1·1065	1·0937	1·0937	1·0865	1·0859	1·0798	1·0800	1·0802	1·0799
90			1·1069	1·1069	1·0987	1·0985	1·0910	1·0912	1·0914	1·0913
100			1·1206	1·1206	1·1113	1·1113	1·1023	1·1026	1·1029	1·1056 ?

By extending the interpolation formulæ above given to temperatures beyond the limits of Louguine's experiments (which process of *extra-polation* has been found in other cases to give results agreeing with those of observation), Kopp has calculated the specific volumes of the five hydrocarbons at the boiling points given by Louguine, that of each hydrocarbon at 0° being taken as unity: for benzene and cymene the numbers deduced from Kopp's own experiments are also given:

According to Louguine.			According to Kopp.		
	Sp. vol.	Diff.		Sp. vol.	Diff.
C ⁶ H ⁶ for 81°	96·1	22·1	C ⁶ H ⁶ for 81°	96·1	4 × 21·9
C ⁶ H ⁶ „ 111°	118·2				
C ⁶ H ¹⁰ „ 138°	140·5	22·3			
C ⁶ H ¹⁴ „ 175°	184·1	2 × 21·8	C ⁶ H ¹⁴ „ 175°	183·5	

Hence it appears that in this series of liquid hydrocarbons, the specific volumes at the boiling points differ by about $n \times 22$ for a difference in the formulæ of n CH₂.

Hydrocarbon C⁶H⁶.

The only hydrocarbon of the series containing 7 at. carbon is **methyl-benzene** or **toluene**, C⁶H⁷(CH³). To the modes of formation of this body already mentioned (v. 851) must be added: α . The passing of the vapour of ethyl-benzene through a red-hot tube, naphthalene, C¹⁰H⁸, and its hydride, C¹⁰H¹⁰, being formed at the same time (Berthelot, *Zeitschr. f. Chem.* [2] iv. 589):

β . The heating of nitric acid with lime (Baeyer, *ibid.* 119).— γ . The dry distillation of the lime-salt of Menhaden oil (p. 278).

Toluene, agitated with an alkaline solution of *potassium permanganate*, yields benzoic acid, and a neutral solid aromatic body, insoluble in water and in alkalis, soluble in ether, but no phthalic acid (Berthelot, *Bull. Soc. Chim.* [2] vii. 124). Heated with 80 pts. of strong *hydriodic acid*, it is completely converted into *septane*, C⁷H¹⁶; with 20 pts. of the acid it yields propane and charcoal:

(Berthelot, *ibid.* 53). Treated with *hydriodide of phosphine*, PH³.HI, it takes up 2 at. H, and is converted into methyl-benzolone, C⁶H¹⁰ (Baeyer, *Zeitschr. f. Chem.* [2] iv. 445). Toluene introduced into the stomach is converted into hippuric acid, which is found in the urine (Schultzen a. Naunyn, *ibid.* 29).

Bromotoluenes. *Monobromotoluene*, C⁶H⁴Br.CH³, boils, according to Kekulé (*Ann. Ch. Pharm.* cxxxvii. 198), at 182·5°–183° (corr. 186°–186·5°), and has a sp. gr. of 1·4109 at 22° (referred to water at 0°). *Benzyl bromide*, C⁶H⁵.CH²Br, boils at 197°–198·5° (corr. 201·5°–202·5°), and has a sp. gr. of 1·4380 at 22°.

* From Roman cumin-oil.

According to Beilstein (*Ann. Ch. Pharm.* cxliii. 369), the action of bromine on boiling toluene always produces benzyl bromide more or less mixed with bromotoluene; but when toluene is acted upon by bromine in presence of iodine, the only product formed, even at the boiling heat, is bromotoluene, which may thus be easily obtained pure. Cannizzaro finds (*Ann. Ch. Pharm.* cxli. 198) that the product formed by the action of bromine on toluene at comparatively low temperatures consists of a mixture of bromotoluene and benzyl bromide. When toluene, boiling between 110° and 114° , is mixed by drops with bromine in a well-cooled vessel, and the brominated product, after washing with water and sodium carbonate, and drying with calcium chloride, is distilled, the liquid which passes over between 160° and 190° consists mainly of bromotoluene, and that which distils at 190° – 200° of benzyl bromide. On these observations Fittig (*Ann. Ch. Pharm.* cxlvii. 39) finds a process for obtaining pure bromotoluene free from benzyl bromide. Pure toluene contained in a retort standing in cold water is mixed gradually, and by very small portions, with somewhat less than the theoretical quantity of bromine, made to flow into it through a funnel-tube; and the mixture, after standing for 12 hours, is washed with soda-ley and water, dried over calcium-chloride, and distilled, the portion which goes over between 178° and 181° being collected apart. The bromotoluene thus obtained is freed from hydrobromic acid, by blowing a stream of air over it while it is briskly agitated; and by a second distillation, a colourless liquid is obtained which boils between 179° and 180° , gives off vapours which do not at all irritate the eyes, and solidifies completely in a freezing mixture.

Monobromotoluene exhibits two modifications besides the metamerie compound benzyl bromide, $C^6H^5.CH^2Br$, viz. *orthobromotoluene* (1,2), which is fluid at ordinary temperatures, and *parabromotoluene* (1,4), which is crystalline. Ordinary liquid bromotoluene, obtained by the processes above described, consists mainly of the solid modification held in solution by a small quantity of the liquid. It may be made to solidify by treating it with fuming sulphuric acid; the portion not attacked by the acid then solidifies on slight cooling, in crystals, which melt at 28° – 29° . Again, if ordinary bromotoluene be freed from benzyl bromide by treatment with alcoholic ammonium sulphide and subsequent distillation, the portions distilling at 178° – 179° , 181° , and 182° being perfectly dried and then cooled, and the crystals which separate be taken out of the still liquid portion and dried on bibulous paper, they will then no longer melt at the ordinary temperature of a room, but only at 28° – 29° (Hübner a. Wallach, *Zeitschr. f. Chem.* [2] v. 22, 138, 499).

Parabromotoluene forms shining, rather hard crystals, belonging to the rhombic system, melting at 28.5° , and boiling at 181° – 183° . By oxidation with chromic acid it is converted into *parabromobenzoic acid*, melting at a temperature above 230° . By converting it into nitrobromotoluene, reducing this compound to bromotoluidine with tin and hydrochloric acid, and treating this base with sodium-amalgam, toluidine is obtained, boiling at 196° and remaining fluid at -21° (identical with Rosenstiehl's pseudo-toluidine).

The liquid bromotoluene, separated from the crystallised modification by pressure between cooled metallic plates, likewise boils at 181° – 183° , but deposits only a few crystals at -20° (Rosenstiehl a. Nikiforoff, *Zeitschr.* [2] v. 635). Wroblevsky (*ibid.* 322) obtains this same modification of bromotoluene by converting nitrate of bromotoluidine, by Griess's process, into the corresponding diazo-compound (v. 867), and decomposing the sulphate of this base with absolute alcohol. The bromotoluene thus obtained is a colourless liquid, having a faint odour and boiling at 182° . By oxidation with chromic acid it is converted into *orthobromobenzoic acid*, melting at 153° , and identical with that which is obtained from ordinary benzoic acid: hence the liquid bromotoluene is orthobromotoluene (1,2).

A mixture of ethyl chlorocarbonate and sodium-amalgam acts upon bromotoluene in the same manner as on bromobenzene (p. 263), forming ethyl toluate, $C^6H^5(C^2H^5)O^2$. Benzyl-bromide treated in like manner yields the ethylic ether of an aromatic acid, $C^6H^4O^2$, which appears to be formed by the union of two benzyl groups (Wurtz, *Zeitschr. f. Chem.* [2] v. 385).

Dibromotoluene, $C^6H^4Br^2$, CH^3 , is formed by the action of bromine in excess on toluene at ordinary temperatures—but only in small quantity, even after a considerable time—and separates in crystals from the portion of the product of higher boiling point. It crystallises from alcohol in long colourless needles, melting at 107° – 108° ; boils without decomposition at about 245° ; and dissolves easily in hot, less easily in cold alcohol. It is not attacked by alcoholic potash, or by a mixture of potassium dichromate and sulphuric acid (Fittig).

Another modification of dibromotoluene is obtained by direct bromination of

orthobromotoluene. It remains liquid at -20° , boils without decomposition at 236° , has a sp. gr. of 1.8127 at 19° , dissolves easily in alcohol, is not oxidised by chromic acid (Wroblevsky, *Zeitschr. f. Chem.* [2] vi. 239).

Benzylene Bromide, $C^6H^5 \cdot CHBr_2$, metameric with the preceding, is obtained by gradually adding phosphorus pentabromide to benzoic aldehyde, $C^6H^5 \cdot CHO$, and digesting the product for a few hours in the water-bath with excess of the pentabromide; purified by washing with aqueous potash and with a strong solution of sodium bisulphite, then drying, and distilling in a vacuum. It is a strongly refracting liquid, which becomes red on exposure to light; very soluble in alcohol and ether, insoluble in water. Decomposed by distillation under ordinary pressure, but distils between 130° and 140° under a pressure of 20 mm. Decomposed by sodium at about 180° , yielding toluene and a black resinous residue, which when distilled in a current of steam, solidifies to a crystalline mass of benzyl, C^6H^5 (Michaelson a. Lippmann, *Bull. Soc. Chim.* [2] iv. 251).

Chlorotoluenes. *Orthomonochlorotoluene*, $C^6H^4Cl \cdot CH_3$, is obtained from chlorinated orthotoluidine (see TOLUIDINES) by converting the latter, by Griess's process, first into nitrate, then into sulphate of diazochlorotoluene, and boiling this sulphate with alcohol. It is a colourless liquid, which boils at 156° and is converted by oxidation into orthochlorobenzoic acid (Wroblevsky, *Zeitschr. f. Chem.* [2] v. 460). *Paramonochlorotoluene*, $C^6H^3ClH^2 \cdot CH_3$, and the metameric body *Benzyl chloride*, $C^6H^5 \cdot CH_2Cl$, are described in vol. v. pp. 853, 854.

Of the three *dichlorinated tolueues*, $C^6H^3Cl^2$,

$C^6H^3Cl^2 \cdot CH_3$
Dichlorotoluene

$C^6H^4Cl \cdot CH^2Cl$
Chlorobenzyl
chloride

$C^6H^5 \cdot CHCl^2$
Benzylene
chloride,

the second and third are also described in vol. v. pp. 854, 855. The following additional observations are by Beilstein a. Geitner (*Jahresb.* 1866, p. 590) and Neuhofer (*Zeitschr. f. Chem.* [2] ii. 653; *Jahresb.* 1866, p. 597).

1. *Dichlorotoluene*, $C^6H^3Cl^2 \cdot CH_3$, is obtained (together with monochlorotoluene) by passing chlorine into toluene mixed with iodine. It is liquid, boils at 198° (Beilstein a. Geitner), 197° – 199° (Neuhof), and retains its two chlorine-atoms with equal force. By oxidation with chromic acid, it is converted into *paradichlorobenzoic* (dichlorodraeylic) acid:

2. *Chlorobenzyl chloride*, $C^6H^4Cl \cdot CH^2Cl$, is produced by the action of chlorine on monochlorotoluene at the boiling heat, or by the action of chlorine in the cold, in presence of iodine, on benzyl chloride. It boils at 212° – 214° , gives up one of its chlorine-atoms more easily than the other, and is accordingly converted by oxidation into *paramonochlorobenzoic* (chlorodraeylic) acid (Neuhof):

By boiling with alcoholic solution of potassium sulphhydrate, it is converted into an oily mercaptan which crystallises from alcohol:

Boiled with alcoholic potassium cyanide, it yields the amide of alpha-toluic acid:

Heated with the solution of potassium cyanide in a sealed tube, it yields the nitrile of alpha-toluic acid (Neuhof).

3. *Benzylene chloride*, *Chlorobenzol*, or *Bitter almond oil chloride*, $C^6H^5 \cdot CHCl^2$, is produced by passing chlorine into benzyl chloride at the boiling heat, or (i. 855) by the action of phosphorus pentachloride on bitter almond oil.

Of the *trichlorinated compound* $C^6H^2Cl^3$, there are four possible modifications, depending on the distribution of the chlorine-atoms between the principal and lateral chains: viz.,

Trichlorotoluene,	$C^6H^2Cl^3 \cdot CH_3$	boiling at 235° .
Benzotrichloride,	$C^6H^3 \cdot CCl^3$,	" 214° .
Dichlorobenzyl- chloride,	$C^6H^4Cl^2 \cdot CH^2Cl$,	" 241° .
Chlorbenzylene- chloride,	$C^6H^4Cl \cdot CHCl^2$,	" 234° .

The first and third may also admit of further modifications depending on the relative positions of the chlorine-atoms in the principal chain.

The second and third of the above compounds are described in vol. v. p. 855.

They have been further studied, together with the other two, by Beilstein a. Kuhlberg (*Ann. Ch. Pharm.* cxlvi. 317). 1. *Trichlorotoluene*, $C^6H^3Cl^3$. CH^3 , is easily obtained by passing chlorine into toluene mixed with iodine, till 100 pts. by weight of the toluene have increased to 215.5 pts. According to Limpricht (*Ann. Ch. Pharm.* cxxxix. 303), it is also found, together with benzotrichloride, and probably also with the other two modifications above mentioned, in the product resulting from the action of chlorine alone upon toluene, and separates in crystals when the portion of the chlorinated product which boils at 230° – 240° is exposed to a low temperature. When recrystallised from ether it forms long vitreous prisms which melt and solidify again at 75° to 76° ; boils without decomposition at 237° , and is not altered by prolonged heating with water to 200° – 220° (Limpricht). By oxidation with chromic acid it is converted into paratrichlorobenzoic (trichlorodracylic) acid (Janasch, *Jahresh.* 1867, p. 660).—2. *Dichlorobenzyl-chloride*, $C^6H^2Cl^2$. CH^2Cl , is obtained by passing chlorine into benzyl chloride, C^6H^5 . CH^2Cl , mixed with iodine, or more readily by treating dichlorotoluene, $C^6H^4Cl^2$. CH^3 , with chlorine at the boiling heat. It boils without decomposition at 241° , and contains a loosely combined chlorine-atom, replaceable by double decomposition; thus when heated with an alcoholic solution of potassium acetate, it yields potassium chloride and paradichlorobenzyl acetate, $C^6H^2Cl^2$. $CH^2(C^2H^3O^2)$ (Beilstein a. Kuhlberg).—3. *Chlorobenzylene chloride* (chlorinated bitter almond oil), C^6H^4Cl . $CHCl^2$, is produced when chlorine is passed into benzylene chloride (chlorobenzol or chloride of bitter almond oil) mixed with iodine, or more readily by the action of chlorine on monochlorotoluene, C^6H^4Cl . CH^3 , at the boiling heat (Beilstein a. Kuhlberg); also by the action of phosphorus pentachloride on dichlorocresol, $C^6H^4(OH)$. $CHCl^2$ (L. Henry, *Zeitschr. f. Chem.* [2] v. 371). Boils at 234° (B. and K.); at 227° – 230° , and has a sp. gr. of 1.4 at 9° (Henry). It is decomposed by water at 170° , with formation of parachlorobenzoic aldehyde, C^6H^3Cl . CHO (chlorosalicylcol, according to Henry), and is oxidised by chromic acid to parachlorobenzoic acid, C^6H^3Cl . CO^2H (Beilstein a. Kuhlberg).—4. *Benzotrichloride*, C^6H^3 . CCl^3 , is easily obtained quite pure by passing chlorine into boiling toluene as long as the product continues to increase in weight (100 pts. toluene take up 112.5 pts. chlorine). It boils constantly at 213° – 214° , and is decomposed by water at 150° , with formation of benzoic acid:

Benzoic acid is also formed, together with chlorobenzoic acid as a secondary product, when benzotrichloride is oxidised by chromic acid (Beilstein a. Kuhlberg). *Nitrobenzotrichloride*, $C^6H^3(NO^2)$. CCl^3 , appears to be formed by the action of fuming nitric acid on benzotrichloride, but is immediately decomposed by water into hydrochloric and nitrobenzoic acids. *Nitrobenzylene chloride*, $C^6H^4(NO^2)$. $CHCl^2$, is formed on dropping benzylene chloride (chlorobenzol), prepared from bitter almond oil, into fuming nitric acid, as a heavy oil which cannot be obtained in the pure state; by oxidation with chromic acid it is converted into nitrobenzoic acid (Beilstein a. Kuhlberg).

Tetrachlorinated Toluenes. $C^6H^4Cl^4$.—This formula includes four possible modifications, viz.,

C^6HCl^4 . CH^3	$C^6H^2Cl^3$. CH^2Cl	$C^6H^3Cl^2$. $CHCl^2$	C^6H^4Cl . CCl^3
Tetrachlorotoluene.	Trichlorobenzyl chloride.	Dichlorobenzylene chloride.	Monochlorobenzotrichloride.

The first and fourth of these bodies, mentioned in vol. v. p. 856, have lately been further studied, together with the other two, by Beilstein a. Kuhlberg (*Zeitschr. f. Chem.* [2] iv. 276).

1. *Tetrachlorotoluene*, C^6HCl^4 . CH^3 , is formed by the prolonged action of chlorine on toluene mixed with iodine, 100 pts. toluene increasing thereby in weight to 250 pts. It is separated by fractional distillation and purified by crystallisation from absolute alcohol. It is very stable; boils without decomposition at 270° ; melts at 92° – 95° ; is slowly acted upon by fuming nitric acid.—2. *Trichlorobenzyl chloride*, $C^6H^2Cl^3$. CH^2Cl , is easily produced by treating trichlorotoluene with chlorine at the boiling heat, 100 pts. taking up 17.6 pts. chlorine. It is a liquid boiling without decomposition at 273° ; one of its chlorine-atoms is easily replaced by double decomposition; thus when boiled with alcoholic potassium acetate, it easily yields *trichlorobenzyl acetate*, with separation of KCl.—3. *Dichlorobenzylene chloride*, $C^6H^3Cl^2$. $CHCl^2$, is formed by the action of chlorine on dichlorotoluene at the boiling heat, 100 pts. increasing in weight by 43 pts. Liquid; boils without decomposition at 257° . Easily exchanges two of its chlorine-atoms; thus when heated with water in a sealed tube it yields hydrochloric acid, and a substance capable of uniting with acid

sodium sulphite, evidently the aldehyde of paradichlorobenzoic acid. By oxidation with chromic acid, it yields *paradichlorobenzoic acid*:

4. *Monochloro-benzotrichloride*, $\text{C}^6\text{H}^5\text{Cl} \cdot \text{CCl}^3$, obtained by passing chlorine into benzotrichloride, is a liquid boiling without decomposition at 245° . When heated with water to 190° , it is completely resolved into hydrochloric acid and *parachlorobenzoic acid*, showing that the three chlorine-atoms in the methyl of the toluene molecule have exerted no influence on the position of the chlorine in the phenyl:

Pentachlorinated Toluenes.—The empirical formula $\text{C}^6\text{H}^2\text{Cl}^4$ likewise admits of four modifications, viz.,

$\text{C}^6\text{Cl}^5 \cdot \text{CH}^1$	$\text{C}^5\text{HCl}^4 \cdot \text{CH}^2\text{Cl}$	$\text{C}^4\text{H}^2\text{Cl}^3 \cdot \text{CHCl}^2$	$\text{C}^3\text{H}^3\text{Cl}^2 \cdot \text{CCl}^3$
Pentachloro- toluene.	Tetrachloro-benzyl chloride.	Trichloro-benzylene chloride.	Dichlorobenzotri- chloride.

1. *Pentachlorotoluene*, $\text{C}^6\text{Cl}^5 \cdot \text{CH}^1$, is prepared by passing chlorine into toluene mixed with iodine as long as it is absorbed, the absorption being ultimately assisted by a gentle heat; then fractionating; and purifying the portion which boils at about 300° by washing with cold carbon bisulphide (which dissolves tetrachlorotoluene easily, but pentachlorotoluene with difficulty), and recrystallising from benzene. Crystallises in shining white slender needles; melts at 218° , and boils at about 300° . Very stable, not being acted on by fuming nitric acid at boiling heat.—2. *Tetrachlorobenzyl chloride*, $\text{C}^5\text{HCl}^4 \cdot \text{CH}^2\text{Cl}$, is produced by treating tetrachlorotoluene with chlorine at the boiling heat, 100 pts. increasing in weight by 15 pts. It is a liquid, boiling without decomposition at 296° – 297° , and easily exchanging one of its chlorine-atoms, yielding, for example, tetrachlorobenzyl acetate when heated with alcoholic potassium acetate. Treated at its boiling heat with chlorine, it is converted into pentachlorobenzeno, C^6HCl^5 (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 527).—3. *Trichlorobenzylene chloride*, $\text{C}^4\text{H}^2\text{Cl}^3 \cdot \text{CHCl}^2$, is prepared by treating trichlorotoluene with chlorine at the boiling heat, 100 pts. taking up 36 pts. Liquid, boiling without decomposition at 285° .—4. *Dichlorobenzotrichloride*, $\text{C}^3\text{H}^3\text{Cl}^2 \cdot \text{CCl}^3$, is produced by passing chlorine into benzotrichloride at the boiling heat as long as it is absorbed. It is a liquid, boiling without decomposition at 277° , and easily exchanging three of its chlorine-atoms: thus when heated with water it yields paradichlorobenzoic acid (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] iv. 277).

Hexachlorinated Toluenes (Beilstein a. Kuhlberg, *ibid.* 561).—The formula C^6HCl^5 admits of the three following modifications:

$\text{C}^6\text{Cl}^5 \cdot \text{CH}^1\text{Cl}$	$\text{C}^5\text{HCl}^4 \cdot \text{CHCl}^2$	$\text{C}^4\text{H}^2\text{Cl}^3 \cdot \text{CCl}^3$
Pentachlorobenzyl chloride.	Tetrachlorobenzylene chloride.	Dichlorobenzotri- chloride.

1. *Pentachlorobenzyl chloride*, $\text{C}^6\text{Cl}^5 \cdot \text{CH}^1\text{Cl}$, is prepared by passing chlorine into benzyl chloride, $\text{C}^6\text{H}^5 \cdot \text{CH}^2\text{Cl}$, mixed with iodine, as long as it continues to increase in weight, washing the product with potash, then adding a few grams of antimony trichloride, and finally passing chlorine into the moderately heated mixture as long as it continues to be absorbed. The antimony chloride is then removed by washing with strong hydrochloric acid, and the expressed product is purified by recrystallisation from alcohol and benzol. It is also produced by the prolonged action of chlorine on pentachlorotoluene at the boiling heat. Crystallises in white shining slender needles; melts at 107° – 108° ; boils without decomposition at about 325° ; dissolves sparingly in absolute alcohol, easily in benzol. By alcoholic potassium acetate at 200° , it is converted into *pentachlorobenzyl alcohol*, $\text{C}^6\text{Cl}^5 \cdot \text{CH}^2\text{OH}$. Decomposed also by an alcoholic solution of hydropotassic sulphide.

2. *Tetrachlorobenzylene chloride*, $\text{C}^5\text{HCl}^4 \cdot \text{CHCl}^2$, is obtained by passing chlorine into tetrachlorotoluene, $\text{C}^5\text{HCl}^4 \cdot \text{CH}^2$, at the boiling heat, as long as it continues to be absorbed, and purified by fractional distillation. It is a liquid of sp. gr. 1.704 at 25° , boiling without decomposition at 305° – 306° . By heating with water to 280° , it is resolved into hydrochloric acid and *tetrachlorobenzaldehyde*:

3. *Trichlorobenzo-trichloride*, $\text{C}^6\text{H}^2\text{Cl}^4 \cdot \text{CCl}^3$, prepared in like manner from trichlorotoluene, forms colourless, highly lustrous needles, soluble in alcohol; boils at 297° – 298° ; melts at 82° , and solidifies to a mass exhibiting patterns like frost-crystals. Heated with water to 250° – 260° , it is easily converted into *paratrichlorobenzoic acid*:

In the preparation of the compound $C^6H^4Cl^3.CCl^3$ there is likewise obtained a liquid boiling at 240° - 250° , and depositing crystals which melt only at 139° . These crystals, which dissolve with difficulty both in absolute alcohol and in a mixture of alcohol and benzene, consist of tetrachlorobenzene, $C^6H^2Cl^4$ (Beilstein a. Kuhlberg, *Zeitschr. f. Chem. n.* [2] v. 529).

Heptachlorotoluenes (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 75).—The formula C^6HCl^7 admits of only two modifications, viz.,

Tetrachloro-benzotrichloride, $C^6HCl^4.CCl^3$, is formed by the action of chlorine on tetrachlorotoluene at the boiling heat. It is not possible, however, to convert the whole of the tetrachlorotoluene into the heptachlorinated compound, the product being a mixture of $C^6HCl^4.CCl^3$, $C^6H^2Cl^4$, $C^6HCl^4.CHCl^4$, and $C^6HCl^4.Cl^3$, which may be approximately separated by fractional distillation. The portions boiling between 310° and 320° solidify after a while; they are freed from adhering oil (consisting of the penta- and hex-chlorinated compounds just mentioned) and purified by crystallisation from alcohol.

Tetrachloro-benzotrichloride thus obtained forms dazzling white crystals; from alcoholic solution it separates by rapid cooling in short needles; by slow cooling in laminae. Boils with slight decomposition at 316° ; melts at 104° . Moderately soluble in hot, slightly in cold absolute alcohol. By heating with water to 270° , it is slowly resolved into hydrochloric and para-tetrachlorobenzoic acids:

It is not acted upon by bromine, or under the ordinary pressure by antimonie chloride.

Pentachloro-benzylene chloride, $C^6Cl^3.CHCl^2$, is not formed by the action of chlorine on pentachlorotoluene at the boiling heat, but may be prepared by treating benzylene chloride, C^6H^2 . $CHCl^2$, with chlorine in presence of iodine, as long as absorption goes on, ultimately with the assistance of antimonie chloride, which, however, must not be added till every trace of iodine has been removed. The washed product is distilled, and the red distillate is washed with aqueous potash and again distilled till a colourless distillate is obtained, which is again to be mixed with antimonie chloride and treated with chlorine as long as that gas is absorbed. The antimony chloride is then removed with hydrochloric acid; the liquid distilled; the distillate mixed with a large excess of antimonie chloride and slowly redistilled; and the portions which go over after the antimonie chloride are washed with hydrochloric acid, and then repeatedly boiled with alcohol of 80 p. c., which dissolves the compound $C^6Cl^3.CHCl^2$, and leaves undissolved another heptachlorinated compound, to be presently noticed. The crystals which separate from the alcoholic solution are purified by repeated crystallisation from alcohol, whereby the compound $C^6Cl^3.CHCl^2$ is obtained in dazzling white, flat, elongated or triangularly acuminate laminae. It melts at 109° - 110° , boils constantly and without decomposition at 333° - 335° ; is not altered by heating with water to 300° , or by bromine.

Iodotoluene, $C^6H^4I.CH^3$, is obtained by decomposing sulphate of diazotoluene with hydriodic acid, washing the product with potash-ley and water, and subsequent distillation. The iodotoluene thus prepared from diazotoluene obtained by the action of nitrous acid on ordinary toluidine, forms shining laminae, melting at 35° , boiling without decomposition at 211.5° , subliming at ordinary temperatures, and converted by oxidation with chromic acid into para-iodobenzoic acid: hence it consists of para-iodotoluene (W. Körner, *Bull. Acad. Belg.* 1867, p. 157; *Jahresb.* 1867, p. 665); but the iodotoluene obtained in like manner from the diazotoluene produced from Rosenstiehl's pseudotoluidine is liquid at ordinary temperatures, and is converted by oxidation with chromic acid mixture into ortho-iodobenzoic acid: hence it consists of ortho-iodotoluene (Körner, *Zeitschr. f. Chem.* [2] v. 636).

Nitrotoluenes. *Mononitrotoluene*, $C^6H(NO^2).CH^3$, was originally obtained as a liquid (i. 574); but Jaworsky (v. 558) and Kekulé (*Zeitschr. f. Chem.* [2] iii. 225) have shown that when this liquid nitrotoluene (prepared by the action of fuming nitric acid on coal-tar toluene) is subjected to fractional distillation, the greater part passes over from 220° - 225° , and only the portion boiling above 233° yields pure nitrotoluene, which boils at 237° - 238° , and solidifies in well-defined crystals melting at 54° . On the other hand, Beilstein a. Kuhlberg have shown that by heating dinitrotoluenes (i. 575) with hydrogen, or by boiling sulphate of paradiazonitrotoluene with absolute alcohol, a liquid mononitrotoluene is obtained which does not solidify, and that the product commonly called nitrotoluene is a mixture of this liquid nitrotoluene with the solid modification. When nitrotoluene is prepared by adding nitric acid

(sp. gr. 1.475) to cooled toluene, and the product is subjected to fractional distillation at intervals of 2° , we obtain, after fifteen to twenty distillations, two portions, one boiling between 222° and 223° , the other between 235° and 236° , the portions of intermediate boiling point being quite insignificant. That which passes over above 230° solidifies for the most part very quickly by separation of solid nitrotoluene; the portion of lower boiling point does not solidify. The liquid nitrotoluene obtained in the manner just described is identical in physical and chemical properties with that obtained from dinitrotoluene; prepared in either way it boils at 222° – 223° , and has a specific gravity of 1.162–1.163 at 23° . The sulpho-acids, toluidines and acetotoluides, prepared from liquid nitrotoluene obtained in either way, likewise agree in their properties, but differ widely from the corresponding derivatives of solid nitrotoluene. For example, toluidine obtained from liquid nitrotoluene is also a liquid which does not solidify, and boils at 199° , whereas toluidine from solid nitrotoluene is crystalline, melts at 45° , and boils at 200° (*Zeitschr. f. Chem.* [2] v. 521).

Ammonium sulphate acts on nitrotoluene in the same manner as on nitrobenzene (p. 268), forming disulphuryl-toluylic acid, $C^6H^4NS^2O^4$ (Carius, *Jahresb.* 1861, p. 635).

Nitrobenzyl chloride, $C^6H^4(NO^2).CH^2Cl$, produced by dissolving benzyl chloride in fuming nitric acid, and freed from an oily body formed at the same time, by pressure and recrystallisation from alcohol, forms laminar crystals melting at 71° . By oxidation with chromic acid it is easily converted into paranitrobenzoic acid (Beilstein u. Geitner, *Ann. Ch. Pharm.* cxxxix. 331). According to Grimaux (*Bull. Soc. Chim.* [2] viii. 433), this compound melts at 73° , remains liquid till cooled to 60° , and then solidifies suddenly when touched, the temperature rising to 69° . Heated with alcoholic solution of potassium acetate, it is converted into nitrobenzyl acetate, $C^6H^4(NO^2).CH^2(C^2H^3O^2)$, which dissolves sparingly in boiling water, easily in alcohol and ether, and crystallises therefrom in thin shining laminae, melting at 85° . Benzyl acetate treated with fuming nitric acid yields a thick oil from which a white solid body may be separated.

Reduction-derivatives of Nitrotoluene.

Amidotoluene. $C^6H^4(NH^2).CH^3$.—See TOLUIDINE (v. 865, and in this volume).

Diazotoluene. $C^6H^4N^2$.—See AZOTOLUIDINE (v. 867).

Azotoluene: $C^6H^4N^2$. *Azotoluol.* *Azotoluid* (Werigo, *Zeitschr. Ch. Pharm.* 1864, pp. 481, 721; Jaworsky, *ibid.* 640).—Produced by the action of sodium-amalgam on nitrotoluene dissolved in aqueous alcohol. On acidulating with acetic acid and removing the unaltered nitrotoluene by distillation, the azotoluene remains as a soft red mass, which, after washing with cold and recrystallisation from hot alcohol, is obtained in shining orange-red needles. It melts at 137° , sublimes without decomposition, is insoluble in water, dilute acids and alkalis, but dissolves in strong sulphuric acid, and is precipitated therefrom by water. By the further action of sodium-amalgam, it is converted into hydrazotoluene, $C^6H^4N^2$.

Azotoluene, like azobenzene, unites directly with bromine, forming the compound $C^6H^4N^2Br^2$; but when bromine is added to a solution of azotoluene (such as that obtained in its preparation), a crystalline precipitate is formed, which after recrystallisation, with addition of animal charcoal, forms white shining laminae. This body has the composition $C^6H^4N^2Br^4$, and has one half of its bromine more intimately combined than the other half. It may be regarded as the tetrahydrobromide of hydrazotoluene, $C^6H^4N^2.4HBr$, or as the dihydrobromide of the diamine $C^6H^4Br^2N^2$. It dissolves in water and in alcohol, but not in ether; sublimes without residue in white needles; decomposes above 100° , with formation of red vapours; reacts strongly acid in aqueous solution; and forms with ammonia or soda a precipitate soluble in excess of the reagent. With chlorine, azotoluene forms the analogous compound $C^6H^4N^2Cl^4$.

On mixing a hot concentrated aqueous solution of the bromine-compound $C^6H^4N^2Br^4$ with a quantity of silver nitrate equivalent to half the bromine, the solution, after removal of the precipitated silver bromide, yields long needle-shaped crystals, soluble in water and alcohol, but not in ether, and consisting of the nitrate $C^6H^4Br^2N^2.2NO^3H$. The aqueous solution of the bromine-compound $C^6H^4N^2Br^4$ forms with caustic soda a white crystalline precipitate, which, after reprecipitation from alcoholic solution by water, forms long colourless needles, easily soluble in alcohol and ether, but only slightly in water. This compound is neutral, melts at 57.6° , and consists of $C^6H^4N^2Br^2$ (Werigo, *Zeitschr. f. Chem.* 1866, p. 631; 1866, p. 196; *Jahresb.* 1866, p. 466).

Nitrazotoluenes.—Nitric acid of sp. gr. 1.5, gradually added to cooled amotoluene,

converts it almost wholly into mononitrazotoluene, $C^4H^3(NO^2)N^2$, which crystallises from alcohol in two forms—first in reddish needles melting at 67° , afterwards in small yellow crystals melting at 63° . When, on the other hand, crystals of azotoluene are gradually added to strong nitric acid without cooling, two other bodies are formed, viz.: (1) *Trinitrazotoluene*, $C^4H^3(NO^2)N^2$, which dissolves with moderate facility in hot alcohol, and separates on cooling in thin yellow needles sparingly soluble in ether, and melting at about 185° .—(2) *Trinitrazoxytoluene*, $C^4H^3(NO^2)N^2O$, nearly insoluble in alcohol, but soluble in nitric acid and in benzol, and separating therefrom in sulphur-yellow crystals melting at 201° , and decomposing at a higher temperature with explosion and separation of charcoal (Petrieff, *Zeitschr. f. Chem.* [2] vi. 264).

Azotoluene, $C^4H^4N^2O$, is obtained, together with azotoluene, by the action of sodium-amalgam on nitrotoluene in alcoholic solution, and separates from the alcoholic mother-liquor in the form of a red oil (Jaworsky, *Jahresb.* 1864, p. 527). Petrieff (*Zeitschr. f. Chem.* [2] vi. 30) has more recently obtained it in red crystalline laminae melting at 57° , more soluble in alcohol than azotoluene, and therefore remaining in the mother-liquor after the latter has separated. By the further action of sodium-amalgam it is reduced to hydrazotoluene, $C^4H^4N^2$.

SULPHO-DERIVATIVES OF TOLUENE.

Toluene-sulphuric Acid. $C^7H^7.SO^2H$ (Engelhardt a. Latschinoff, *Zeitschr. f. Chem.* [2] v. 617).—Toluene heated with sulphuric acid yields two isomeric sulpho-acids. To prepare them, 500 grms. of pure toluene are heated for two days in the water-bath with an equal volume of fuming sulphuric acid; the resulting mass is dissolved in water and neutralised with lime; the filtered solution is freed from excess of sulphuric acid by barium hydrate; the excess of lime and baryta precipitated by carbonic acid; the filtered solution decomposed by potassium carbonate; and the solution of the potassium salts concentrated by evaporation. This solution, not too concentrated, deposits on slow cooling two potassium salts, α and β , sharply distinguished from one another by their crystalline forms; the former separating in large prismatic crystals; the latter, which is the more soluble of the two, in loose nodular groups of slender needles. They crystallise together, but may be mechanically separated by a sieve, the α salt remaining thereon, while the β salt passes through with the mother-liquor. The α salt is easily purified by recrystallisation from water; but the β salt can only be approximately purified by several crystallisations, first from water, afterwards from alcohol. To prepare the other salts of these two acids, the potassium salts are decomposed by sulphuric acid, and the separated acids are dissolved out by alcohol and neutralised with barium carbonate, &c.

α Toluene-sulphates.—The potassium salt $C^7H^7SO^2K.H^2O$ dissolves easily in hot water, and crystallises by slow cooling of the moderately concentrated solution, in beautiful elongated, six-sided tables, or long prisms resembling saltpetre; from highly concentrated solutions in long needles. It is soluble in hot alcohol, and crystallises therefrom in needles. The crystals effloresce in the air. The sodium salt crystallises from alcohol in shining laminae. The barium salt $(C^7H^7SO^2)^2Ba$ is easily soluble in boiling water, and crystallises on cooling in shining laminae. The calcium salt crystallises from alcohol in needles.

β Toluene-sulphates.—The potassium salt $2C^7H^7SO^2K.3H^2O$ is very soluble in water and in boiling alcohol, and crystallises from the former in nodular groups of slender needles, from the latter in shining laminae. The barium salt $(C^7H^7SO^2)^2Ba.H^2O$ is easily soluble in boiling water and crystallises in white nodules.

ORTHO-BROMOTOLUENE-SULPHURIC ACID, $(C^6H^4CH^2Br.SO^2H)$, is produced by heating toluene bisulphoxide with excess of bromine in sealed tubes and remains on evaporation as a yellow mass. Its barium salt, $(C^6H^4CH^2Br.SO^2)^2Ba.2H^2O$, forms beautiful laminae, very slightly soluble in water, and sustaining a heat of 200° without decomposition (Otto, Löwenthal a. Gruber, *Zeitschr.* [2] iv. 626). The calcium salt $(C^6H^4CH^2Br.SO^2)^2Ca.3H^2O$ crystallises from water in slender needles, which have a great tendency to creep over the sides of the vessel. When slowly crystallised from alcohol or water it forms thick, often crossed needles, having a silky lustre (Hübner a. Wallach, *ibid.* 502).

METABROMOTOLUENE-SULPHURIC ACID, $C^6H^3BrCH^3.SO^2H$.—Hübner a. Wallach (*Zeitschr. f. Chem.* [2] v. 500) describe two modifications of this acid—the one obtained from fluid, the other from crystallised bromotoluene; they may be distinguished by the prefixes *f* and *c*.

f **Metabromotoluene-sulphuric acid** is easily produced by dissolving liquid bromotoluene in fuming sulphuric acid; it salts crystallise well; the calcium salt

($C^6H^4BrSO^2$) $\cdot Ca.1\frac{1}{2}H^2O$ in tufts of delicate crystals which give off their water at 100° . The sodium salt $C^6H^4BrSO^2Na$ crystallises from water in nodular groups of needles, from alcohol in transparent laminae. The crystals contain water, which escapes so easily that its amount could not be determined.

c *Metabromotoluene-sulphuric acid*, prepared from solid bromotoluene, crystallises from water or ether in very small colourless needles or plates, which appear obliquely-angled under the microscope. A very concentrated solution of solid bromotoluene in fuming sulphuric acid, mixed with a small quantity of water, deposits the acid on cooling in small shining laminae. The lead salt of this acid, ($C^6H^4BrCH^3SO^2$) $\cdot Pb$, crystallises in furcate groups of long transparent needles, which in thick layers appear opaque and exhibit a fine satiny lustre. The sodium salt, crystallised from alcohol, forms small needles, passing by slower crystallisation into large very thin plates; they also give off their water of crystallisation too easily to allow of its exact determination.

f *Metabromotoluene-sulphochloride*, $C^6H^4BrCH^3\cdot SO^2Cl$, is produced by heating the sodium salt of the corresponding sulpho-acid with phosphorus pentachloride. On adding water to the product the sulphochloride separates as a light brown fetid oil, which does not solidify even in a freezing mixture. It dissolves easily in alcohol.

c *Metabromotoluene sulphochloride* from solid bromotoluene, does not differ sensibly from the compound just described.

CHLOROTOLUENE-SULPHURIC ACID, $C^6H^4Cl\cdot SO^2H$, is formed, as above mentioned, by the action of chlorine on toluene bisulphoxide suspended in water, and remains on evaporation as a colourless syrup, gradually crystallising over oil of vitriol. The barium salt of this acid crystallises in splendid shining flat needles, almost an inch long, very slightly soluble in cold water, and consisting of ($C^6H^4ClSO^2$) $\cdot Ba.2H^2O$ (Otto, Löwenthal a. Gruber).

1. NITROTOLUENE-SULPHURIC OR SULFONITROTOLUOLIC ACID. $C^6H^4(NO^2)\cdot SO^2H$.—This acid has been supposed to exhibit two modifications, accordingly as it is prepared on the one hand by the action of sulphuric acid on nitrotoluene (Jaworsky), or on the other by the oxidation of metabenzylsulphhydrate with nitric acid (Märcker), or by the action of fuming nitric acid on toluene-sulphurous acid (Otto); see vol. v. p. 880. These acids have been further examined by Engelhardt a. Beck (*Zeitschr. f. Chem.* [2] v. 209) with the following results: (1) The barium salt of Jaworsky's acid has the same composition as that of Märcker's acid, viz. [$C^6H^4(NO^2)SO^2$] $\cdot Ba.2H^2O$. This salt is sparingly soluble in cold water.—(2) In the action of nitric acid on toluene-sulphurous acid, there is obtained, as principal product, a nitrotoluene-sulphuric acid, not differing in any essential particular from the acid obtained from nitrotoluene.—(3) The nitro-acid obtained from either source yields, by reduction with hydrogen sulphide, one and the same amidotoluene-sulphuric acid, which is different from the two sulpho-acids obtained by the action of sulphuric acid upon toluidine (p. 288). (4) The action of nitric acid on toluene-sulphurous acid likewise yields, as a secondary product, another nitro-acid, which, when reduced by hydrogen sulphide, yields an amidated acid very similar to the toluidine-sulphuric acids just mentioned. The barium salt of this nitro-acid, which was not obtained pure, remains in solution after the above-mentioned sparingly soluble barium salt has crystallised out.

Nitrotoluene-sulphochloride, $C^6H^4(NO^2)SO^2Cl$, produced by the action of 1 mol. phosphorus pentachloride on 1 mol. sodium nitrotoluene-sulphate, is a yellowish oil, insoluble in water, but easily soluble in alcohol and ether, and is decomposed by alkalis, with formation of nitrotoluene-sulphuric acid (Otto a. v. Gruber, *Jahresb.* 1867, p. 678).

Nitrotoluene-sulphamide or *Nitrosulphotolulolamide*, $C^6H^4(NO^2)NSO^2$, produced by the action of ammonia on the sulphochloride, crystallises in four-sided rhombic prisms or long needles, which melt at 120° , and dissolve readily in hot water and alcohol (Otto a. v. Gruber).

2. AMIDOTOLUENE-SULPHURIC ACID, $C^6H^4(NH^2)SO^2$, is prepared by saturating the solution of ammonium nitrotoluene-sulphate in ammonia with hydrogen sulphide, boiling the solution to expel the excess of ammonium sulphide, mixing the filtered liquid with hydrochloric acid at the boiling heat, again concentrating, and filtering to separate any sulphur that may still be present. On cooling, the amidated acid separates in slightly coloured prismatic crystals, which may be purified by treatment with animal charcoal and recrystallisation. Amidotoluene-sulphuric acid is sparingly soluble in cold, more easily in boiling water, almost insoluble in alcohol, and crystallises from the aqueous solution by slow cooling, in long shining four-sided prisms with end-faces, by rapid cooling in needles, the crystals in both cases containing

$C^6H^4(NH^2)SO^2 \cdot H^2O$. The acid decomposes carbonates, and its solutions have a strong acid reaction. Its salts are easily soluble in water and crystallise well. On adding silver nitrate to the solution of an amidotoluene-sulphate, and heating to the boiling point, metallic silver separates, and the solution turns violet. The *barium salt* $2[C^6H^4(NH^2)SO^2]^2Ba \cdot 5H^2O$ crystallises in beautiful tables; the *calcium salt* $[C^6H^4(NH^2)SO^2]^2Ca \cdot 2H^2O$, in shining six-sided tables; the *potassium salt* $C^6H^4(NH^2)SO^2K \cdot H^2O$ is easily soluble in water; the *sodium salt* $C^6H^4(NH^2)SO^2Na \cdot 4H^2O$ crystallises from a boiling alcoholic solution in shining flat needles.

The ammonium salt of the nitrotoluene-sulphuric acid corresponding to the easily soluble barium salt above mentioned, yields in like manner by reduction with hydrogen sulphide, a small quantity of an amidotoluene-sulphuric acid which crystallises in rhombic tables, and closely resembles β -sulphotoluidic acid (Engelhardt & Beck).

TOLUIDINE-SULPHURIC OR SULPHOTOLUIDIC ACID. $C^6H^4NSO^3$ (Malyseff, *Zeitschr. f. Chem.* [2] v. 212).—An acid of this composition (sulphotoluidic acid) was obtained by Sell (v. 527) by heating toluidine with fuming sulphuric acid, together with another acid which he regarded as toluidine-disulphuric (benzylidylsulphamic) acid. Malyseff has found, however, that the two acids thus obtained are isomeric, both having the composition $C^6H^4NSO^3$, and being likewise isomeric with Beck's amidotoluene-sulphuric acid.

In preparing these acids it is of special importance to regulate the heat carefully, as if it rises too high, the mass chars, and if the heat is insufficient, nothing but toluidine sulphate is obtained. The product of the properly conducted action is a black thick liquid, which, when diluted with water and left to itself, deposits a black crystalline mass, to be decolorised by solution in boiling water and treatment with animal charcoal. The solution filtered at the boiling heat deposits on cooling slender needles of α -toluidine-sulphuric acid and large well-defined rhombic plates of β -toluidine-sulphuric acid, which may be separated from one another, first by levigation—the α -acid being carried away by the water more easily than the β -acid—and finally by recrystallisation, the α -acid dissolving more readily than the β -acid when hot water is poured upon the mixed crystals of the two.

α *Toluidine-sulphuric acid*, $C^6H^4NSO^3 \cdot 1\frac{1}{2}H^2O$ (air-dried), the acid described by Sell, crystallises in slender light yellow needles, which cannot be completely decolorised by animal charcoal; it is moderately soluble in cold, more easily in boiling water. The *barium salt* $5(C^6H^4NSO^3)^2Ba \cdot 8H^2O$ dissolves easily in boiling water, somewhat less easily in cold water, and crystallises from a hot solution on cooling in beautiful shining plates, which do not give off their water over oil of vitriol. The *silver salt* $C^6H^4NSO^3Ag$ forms colourless shining laminae. The *potassium salt* $C^6H^4NSO^3K \cdot \frac{1}{2}H^2O$ crystallises in needles or in elongated six-sided plates, very soluble in boiling, somewhat less in cold water and alcohol.

β *Toluidine-sulphuric acid*, $C^6H^4NSO^3 \cdot H^2O$, is formed in larger quantity than the α -acid in the process above described. It is very slightly soluble in cold, moderately soluble in boiling water, and crystallises in fine large shining rhombic plates, which are commonly yellowish, but may be decolorised by animal charcoal. The aqueous solution has an acid reaction and dissolves carbonates, with evolution of carbon dioxide. The salts of the β -acid are easily soluble in water; the solutions, when evaporated over the water-bath, decompose partially and turn red. On adding *silver nitrate* to the ammoniacal solution of the β -acid, and warming, silver separates in the specular form, and the liquid acquires a violet-red colour.

Potassium salt, $C^6H^4NSO^3K$,	shining six-sided laminae.
Ammonium „	colourless laminae.
Barium „ $(C^6H^4NSO^3)^2Ba \cdot 3H^2O$,	shining laminae.
Lead „ $(C^6H^4NSO^3)^2Pb$,	crystalline powder.

Toluene-sulphurous Acid. $C^6H^5SO^2 = C^6H^5 \cdot SO^2H$.—The following additional observations on this acid have been made by Otto & v. Gruber (*Ann. Ch. Pharm.* cxlv. 10; *Jahresb.* 1867, p. 678). A mixture of this acid with phosphorus pentachloride in equivalent quantities forms, with violent action, a liquid mass, which solidifies on cooling, and when treated with water yields (together with a small quantity of an oily product) toluene-sulphochloride, $C^6H^5SO^2Cl$, melting after recrystallisation from ether at 69° – 70° . Toluene-sulphurous acid is not acted upon by sodium-amalgam in alkaline solution; heated with water to 130° , it is resolved into oxybenzylidylsulphide and toluene sulphuric acid:

Heated to 300° with potassium hydrate, it is resolved into potassium sulphite and toluene:

From a solution of toluene-sulphurous acid in fuming nitric acid, a compound $\text{C}^7\text{H}^7\text{N}^2\text{S}^2\text{O}^6$, called diazotrisulphotoluene hydride, is precipitated, whilst nitrotoluene-sulphuric acid, $\text{C}^7\text{H}^7(\text{NO}^2)\text{SO}^2$, remains in solution. The diazo-compound is insoluble in water, slightly soluble in hot alcohol, easily in benzol, and crystallises from the latter in white hard rhombic tablets, melting at 190°. The same compound is produced by the prolonged action of nitrous acid on an aqueous or alcoholic solution of toluene-sulphurous acid, its formation in this latter case being preceded by that of another azotised body of lower melting point, which crystallises out first on cooling. The formation of diazotrisulphotoluene hydride is represented by the equations,

Nitrotoluene-sulphurous Acid. $\text{C}^7\text{H}^7(\text{NO}^2)\text{SO}^2$.—The sodium salt of this acid, $\text{C}^7\text{H}^7(\text{NO}^2)\text{SO}^2\text{Na}$, $\frac{1}{2}\text{H}^2\text{O}$, is produced by the action of sodium-amalgam on a solution of nitrotoluene-sulphochloride in pure ether. It is easily soluble in water and in hot alcohol, and crystallises in feathery tufts of striated needles (Otto a. Gruber).

Sulphotoluide. $\text{C}^7\text{H}^7\text{SO}^2 = \text{C}^7\text{H}^7(\text{CH}^3) - \text{SO}^2 - \text{C}^7\text{H}^7(\text{CH}^3)$.—First obtained by Deville (*Ann. Ch. Pharm.* xlv. 306); further examined by Otto a. Gruber (*Zeitschr. f. Chem.* [2] vi. 33). Prepared like sulphobenzide by passing vapour of sulphuric anhydride into toluene:

On pouring the oily mass into water, washing the precipitate with water, and crystallising from benzol, sulphotoluide is obtained in transparent clinorhombic prisms having a vitreous lustre; from hot alcohol it crystallises in small tabular prisms. It melts at 155°–156°, is insoluble in water, slightly soluble in cold alcohol and ether, more freely in boiling alcohol and in benzol, chloroform, and carbon bisulphide. When heated in small quantities, it volatilises without decomposition. Heated with strong sulphuric acid, it dissolves as toluene-sulphuric acid. Red fuming nitric acid dissolves it without decomposition, but a mixture of this acid with sulphuric acid converts it, with aid of heat, into crystallisable nitro-derivatives. It is not altered by heating to 160° with alcoholic potash. With chlorine and phosphorus pentachloride, it appears to react like sulphobenzide, but the products are less definite and have not been thoroughly examined (Otto a. Gruber).

Tolyl Bisulphoxide. $\text{C}^7\text{H}^7\text{S}^2\text{O}^2$ (Otto, Löwenthal a. Gruber, *Zeitschr. f. Chem.* [2] iv. 623).—This compound, first obtained by Märcker (benzyl-dioxy-sulphide, v. 859) by oxidising toluene sulphhydrate with nitric acid, was afterwards prepared by Otto a. von Gruber (*Zeitschr.* [2] iii. 600, 611) by heating toluene-sulphurous acid with water to 120°–130° in sealed tubes:

It is insoluble in water, but dissolves easily in boiling alcohol, ether, and benzol, and crystallises in large transparent glassy crystals resembling the scalenohedrons of calc spar and melting at 76° (not at 74° as stated by Märcker). By nascent hydrogen (evolved either by zinc and sulphuric acid or by sodium-amalgam) it is converted into tolyl sulphhydrate: $\text{C}^7\text{H}^7\text{S}^2\text{O}^2 + 3\text{H}^2 = 2\text{H}^2\text{O} + 2\text{C}^7\text{H}^7\text{S}$. By boiling with alcoholic potash, it is converted into toluene-sulphite and toluene-sulphate of potassium, which dissolve, and toluene bisulphide (or metabenzylie bisulphide, v. 659), which remains undissolved:

Tolyl bisulphide is not attacked by boiling potash. Fuming sulphuric acid colours it first yellow and then green in the cold, and dissolves it on warming to a deep indigo-coloured liquid which is decolorised by water.

Sup.

U

Bromide of Toly Bisulphoxide. $(C^1H^1S^2O^2)^2Br^2$.—Obtained by dropping 1 at. bromine into a molecule of the bisulphoxide suspended in water, and heating the liquid to the melting point of the bisulphoxide. Small white needles insoluble in water, easily soluble in ether and in benzol. By boiling with strong aqueous ammonia, it is resolved into ammonium bromide, sulphotoluamide (v. 527), and tolyl bisulphide:

With strong aqueous potash, it yields bromide, toluene-sulphite, and toluene-sulphate of potassium, together with tolyl bisulphide, probably in two stages, the first consisting in the formation of potassium toluene-sulphite and tolyl bisulphoxide:

and the second in the conversion of the bisulphoxide into toluene-sulphurous acid, toluene-sulphuric acid, and tolyl bisulphide, in the manner already explained.

Toly bisulphide exposed for some time under water at 100° to the action of bromine in excess is oxidised to tolyl sulphobromide (i. 859):

Heated for an hour or two with excess of bromine and water in sealed tubes, it dissolves almost completely as bromotoluene-sulphuric or sulphobromotoluic acid:

Chlorine acts on the bisulphoxide in the same manner as bromine, but more energetically. On passing the gas into water at about 80° in which tolyl bisulphoxide is suspended, long needles of tolyl sulphochloride, $C^1H^1ClSO^2$ (i. 859), melting at 68° , sublime in the stream of chlorine, and the bisulphoxide gradually dissolves, leaving only a very small residue of secondary products, while the solution contains chlorotoluene-sulphuric acid, $C^1H^1ClSO^3$.

Toly Sulphide. $C^1H^1S = (C^1H^1)^2S = \frac{C^1H^1(CH^3)}{C^1H^1(CH^3)}S$, may be obtained by distilling the lead-compound of the sulphhydrate, $(C^1H^1)^2PbS^2 = PbS + (C^1H^1)^2S$, and is easily purified by redistillation. It is a colourless oil, smelling like the sulphhydrate, heavier than water, insoluble therein, easily soluble in absolute alcohol, ether, and benzeno (Otto, Löwenthal a. v. Gruber, *loc. cit.*).

Toly Sulphhydrate. $C^1H^1S = C^1H^1(SH).CH^3$. *Metabenzyl Sulphhydrate. Cresylia Mercaptan* (v. 858).—In preparing this compound by the action of zinc and sulphuric acid on tolyl sulphochloride, the zinc often becomes enveloped by the sulphochloride in such a manner as greatly to interfere with the action. To avoid this inconvenience, it is best, first to convert the sulphochloride into the sodium salt of toluene-sulphurous acid by the action of sodium-amalgam, and distil the aqueous solution of this salt—without previous separation of sodium chloride—with zinc and dilute sulphuric acid. The process thus modified yields almost the theoretical quantity of tolyl sulphhydrate. The same compound is produced by the action of nascent hydrogen on tolyl bisulphoxide (Otto, Löwenthal a. Gruber, *Zeitschr.* [2] iv. 623, 628).

Metabromotoly Sulphhydrate, $C^1H^1Br(SH).CH^3$, is obtained in two modifications—fluid (f) and crystalline (c)—by the action of nascent hydrogen on the corresponding sulphochlorides (p. 287) (Hübner a. Wallach, *Zeitschr. f. Chem.* [2] v. 500).

f *Metabromotoly Sulphhydrate* may be prepared by boiling the corresponding sulphochloride with zinc and sulphuric acid, but much more quickly with tin and hydrochloric acid: it may be conveniently distilled off the metallic chloride by means of a current of steam. It is a mobile liquid, of disagreeable odour, not solidifying at -20° ; it may be dried over calcium chloride or potassium hydrate, and then boils, with slight decomposition, at 215° – 216° . Insoluble in water, easily soluble in alcohol; dissolved by strong sulphuric acid, with fine blue colour and copious evolution of sulphurous oxide. The hydrogen-atom of the SH group is easily exchanged for metals, forming amorphous salts which are distinguished by very sparing solubility in water and for the most part also in alcohol.

f *Metatoly Sulphhydrate*, $C^1H^1CH^3.SH$, is produced by agitating the preceding compound for several days with sodium-amalgam. It is also a mobile oil having a pungent odour like that of the brominated compound, but stronger. Boils constantly and without decomposition at 187° – 188° , and does not solidify in a freezing mixture. Towards solvents and metallic solutions it behaves like the brominated sulphhydrate, but its salts are much more soluble.

c *Metabromotoly Sulphhydrate* prepared from the corresponding sulphochloride with tin and hydrochloric acid, boils, not quite without decomposition, at 245° , and

solidifies at about 7° to a white radio-crystalline mass. Its salts resemble those of the corresponding sulphydrate obtained from liquid bromotoluene.

c Metatolyl Sulphydrate, obtained from the last compound by the action of sodium-amalgam, boils at 188° and solidifies in a freezing mixture to a splendid, perfectly uniform, colourless crystalline mass, melting at about 2°. Its salts do not differ perceptibly from those of the corresponding sulphydrate obtained from liquid bromotoluene.

The following table gives a comparative view of the physical properties of these metatolyl sulphydrates and their salts, together with those of orthotolyl sulphydrate (Märcker's metabenzyl sulphydrate, v. 858), and of benzyl sulphydrate or benzylic mercaptan :

	Benzylsulphydrate	Orthotolyl sulphydrate	Metatolyl sulphydrate from liquid bromotoluene	Metatolyl sulphydrate from solid bromotoluene
Boiling point .	194°-195°	188°	188°	188°
Melting point		42.5° Crystallises very easily in large laminae.	Still fluid at -20°.	+ 2 Crystallises in beautiful broad transparent needles.
Solubility .	Soluble in alcohol.	Insol. in water; sol. in alcohol; dissolving in strong sulphuric acid with splendid blue colour.		
Lead salt .	Light yellow laminae	Orange-yellow flocks, decomposable by light.	Deep yellow; amorphous. Melts at about 70°; not altered by light; white needles with fine lustre.	Deep yellow; amorphous. Melts at 76°-78°; not altered by light; white needles with fine lustre.
Mercury salt .	Long silky needles.	White laminae decomposable by light.	Melts at 100°; not altered by light.	Melts at 123°-126°; not altered by light.
Silver salt .	White.	Sickin-green.	Light yellow.	White (soon turning yellow).
Copper salt .	Green.	Green.	Dirty yellow.	Dirty yellow.
Reaction with nitric acid .	Yields sulphuric acid, small quantities of benzoic acid and benzoic aldehyde.	Yield small quantities of sulphuric acid.		

Hydrocarbons C⁸H¹⁰. Xylenes.

This formula admits of the two metameric modifications:

the second of which is further susceptible of isomeric modification, as *ortho*-, *meta*-, and

para-, according to the relative position of the two methyl-atoms, viz. 1 : 2, 1 : 3, 1 : 4.

Ethyl-benzene. $C^6H^5.C^2H^5$.—The synthetical formation of this body by the action of sodium on a mixture of monobromobenzene and ethyl bromide has been already noticed (v. 1056). It is also produced, together with diethyl-benzene and a small quantity of benzene, by heating naphthalene for some time with 20 pts. of saturated aqueous hydriodic acid :

(Berthelot, *Bull. Soc. Chim.* [2] ix. 289.) See NAPHTHALENE. Also by heating cinnamene (styrol), C^9H^8 , with 20 pts. of hydriodic acid (Berthelot, *Jahresb.* 1867, p. 349).

Ethyl-benzene is almost completely decomposed when its vapour is passed through a red-hot tube, yielding cinnamene with smaller quantities of benzene, toluene, naphthalene, and naphthalene hydride, $C^{10}H^{10}$:

(Berthelot, *Zeitschr. f. Chem.* [2] iv. 589).

By prolonged oxidation with dilute nitric acid, or by chromic acid, ethyl-benzene is converted into benzoic acid, without previous formation of α -toluic acid (Fittig a. König, *Jahresb.* 1867, p. 609).

The *bromo-* and *nitro-*derivatives of ethyl-benzene are partly described in vol. v. pp. 1057, 1058.

Bromethyl-benzene, $C^6H^4Br(C^2H^5)$, has a sp. gr. of 1.34 at 35° and boils at 199° . By oxidation with chromic acid mixture it yields parabromobenzoic acid (Fittig a. König). By the action of carbon dioxide and sodium it is converted into ethyl-benzoic acid, isomeric with xylie (dimethyl-benzoic acid) (Kekulé, *Ann. Ch. Pharm.* cxxxvii. 178; Kekulé a. Thorpe, *Chem. Soc. J.* [2] vii. 366):

Beilstein a. Kuhlberg (*Zeitschr. f. Chem.* [2] v. 524) have recently demonstrated the existence of two modifications of *mononitro-ethyl-benzene*. When nitric acid of sp. gr. 1.475 is added to ethyl-benzene till a clear solution is formed, and the product after washing with water and ammonia, is distilled, it passes over on the first distillation at 226° – 251° , and if then fractionated twenty times at intervals of 2° , separates almost entirely into two portions, viz. α and β , both of which are liquids not solidifying even in a freezing mixture. α -*nitroethylbenzene* boils at 245° – 246° , has a sp. gr. of 1.124 at 25° , and is easily oxidised by chromic acid mixture yielding nitrodracrylic acid. β -*nitroethylbenzene* boils at 227° – 228° , has a sp. gr. of 1.126 at 24.5° , and when treated with the chromic acid mixture does not yield any acid, but if the action be continued, suffers complete combustion.

The xylidines and sulpho-acids obtained from these two nitroethylbenzenes likewise exhibit different properties. The α -*xylidine*, $C^6H^4(NH^2).C^2H^5$, is a clear liquid of sp. gr. 0.975 at 22° , boiling at 213° – 214° , and quickly becoming brown in contact with the air. The β -*xylidine* has a sp. gr. of 0.975 at 22° , boils at 210° – 211° , and also becomes coloured on exposure to the air. Of the aceto-xylides $C^6H^5.C^2H^4NH(C^2H^3O)$ formed by continuous boiling of these bases with acetic acid, the α modification melts at 94° , boils at 315° – 317° , and is very slightly soluble in boiling water, whereas the β modification boils at 304° – 305° , and dissolves very easily in boiling water.

The α and β sulpho-acids are produced by very prolonged contact of the corresponding nitroethylbenzenes with fuming sulphuric acid at 100° . The barium salt of the α sulpho-acid crystallises in broad flat needles half an inch long, containing water of crystallisation and very slightly soluble in cold water. The barium salt of the β sulpho-acid crystallises in shining silver-white anhydrous laminae, also very slightly soluble in cold water.

Dimethyl-benzene or Xylene. $C^6H^4(CH^3)^2$.—The three modifications of this hydrocarbon are represented by the following formulæ :

Orthoxylene (1 : 2).

Metaxylene (1 : 3).

Paraxylene (1 : 4).

Xylene from coal-tar was formerly supposed to be identical with methyl-toluene produced synthetically by the action of sodium on a mixture of monobromotoluene and methyl iodide (v. 1056); but in 1867, Fittig, Ahrens, and Matthies (Ann. Ch. Pharm. cxlvii. 15) showed that the brominated, nitrated, and amidated derivatives of methyl-toluene differ in many important particulars from those of coal-tar xylene, so that these two hydrocarbons must be regarded as isomeric, not identical. In the same year, Fittig and Velguth (Zeitschr. f. Chem. [2] iii. 526), by heating mesitylenic acid, $C^9H^{10}O_2$, with lime, obtained a modification of the hydrocarbon C^9H^{10} , which they called isoxylene:

This hydrocarbon differs from methyl-toluene in not being oxidised, or but very slowly, by dilute nitric acid, and not yielding toluic acid, whereas that acid is easily obtained by oxidising methyl-toluene with nitric acid. When oxidised with chromic acid, it yields, not pulverulent terephthalic acid, but an isomeric compound, *isophthalic acid*, which crystallises in long slender needles, nearly insoluble in cold, very slightly soluble in hot water, easily soluble in alcohol. Quite recently (1869) Fittig has shown (Zeitschr. [2] v. 19) that coal-tar xylene is not a definite substance, but a mixture of methyl-toluene and isoxylene, the latter greatly predominating. By oxidation with potassium dichromate and sulphuric acid, Fittig obtained isophthalic acid and a small quantity of terephthalic acid, which were separated by means of boiling water, the terephthalic acid being nearly insoluble therein. Nearly half of the hydrocarbon, however, remained unattacked after 12 to 14 hours' treatment with the oxidising mixture, and this, after further oxidation for 16 hours, was for the most part converted into isophthalic acid with only a very minute quantity of terephthalic acid. The result showed that the coal-tar xylene examined contained about 90 p. c. of isoxylene, the rest consisting of methyl-toluene.

As isoxylene is formed by the decomposition of mesitylenic acid, the two methyl-atoms in its molecule have in all probability the arrangement 1 : 3, whereas in methyl-toluene, which corresponds to parachlorobenzoic acid, &c., the arrangement of the methyl-atoms is 1 : 4 (p. 199). In other words, the so-called isoxylene is a meta-compound, and is better designated as *metaxylene* or *metadimethyl-benzene*; and methyl-toluene is a para-compound, and may be called *paraxylene* or *paradimethyl-benzene*.

Now it has been shown by Fittig, Laubinger, and Jannasch (Zeitschr. f. Chem. [2] iii. 577) that when an additional methyl-atom is introduced into dimethyl benzene, the compound obtained—the so-called *pseudocumene*, $C^9H^{10}(CH^3)^3$ —is identically the same whether the dimethylbenzene used be synthetically prepared methyl-toluene, or coal-tar xylene; hence, according to the results above explained, the pseudocumene obtained will be the same, whether prepared for iso- or meta-xylene, or from paraxylene (methyl-toluene). Consequently in the trimethyl-benzene or pseudocumene obtained from either source the three methyl-atoms must exhibit the arrangement 1 : 3 : 4. Further, pseudocumene, when oxidised with dilute nitric acid, yields simultaneously two isomeric acids, *xylic* and *paraxylic*, $C^9H^8O_2$, which can differ from one another constitutionally only in this respect, that of the three methyl-atoms in pseudocumene, *one* has been converted into carboxyl, CO_2H , in the formation of *xylic*, and *another* in the formation of *paraxylic* acid. Pseudocumene must therefore contain two equally oxidisable methyl-atoms. To determine which two out of the three possess this character, and which of the two is concerned in the formation of *xylic* or *paraxylic* acid respectively, it is necessary to remove the carboxyl groups from the two acids, and observe what modifications of dimethyl-benzene are thereby produced. Now when *xylic* acid prepared from synthetically formed pseudocumene is moderately heated with quicklime, it yields a distillate which, after one rectification, exhibits all the characters of pure metaxylene, boiling at $137^\circ-138^\circ$, giving isophthalic acid by oxidation with chromic acid, and not being attacked by dilute nitric acid.

Since then in metaxylene the methyl-atoms have the places 1 : 3, it follows that in the formation of xylic acid from pseudocumene, the methyl-atom standing at the place 4 must have been oxidised to carboxyl; and from this it may be inferred that in the formation of paraxylic acid, the methyl-atom standing either at 1 or at 3 must have been oxidised to carboxyl. If in this acid the carboxyl group CO^2H stands at the place 3, its removal must yield methyl-toluene or paraxylene (1 : 4); in the contrary case a third hitherto unknown modification of dimethyl-benzene, viz. orthoxylyene (1 : 2), must be formed. Now it has quite recently been shown by Bieler u. Fittig (*Zeitschr. f. Chem.* [2] v. 495) that paraxylic acid heated with quicklime yields a hydrocarbon C^8H^{10} differing both from para- and from meta-xylene. The decomposition of the paraxylic acid requires a very high temperature, but nevertheless takes place quite definitely, the hydrocarbon which distils off being obtained pure after one rectification. This hydrocarbon, orthoxylyene, boils constantly at $140^\circ\text{--}141^\circ$, that is to say, 3° higher than metaxylene, and has a peculiar odour, much less agreeable than that of meta- or of para-xylene. It is most readily distinguished from these two modifications by its behaviour with a mixture of nitric and sulphuric acids, para- and meta-xylene being easily and rapidly converted thereby at a gentle heat into well-crystallised trinitro-compounds; whereas from orthoxylyene it is very difficult to obtain a solid nitro-compound (*infra*).

Dilute nitric acid slowly oxidises orthoxylyene to a volatile acid, isomeric with toluic acid, which may be called *orthotoluic acid*. (See TOLUIC ACID.)

Xylene is produced, together with other hydrocarbons of the series, in the dry distillation of camphor (B. P. $138^\circ\text{--}143^\circ$), and of the lime-soap of Menhaden oil (B. P. $140^\circ\text{--}144^\circ$).

By *hydriodic acid* xylene appears to be converted into octane, C^8H^{18} (Berthelot, *Jahresb.* 1867, p. 347); by *phosphonium iodide*, PH_4I , into dimethyl-benzolin, C^8H^{14} (Baeyer, *Zeitschr.* [2] iv. 455).

In the animal organism it is converted into a peculiar modification of toluic acid (Schultzen u. Naunyn, *ibid.* 29).

BROMOXYLENES.—*Dibromometaxylene*, $\text{C}^8\text{H}^4\text{Br}_2 \cdot 2\text{CH}_3$, formed by treating coal-tar xylene for twenty-four hours with excess of bromine, crystallises from alcohol in macerous laminae, melts at 69° , boils without decomposition at $255^\circ\text{--}256^\circ$, and does not give up any of its bromine to alcoholic potash at the boiling heat. Paradi-dibromoparaxylene (from methyl-toluene) differs from the preceding only by its higher boiling point ($72^\circ\text{--}73^\circ$) (Fittig, Ahrens u. Mattheides, *Ann. Ch. Pharm.* cxlvii. 15; *Jahresb.* 1867, p. 697).

CHLOROXYLENES. See vol. v. p. 1057.

NITROXYLENES.—The properties of the nitrometa- and nitropara-xylenes, as determined by Fittig, Ahrens, u. Mattheides, agree for the most part with those previously obtained by Glinzer u. Fittig (v. 1058); but the former have further obtained two modifications of dinitroparaxylene from artificially prepared methyl-toluene [? arising from different distribution of the two atoms of NO^2].

Dinitrometaxylene (from coal-tar xylene) crystallises from alcohol in colourless, generally flattened, needles, easily soluble in hot, slightly in cold alcohol, melting at 93° .

Dinitro-paraxylene is separated by repeated crystallisation from alcohol into two modifications, α and β , the former, which is the less soluble, crystallising in very brittle needles an inch long, melting at 123.5° , the latter in rather large monoclinic crystals, melting like dinitrometaxylene at 93° .

Trinitrometaxylene, $\text{C}^8\text{H}^3(\text{NO}^2)^3$, is very easily formed by gently heating coal-tar xylene with a mixture of nitric and sulphuric acids; it is very slightly soluble in boiling, nearly insoluble in cold alcohol, and crystallises in thin, sometimes flattened needles, melting at $176^\circ\text{--}177^\circ$. *Trinitroparaxylene*, from methyl-toluene, is much more soluble in hot alcohol, and crystallises in larger needles, melting at 137° (Fittig, Ahrens u. Mattheides). *Trinitro-orthoxylyene* differs from the other two modifications in being much more difficult to crystallise. When orthoxylyene is heated for an hour with the nitrating mixture, and the product poured into water, the mass which separates is almost wholly fluid, and even after six or eight hours' action, with a large excess of the acid mixture, only a semifluid mass is obtained, which gradually solidifies, and yields by solution in a little alcohol and evaporation in a vacuum, groups of small colourless crystals melting at 55° , and afterwards drops of oily liquid (Bieler u. Fittig).

Nitrobromoxylyene, $\text{C}^8\text{H}^4\text{NO}^2\text{Br}$, prepared by dissolving monobromoxylyene (B. P. $203^\circ\text{--}204^\circ$) in cooled fuming nitric acid, is a slightly yellow liquid, which turns reddish on exposure to light, and boils, with partial decomposition, at $260^\circ\text{--}265^\circ$.

Nitrodibromo-metaxylene, $C^6H^4(NO^2)Br^2$, crystallises from alcohol in long needles, melting at 108° . **Nitrobromo-paraxylene**, which is very similar to the latter, melts at about 112° (Fittig, Ahrens a. Mattheides).

AMIDOXYLENES. See **XYLIDINES**.

AZOXYLENE. $C^6H^4N^2$.—Produced by the action of sodium-amalgam on nitroxylene. Crystallises in brick-red needles, easily soluble in alcohol and ether; melts at 120° , and volatilises completely at higher temperatures, producing a vapour having the colour of that of bromine. Treated with excess of sodium-amalgam it is converted into a colourless body, which easily sublimes in needles; probably hydrazoxyylene (Werigo, *Zeitschr. Ch. Pharm.* 1865, p. 312).

Sulpho-derivatives of Xylene.

XYLENE-SULPHUROUS ACID, $C^6H^4SO^2H$, prepared by the action of sodium-amalgam on an ethereal solution of xylene-sulphochloride (v. 1058), is a faintly yellowish inodorous thickish oil, slightly soluble in boiling water, easily soluble in alcohol, ether, and benzol, not volatile without decomposition. It absorbs oxygen from the air, but much less quickly than benzene- or toluene-sulphurous acid, passing into xylene sulphuric acid. Its salts are not altered by oxygen. The *potassium* and *sodium salts* are easily soluble in water. The *barium salt* $(C^6H^4SO^2)^2Ba \cdot 2H^2O$ forms small white laminae easily soluble in water, less soluble in alcohol. The *calcium salt* is similar in composition and properties. The *silver* and *lead salts* are heavy white precipitates slightly soluble in water. The *ethyl ether* $C^6H^4SO^2C^2H^5$, obtained by boiling the acid with alcohol containing hydrochloric acid, is at ordinary temperatures an amber-yellow, scarcely fluid, nearly inodorous mass, not volatile without decomposition, insoluble in water, easily soluble in alcohol and ether.

Xylene-sulphurous acid is converted by *chlorine* into xylene-sulphochloride, $C^6H^4SO^2Cl$; by *zinc* and *sulphuric acid* into xylol sulphhydrate, $C^6H^4(SH)$; by melting *potash* into potassium sulphite and xylene; by *nitrous acid*, in alcoholic solution, into nitroxylene-sulphuric acid, and a resinous mass probably containing xylene-sulphurous ether. Heated with *water* in a sealed tube, it yields xylene-sulphuric acid and xylol oxysulphide:

Xyloxyxysulphide, $C^6H^4S^2O^2$, is a yellowish inodorous oil, insoluble in water and in aqueous alkalis, soluble in ether, alcohol, and benzol. Nascent hydrogen quickly converts it into xylene sulphhydrate: $C^6H^4S^2O^2 + H^2 = 2H^2O + 2C^6H^4S$. Its alcoholic solution is not precipitated by silver or lead salts. With bromine it forms an uncrystallisable substitution-product, which is insoluble in water, soluble in ether and in alcohol, and dissolves partially in aqueous ammonia, forming ammonium bromide, and an amide which crystallises from the hot solution on cooling (Lindow a. Otto, *Zeitschr. f. Chem.* [2] iv. 37).

Hydrocarbons C^6H^4 . Cumenes.

This molecule admits of the three metameric modifications

All three have been formed synthetically, the first by the action of sodium and propyl iodide on bromobenzene; the second by that of sodium and ethyl bromide on bromotoluene; the third by that of sodium and methyl bromide on bromoxylene.

Propyl benzene prepared as above is very much like ordinary cumene obtained by distilling cumic acid with lime, and existing ready formed in Roman cumin-oil, but boils at a temperature about 6° higher, namely at 157° , whereas ordinary cumene boils at 151° – 151.5° . The synthetical compound further differs from ordinary cumene in not yielding a crystalline trinitro-derivative when treated with strong nitric and sulphuric acids, and in forming with excess of bromine a viscous tetrabrominated product, $C^6H^4Br^4$, instead of the finely crystalline pentabrominated compound $C^6H^4Br^5$, obtained from ordinary cumene. Both, however, when oxidised with chromic acid mixture yield the same product, namely benzoic acid. Hence it is probable that ordinary cumene likewise has the composition $C^6H^4.C^2H^5$, but that it consists of *isopropyl-benzene*, $C^6H^4.CH(CH^3)^2$, whereas the product obtained by the action of sodium and propyl iodide consists of *normal propyl-benzene*, $C^6H^4.CH^2CH^2CH^3$. This supposition is in accordance with the lower boiling point of ordinary cumene, as it is a general rule that isopropyl-compounds boil at lower temperatures than the corre-

sponding normal propyl-compounds. It has not, however, been found possible to verify this conclusion by the synthetical preparation of isopropyl-benzene, isopropyl iodide not being attacked by sodium even when heated with it in sealed tubes (Fittig, Schäffer a. König, *Ann. Ch. Pharm.* cxlix. 324).

The compounds $C^6H^3(CH^3)(C^2H^3)$ and $C^6H^3(CH^3)^3$ each admit of three isomeric modifications, those of the former being denoted by the formulæ 1 : 2, 1 : 3, 1 : 4; those of the latter by 1 : 2 : 3, 1 : 2 : 4, and 1 : 3 : 5. Of ethyl-methyl-benzene, however, only one modification is actually known; but of trimethyl-benzene two have been distinguished with certainty, and the third appears also to occur in coal-naphtha.

Fittig has shown that the trimethyl-benzenes, or pseudocumenes, produced synthetically by the introduction of an atom of methyl into metaxylene and paraxylene (p. 293), are identical, both boiling at 166° and exhibiting exactly the same behaviour with various agents, yielding, for example, the same highly characteristic bromo- and nitro-substitution-products, and the same oxidation-products, viz. two isomeric monobasic acids, xylie and paraxylie, and one bibasic acid, xylidic acid. The identity of the two trimethyl-benzenes thus produced is easily explained, if we suppose that when an atom of bromine is introduced into metaxylene and paraxylene respectively, it takes the place of a hydrogen-atom which, in the isomeric compound, is replaced by methyl: thus the compounds

must evidently, when the bromine in each is replaced by methyl, yield the same trimethyl-benzene, 1 : 3 : 4 or $C^6MeHMeMeIII$.

The 9-carbon homologue of benzene, boiling at about 164° – 167° , obtained from coal-naphtha, is generally regarded as a definite modification of trimethyl-benzene and designated as pseudocumene. But the recent experiments of Fittig a. Wackenroder have shown that this portion of coal-naphtha contains in all cases two, and sometimes three modifications of trimethyl-benzene, one of which, often greatly predominating, is mesitylene; the second identical with the synthetically formed compound just mentioned; while the third is a modification not hitherto observed. These three modifications are separated by treatment with a mixture of nitric and sulphuric acid, whereby they are converted into trinitro-compounds, $C^9H^3(NO_2)^3$, easily separable by solution in hot benzol, the trinitromesitylene, melting at 232° , separating out first; then the trinitro-pseudocumene, melting at 185° (identical with that obtained from synthetically prepared pseudocumene); and lastly the trinitro-compound of the third modification above mentioned, which melts at a lower temperature. The relative positions of the three methyl-atoms in the three modifications have not yet been determined. The hydrocarbon boiling between 164° and 167° obtained by distilling camphor with zinc chloride appears also to consist mainly of mesitylene (Fittig, *Zeitschr. f. Chem.* [2] iv. 577–584).

Pseudocumene (from coal-tar) is almost completely decomposed when its vapour is passed through a red-hot tube, yielding benzene, toluene, xylene, naphthalene, and a naphthalene hydride boiling at 200° , together with smaller quantities of liquid hydrocarbons boiling between 250° and 320° ; also anthracene and chrysene, and a gaseous mixture of hydrogen and marsh-gas, with a small quantity of ethylene and a trace of acetylene. The formation of naphthalene appears to be correlative with that of the lower homologues of cumene; thus:

(Berthelot, *Bull. Soc. Chim.* [2] vii. 229; *Jahresh.* 1866, p. 543.)

Pseudocumene heated with 80 pts. of strong hydriodic acid is converted into nonane, C^9H^{20} , with separation of a large quantity of iodine; with 20 pts. of the acid, the products are propane and free carbon:

(Berthelot, *Bull. Soc. Chim.* [2] vii. 53; *Jahresh.* 1867, p. 346.)

Pseudocumene (obtained from coal-tar and by synthesis) yields by oxidation with chromic acid the two isomeric acids xylie and paraxylie, $C^9H^8O^2$; according to Beilstein (*Zeitschr.* [2] iv. 672), coal-tar cumene also yields another acid isomeric with these, viz. mesitylenic acid.

Propyl-benzene, from Roman cumin-oil, is converted by bromine in contact with water into dibromobenzoic acid (Meusel, *Jahresh.* 1867, p. 698).

BROMOCUMENES.—*Monobromocumene*, $C^9H^7Br.C^9H^7$, formed when bromine is left in contact with cumene from Roman cumin-oil, boils after repeated rectification

at 218° – 220° , and has a sp. gr. of 1.3223 at 13° . It is not attacked by alcoholic potash, and when oxidised with potassium dichromate and sulphuric acid yields parabromobenzoic (bromodracrylic) acid and acetic acid. The same hydrocarbon treated for a considerable time with excess of bromine forms the compound $C^6H^3Br^3$, or probably $C^6H^2Br^4$, which crystallises from warm alcohol in concentric groups of prisms melting at 90° – 100° , and decomposing at a higher temperature (E. Meusel, *Zeitschr. f. Chem.* [2] iii. 322; *Jahresb.* 1867, p. 698). Synthetically prepared propyl benzene forms with excess of bromine a viscid uncrystallisable product, $C^6H^3H^4$ (p. 294).

Pseudocumene gently treated with 6 at. bromine forms the tribrominated compound $C^6H^3Br^3$, which crystallises in a freezing mixture. With 4 at. bromine, a dibrominated compound appears to be formed, since it is converted by fuming nitric acid into $C^6H^3(NO^2)^2Br^2$ (Riche a. Bérard, *Bull. Soc. Chim.* [2] ii. 305).

When bromine is dropped into cooled pseudocumene, prepared synthetically from bromometaxylylene, the whole quickly solidifies to monobromopseudocumene, C^6H^5Br . (CH^3)²; but on adding more bromine, the whole again becomes liquid, and is converted into tribromopseudocumene, $C^6H^3Br^3$, or probably $C^6H^2Br^4$. (CH^3)³, which dissolves very sparingly in boiling alcohol, and crystallises therefrom in capillary needles an inch long, melting at 225° , and resembling tribromomesitylene in every respect, excepting that they are flexible, whereas the crystals of tribromomesitylene are brittle and easily crumbled to powder (Fittig a. Laubinger, *Zeitschr. f. Chem.* [2] iv. 578).

NITROCUMENES.—Mononitropseudocumene is formed when pseudocumene (prepared from bromometaxylylene) is dropped into cold fuming nitric acid; also as a by-product in the oxidation of pseudocumene by dilute nitric acid. It crystallises from alcohol in long colourless needles, melting at 71° , and boiling without decomposition at 265° . By reduction with tin and hydrochloric acid it yields the double salt of cumidine hydrochloride and stannous chloride, $(C^6H^4(NH^2)^2) \cdot HCl \cdot SnCl^2$. By oxidation with chromic acid, it is converted into paranitroxylie acid, $C^6H^4(NO^2)O^2$ (Schaper, *Zeitschr. f. Chem.* [2] iii. 12; Fittig a. Laubinger, *ibid.* iv. 577). Ammonium sulphite converts nitrocumene into disulphuryl-cumenylic acid, $C^6H^4NS^2O^4$ (Carius, *Jahresb.* 1861, p. 635).

Dinitropseudocumene was not obtained by Fittig a. Laubinger in the pure state, but it appears to be fluid at ordinary temperatures.

Trinitropseudocumene, $C^6H^3(NO^2)^3$, is obtained by dropping the hydrocarbon into a cooled mixture of fuming nitric and sulphuric acids, and separates immediately as a crystalline mass. It is very slightly soluble in boiling alcohol, more soluble in benzol, and crystallises from alcohol by slow cooling in stellate groups of colourless needles; from benzol in short compact hard prisms mostly flattened. It melts at 185° and sublimates at a stronger heat. Treated in alcoholic ammoniacal solution with hydrogen sulphide, it is at first converted into a compound very much like dinitro-amidomesitylene, but much less stable, which is dissolved by strong hydrochloric acid, but precipitated therefrom by water. By prolonged treatment with the reducing agent, there is formed a well-marked very stable base, crystallising from water and alcohol in golden-yellow prisms, melting at 137° , but consisting, not, as might be supposed, of diamido-nitropseudocumene, $C^6H^4(NH^2)^2NO^2$, but of amido-nitropseudocumene, $C^6H^4(NH^2)NO^2$. The diamidono-compound is doubtless formed in the first instance, but afterwards loses an atom of NH^2 by inverse substitution. Amidonitropseudocumene is distinguished by the sparing solubility and great crystallising tendency of its salts, especially the sulphate, $[C^6H^4(NH^2)NO^2]^2HSO^4 \cdot H^2O$, which is quite insoluble in cold water, and crystallises from boiling water in extremely thin, perfectly transparent and colourless quadratic tables (Fittig a. Laubinger).

Trinitropseudocumene is also formed by the action of the nitro-sulphuric acid mixture on the cumene of coal-tar, but not nearly in so large a quantity as the isomeric compound trinitro-mesitylene (p. 299).

PSEUDOCUMENE-SULPHURIC ACID, $C^6H^5SO^4H$, is obtained by the action of a mixture of ordinary and fuming sulphuric acid on rectified coal-tar cumene. The solution diluted with water and neutralised with barium carbonate, yields barium pseudocumene-sulphate, $(C^6H^5SO^4)^2Ba \cdot 2H^2O$, as a white, fine-grained powder, which is but slightly soluble in water, and gives off its water of crystallisation above 170° . The lead, copper, and calcium salts are very soluble in water. The acid separated from the barium salt is resolved by heating its concentrated solution in the oil-bath into sulphuric acid and pseudocumene boiling at 166° .

Fuming sulphuric acid alone acts with great violence on pseudocumene, forming a smaller quantity of pseudocumene-sulphuric acid; and on diluting with water, a solid

body separates, insoluble in water, alcohol, ether, and benzene, and probably consisting of sulphocumide, $(C^6H^5)_2SO_2$.

Pseudocumene-sulphochloride, $C^6H^5SO_2Cl$, which separates as an oil on triturating sodium pseudocumene-sulphate with phosphorus pentachloride, and adding water, is converted by the action of zinc and sulphuric acid into a solid, inodorous body having the composition of cumyl sulphhydrate, C^6H^5SH ; it crystallises from alcohol in macrose laminae, melting at $86^\circ-87^\circ$ and boiling at about 235° (Beilstein a. Kögler, *Ann. Ch. Pharm.* cxxvii. 117; *Jahresb.* 1865, p. 559).

Mesitylene. $C^6H^4(CH^3)_3$.—This hydrocarbon, originally obtained by the action of sulphuric acid upon acetone, has been shown by Fittig a. Wackenroder to constitute the chief portion of the fraction of coal-naphtha which boils at $164^\circ-167^\circ$, also of that portion of the distillate obtained by heating camphor with zinc chloride which boils at the same temperature. This being the case, it is evident that many of the supposed derivatives of pseudocumene obtained by former experimenters were not pure products, but consisted to a great extent of derivatives of mesitylene, the latter sometimes greatly predominating. Even the purified pseudocumene which Beilstein a. Kögler obtained by distilling the sulpho-acid prepared from coal-tar cumene (p. 297) has been shown by Fittig a. Wackenroder to consist of mesitylene. On the other hand, the great similarity between pseudocumene and mesitylene, as exhibited especially in their tribromo- and trinitro- derivatives, while it shows that mesitylene is in all probability an isomeric variety of trimethyl-benzene, renders it a matter of great difficulty to separate mesitylene from pseudocumene in mixtures of the two, such as coal-tar cumene. Hence to obtain pure mesitylene we must still resort to Kane's mode of preparation from acetone.

Fittig a. Brückner (*Ann. Ch. Pharm.* cxlvii. 42) prepare mesitylene as follows: 1 vol. commercial acetone is introduced into a large tubulated retort containing dry sand; a cooled mixture of 1 vol. sulphuric acid and $\frac{1}{2}$ vol. water is added in a slow but continuous stream; and the mixture, after standing for 24 hours, is distilled, the receiver being changed as soon as oily streaks appear in the neck of the retort. There then passes over, together with the watery vapours, an oil, chiefly consisting of mesitylene, after which sulphurous anhydride is evolved, and the contents of the retort acquire a transient but deep indigo-blue colour. The oily distillate washed with water and soda-ley yields by fractional distillation, finally over sodium, pure mesitylene boiling constantly at 163° . The higher portion of the crude mesitylene, passing over up to 300° , contains a hydrocarbon boiling at $191^\circ-196^\circ$, probably $C^{10}H^{14}$.

Mesitylene boiled for 16 to 20 hours with dilute nitric acid, is oxidised to mesitylenic acid, $C^6H^4O_2$, isomeric with xylic acid (Fittig, *Jahresb.* 1866, p. 610). With potassium dichromate and sulphuric acid it yields a large quantity of acetic acid, and by complete oxidation also a small quantity of an acid which is sparingly soluble in cold water, sublimable, crystallises in prisms, and forms a barium salt crystallising from hot water in long needles (Fittig, *Jahresb.* 1865, p. 560). By phosphonium iodide at 280° , it is converted into a hydrocarbon, C^6H^{12} , boiling at 138° (Baeyer, *Zeitschr. f. Chem.* [2] v. 320).

BROMOMESITYLENES.—**Monobromomesitylene**, C^6H^4Br , produced by carefully mixing well-cooled mesitylene with 2 at. bromine, and purified in the usual way, is a limpid oil, having an aromatic odour, a sp. gr. of 1.3191 at 10° , boiling at 225° , solidifying completely in a freezing mixture, and melting again at $+1^\circ$; not attacked by sodium-amalgam at any temperature. **Di- and tri-bromomesitylene** are contained in the residue left after distilling off the monobrominated compound obtained as above, and are produced in larger quantity by the action of 4 at. bromine on mesitylene. On recrystallising from alcohol, the tribrominated compound separates out almost completely, while dibromomesitylene, $C^6H^2Br_2$, remains in the mother-liquor, and may be crystallised therefrom in colourless needles an inch long, melting at 60° , and distilling without decomposition at 285° . **Tribromomesitylene**, $C^6H^3Br_3$, previously obtained by Hofmann and Cahours (iii. 930), is nearly insoluble in cold alcohol, and crystallises from benzol by spontaneous evaporation in transparent monoclinic prisms melting at 224° (Fittig a. Storer, *Ann. Ch. Pharm.* cxlvii. 1; *Jahresb.* 1867, p. 703).

CHLOROMESITYLENES (Fittig a. Hoogewerff, *Zeitschr. f. Chem.* [2] v. 168).—Chlorine acts very strongly on mesitylene, even in the cold, the three hydrogen-atoms in the benzene residue, C^6H^3 , being easily replaced by chlorine. The di- and trichlorinated compounds are indeed always produced, together with monochloromesitylene, even when the quantity of chlorine passed into the liquid is less than sufficient for the complete conversion of the mesitylene into the latter. To separate the three

chlorinated compounds, the mixture is washed with soda-ley and dissolved in boiling alcohol. The solution on cooling deposits nearly the whole of the trichloromesitylene, which is easily obtained quite pure by recrystallisation from alcohol. The mono- and dichlorinated compounds may be separated from the mother-liquor by evaporating off the alcohol and subjecting the remaining liquid to fractional distillation. When monochloromesitylene is the only product sought, it is best to treat the mesitylene with only half the required quantity of chlorine, and immediately subject the liquid to fractional distillation.

Monochloromesitylene, $C^6H^5Cl.(CH^3)^3$, is a transparent colourless liquid, very soluble in alcohol, and boiling without decomposition at 204° – 206° . It is slowly oxidised by a mixture of *potassium dichromate* and *sulphuric acid*, yielding acetic acid, together with other products. By *dilute nitric acid* it is easily oxidised to chloromesitylenic acid. *Fuming nitric acid* attacks it very strongly, even when well cooled, converting it instantly into a mixture of mono- and dinitro-chloromesitylene. **Mononitrochloromesitylene**, $C^6H(NO^2)Cl.(CH^3)^3$, is found, in small quantity only, in the reaction just mentioned; also as a bye-product in the oxidation of chloromesitylene by dilute nitric acid. It forms groups of spicular crystals melting at 56° – 57° , easily soluble in alcohol. **Dinitrochloromesitylene**, $C^6(NO^2)_2Cl.(CH^3)^3$, the chief product of the action of fuming nitric acid on chloromesitylene, crystallises from alcohol in long colourless needles, which melt at 176° – 177° , may be sublimed without decomposition, dissolve easily in hot, sparingly in cold alcohol.

Dichloromesitylene, $C^6HCl_2.(CH^3)^3$, crystallises from alcohol in splendid colourless shining prisms, melting at 59° , boiling without decomposition at 243° – 244° , very soluble in hot alcohol, also in ether and in benzol. Scarcely attacked by chromic acid mixture, even after several days' boiling, yielding a barely perceptible quantity of acetic acid and not a trace of any aromatic acid.

Trichloromesitylene, $C^6Cl_3.(CH^3)^3$.—This compound, first prepared by Kane (iii. 930), is the only product formed when mesitylene is treated at ordinary temperatures with excess of chlorine. It is very slightly soluble in cold alcohol, somewhat more in hot alcohol, easily in ether. From boiling alcohol it crystallises in long, slender, colourless needles, melting at 204° – 205° , and subliming without decomposition in long brilliant spicules. It does not suffer the least alteration by boiling for several days with nitric acid, chromic acid, or potassium permanganate (Fittig u. Hoogewerff).

HYDROXYL-MESITYLENE. See MESITYLENOL.

NITROMESITYLENES.—**Mononitromesitylene**, $C^6H^5(NO^2).(CH^3)^3$, is formed on warming mesitylene with nitric acid of sp. gr. 1.38; also as a bye product in the preparation of mesitylenic acid; it is purified by distillation with aqueous vapour, rectification *per se*, and crystallisation of the solidifying portion from alcohol. Crystallises in well-defined transparent prisms an inch long, or in large tabular crystals; dissolves in almost all proportions of boiling alcohol, melts at 41° , and boils without decomposition at 240° – 250° . It is not converted into nitromesitylenic acid by boiling with potassium dichromate and dilute sulphuric acid. **Nitrobromomesitylene**, $C^6H^5(NO^2)Br.(CH^3)^3$, formed, together with a small quantity of the following compound, by leaving bromomesitylene in contact with a mixture of equal volumes of fuming and ordinary nitric acid at ordinary temperatures, is moderately soluble in alcohol, and separates therefrom by spontaneous evaporation in colourless crystals, very much like those of sal-ammoniac, crystallised from water; they melt at 54° . **Dinitrobromomesitylene**, $C^6H^5(NO^2)_2Br.(CH^3)^3$, formed at ordinary temperatures by drenching bromomesitylene with fuming nitric acid, dissolves slightly in cold, more freely in boiling alcohol, crystallises in colourless needles, and melts at 189° – 190° , emitting a musk-like odour (Fittig u. Störck).

Dinitromesitylene, $C^6H^5(NO^2)_2$, is easily formed by dropping mesitylene into cooled fuming nitric acid; melts at 86° ; dissolves with moderate facility in hot, less easily in cold alcohol; and crystallises in colourless rhombic prisms an inch long, exhibiting the combination $\infty P . \infty P \infty . oP$, the ratio of the macrodiagonal to the brachydiagonal being $1 : 0.5475$; angle $\infty P : \infty P \infty = 118^{\circ} 62'$.

Trinitromesitylene, $C^6H^5(NO^2)_3$, obtained by dropping mesitylene into a mixture of 1 vol. fuming nitric and 2 vol. strong sulphuric acid, is nearly insoluble in cold, very sparingly soluble in boiling alcohol, and crystallises therefrom in slender colourless needles; from acetone in large prisms having a glassy lustre; melts at 230° – 232° (Fittig, *Ann. Ch. Pharm.* cxli. 129). The preparation of this compound from the mixture of hydrocarbons constituting coal-tar cumene has already been noticed (p. 296).

AMIDOMESITYLENE or MESIDINE. $C^6H^{11}(NH^2) = C^6H^2(NH^2) \cdot (CH^3)^9$ (Fittig a. Storer, *Ann. Ch. Pharm.* cxlvii. 1).—Produced by boiling nitromesitylene with tin and hydrochloric acid, and separated from the hydrochloride by ammonia in colourless oil-drops which do not solidify at 0° . The *hydrochloride*, $C^6H^{11}(NH^2) \cdot HCl$, forms feathery crystals or large transparent prisms easily soluble in water and in alcohol. The *stannoso-chloride*, $2(C^6H^{11}N \cdot HCl) \cdot SnCl_2$, forms needle-shaped, rather sparingly soluble crystals, which are decomposed by pure water. The *oxalate*, $(C^6H^{11}N)^2 \cdot C^2H^2O_4$, is a precipitate, consisting of crystalline laminae, sparingly soluble in cold water, and dissolving with decomposition in boiling water, so that the salt cannot be recovered from the solution.

Dinitro-amidomesitylene or *Dinitromesidine*, $C^6H^2(NO^2)^2 \cdot NH^2$, is formed, together with nitro-diamidomesitylene, by prolonged treatment of trinitromesitylene with ammonium sulphide. From the evaporated residue the latter base is extracted by dilute hydrochloric acid, and the undissolved portion treated with more concentrated acid yields the dinitro-amidomesitylene, which may be purified by precipitation with water and recrystallisation from alcohol. It is insoluble in water, but dissolves easily in hot alcohol, and crystallises therefrom in sulphur-yellow, very well defined short prisms, melting at 193° – 194° , and volatilising without decomposition. The only acid with which it appears to unite is concentrated hydrochloric acid, and even the compound thus formed is easily decomposed by water (Fittig).

DIAMIDOMESITYLENE or MESITYLENE-DIAMINE, $C^6H^{10}(NH^2)^2$, is produced by heating dinitromesitylene with tin and concentrated hydrochloric acid, precipitating the tin by hydrogen sulphide, evaporating the filtrate to dryness, recrystallising the salt from moderately strong hydrochloric acid, and precipitating with ammonia. It then separates as a nearly colourless oil, which gradually solidifies to a pulp of long slender crystals. It dissolves easily in hot water, alcohol, or ether, and crystallises from water in long capillary needles, from ether in large monoclinic crystals; becomes yellow or reddish on exposure to light; melts at 90° , and sublimes in needles without decomposition. Bromine water added to the aqueous solution throws down a liquid compound insoluble in hydrochloric acid. The *hydrochloride*, $C^6H^{11}N^2 \cdot 2HCl$, crystallises in square tables, easily soluble in water and in alcohol, and is precipitated almost completely from the aqueous solution by hydrochloric acid of a certain strength; does not form a double salt with platinum chloride. The *nitrate* is very soluble and crystallisable. The *oxalate*, $C^6H^{11}N^2 \cdot C^2H^2O_4$, is sparingly soluble in alcohol, and crystallises from hot water in hard grains. The *sulphate*, $C^6H^{11}N^2 \cdot SH^2O_4$, is very soluble in water, scarcely at all in cold alcohol, and crystallises from alcohol in broad transparent laminae, which quickly become dull when exposed to the air (Fittig).

Nitro-diamidomesitylene or *Nitromesitylene-diamine*, $C^6H^2(NO^2)(NH^2)^2$, is formed, as already observed, simultaneously with dinitro-amidomesitylene, by the action of ammonium sulphide on trinitromesitylene, and is extracted from the evaporated residue by dilute hydrochloric acid. From this solution it is separated by ammonia, as a deep yellow amorphous precipitate, which dissolves but sparingly in hot water, easily in alcohol and ether. From water it crystallises in large orange-coloured laminae; from alcohol, by spontaneous evaporation, in very large well-defined monoclinic prisms having a very brilliant lustre and nearly the colour of sodium nitroprusside. They exhibit the combination $\infty P : [P\infty] : oP$, and are shortened in the direction of the principal axis. Angle $\infty P : \infty P$, in the orthodiagonal principal section, = $113^\circ 14'$; $\infty P : oP = 101^\circ 20'$; $[P\infty] : oP = 158^\circ 44'$; $[P\infty] : [P\infty]$ at the principal axis = $137^\circ 28'$; acute angle of axes = $60^\circ 4'$. Ratio of clinodiagonal, orthodiagonal, and principal axis = 1.6248 : 1 : 0.4167. Melting point 184° . The *hydrochloride*, $C^6H^2NO^2(NH^2)^2 \cdot 2HCl$, dissolves easily in water and in alcohol, and crystallises in colourless square tables (Fittig).

Sulpho-derivatives of Mesitylene.

MESITYLENE-SULPHURIC or SULPHOMESITYLIC ACID, $C^6H^{11} \cdot SO^3H$, is formed by dissolving mesitylene in warmed fuming sulphuric acid, and separates for the most part in needles as the solution cools. The pure acid separated from the barium salt forms, when evaporated over oil of vitriol, a syrup which soon solidifies to a colourless radio-crystalline mass. The *barium salt* $(C^6H^{11}SO^3)^2Ba$ crystallises from hot water in colourless laminae. The *potassium salt* $C^6H^{11}SO^3K$ is very soluble in water, and crystallises from alcohol in small laminae, united in spherical groups (Fittig, *Jahresb.* 1866, p. 610). The *silver* and *lead* salts were examined by Hofmann (iii. 931).

The sulpho-acid which Beilstein and Kögler obtained (*Ann. Ch. Pharm.* cxxvii.

117) from coal-tar cumene has been shown by Fittig a. Wackenroder (*Zeitschr. f. Chem.* [2] iv. 583) to consist mainly of mesitylene-sulphuric acid, with smaller quantities of pseudocumene-sulphuric acid, and another sulpho-acid isomeric therewith.

Mesitylene Sulphochloride, $C^9H^{11}SO^2Cl$, separates on pouring a heated mixture of sodium mesitylene-sulphate and phosphorus pentachloride into cold water, as an oil which quickly solidifies. It is insoluble in water, easily soluble in alcohol and ether, crystallises from the latter in large wedge-shaped tables, and melts at 57° . With soda-ley it forms sodium mesitylene-sulphate, and with alcohol an oil which is probably the ether of mesitylene-sulphuric acid (Holtmeyer, *Zeitschr. f. Chem.* 1867, p. 686).

Mesitylene Sulphosamide, $C^9H^{11}SO^2NH_2$, produced by the action of alcoholic ammonia on mesitylene sulphochloride, is a white mass, which crystallises from water or alcohol in long glassy needles, melts at 141° – 142° , and does not unite either with acids or with bases.

Mesityl Sulphydrate, $C^9H^{11}SH$, is easily formed by treating the sulphochloride with zinc and sulphuric acid, and distils with the watery vapours as a liquid, which does not solidify at low temperatures, dissolves easily in alcohol, ether, and benzol, has a sp. gr. of 1.0192, and boils at 228° – 229° . Its *silver salt*, $C^9H^{11}SAg$, is a light yellow precipitate soluble in hot alcohol. The *mercury-compound* $(C^9H^{11}S)_2Hg$ crystallises from alcohol in white silky needles. Mesityl bisulphide, $(C^9H^{11})_2S_2$, produced by mixing the sulphydrate with soda-ley, forms light yellow shining laminae or tables, melting at 125° , insoluble in water, but soluble in alcohol, ether, or benzol. The same compound is gradually produced from the sulphydrate in contact with alcoholic ammonia or a solution of calcium chloride (Holtmeyer).

Mesitylene-sulphurous acid, $C^9H^{11}SO^2H$, is obtained by adding mesitylene-sulphochloride triturated with sodium-amalgam to a dry mixture of benzene and toluene, decanting the hydrocarbons after the reaction has taken place, repeatedly treating the pulpy mass with a small quantity of water, and decomposing the concentrated sodium salt with hydrochloric acid. The acid is slightly soluble in cold, more easily in hot water, and crystallises therefrom in needles an inch long; from alcohol in fan-shaped groups of needles. It is permanent in the air and melts at 98° – 99° . Its *silver salt*, $C^9H^{11}SO^2Ag$, is a light yellow gelatinous precipitate; the *barium salt* $(C^9H^{11}SO^2)_2Ba$ crystallises in long hydrated efflorescent needles or large rhombohedral tables. The *calcium salt* forms tufts of easily soluble needles; the *copper salt*, dark green crystals resembling cupric sulphate; the *lead salt*, long easily soluble needles. The aqueous acid is precipitated orange-yellow by ferric chloride, white by mercuric nitrate (Holtmeyer).

Hydrocarbons $C^{10}H^{14}$.

The molecule $C^{10}H^{14}$ admits of the five following modifications:

Butyl-benzene	$C^4H^9 \cdot C^6H^5$
Propyl-methyl-benzene	$C^3H^7 \cdot CH^3 \cdot C^6H^5$
Diethyl-benzene	$C^2H^5 \cdot C^2H^5 \cdot C^6H^5$
Dimethyl-ethyl-benzene	$C^2H^5 \cdot (CH^3)_2 \cdot C^6H^5$
Tetramethyl-benzene	$C^4H^9 \cdot (CH^3)_4$

Of these, the second, third, and fourth have been formed synthetically; the second by the action of sodium and propyl iodide on monobromotoluene; the second and third by the action of sodium and ethyl bromide on bromethyl-benzene and bromodimethyl-benzene (xylene) respectively.

Propyl-methyl benzene or **Propyl-toluene** boils at 178° – 179° , has an agreeable odour like that of benzene, yields a viscid nitro-product with a mixture of strong nitric and sulphuric acids, and when treated with chromic acid mixture, is oxidised to toluic acid (Fittig, Schäffer a. König, *Ann. Ch. Pharm.* cxlix. 334).

Diethyl-benzene, also produced, together with ethyl-benzene, by heating naphthalene with 20 pts. of strong hydriodic acid (Berthelot, p. 292), boils at 178° – 179° , and has a sp. gr. of 0.8707 at 15.5° . Fuming nitric acid converts it into a liquid nitro-compound; with a mixture of nitric and sulphuric acids, it forms an easily fusible acid crystallising in fan-shaped groups of laminae (Fittig, *Zeitschr. f. Chem.* [2] ii. 358).

By oxidation with a mixture of potassium dichromate and dilute sulphuric acid it yields terephthalic (paraphthalic) acid:

Dilute nitric acid, on the other hand, oxidises only one of the ethyl-atoms, producing ethyl-benzoic acid, isomeric with xylic acid:

By further oxidation, however, with stronger nitric acid, the ethyl-benzoic acid is converted into terephthalic acid (Fittig a. König, *Ann. Ch. Pharm.* cxliv. 277).

Diethyl-benzene dissolves in fuming sulphuric acid, forming diethylbenzene-sulphuric acid, $C^6H^3(C^2H^5)^2 \cdot SO^3H$, which crystallises in deliquescent laminae. Its barium salt, $(C^6H^3SO^3)^2Ba$, crystallises from alcohol in nodules or laminae; the potassium salt $C^6H^3SO^3K$ in slender needles (Fittig a. König).

Ethyl-dimethyl-benzene or **Ethyl-xylene**, $C^6H^4(CH^3)^2C^2H^5$, has a sp. gr. of 0.8783 at 30° and boils at 183°–184°. By warming with a mixture of nitric and sulphuric acids, it is converted into a trinitro-compound which crystallises from alcohol in needles melting at 119°. By oxidation with chromic acid, it yields, together with acetic acid, an acid similar to terephthalic acid, but more soluble in alcohol (Fittig a. Ernst, *Zeitschr. f. Chem.* [2] i. 572).

Cymene. There are two metameric hydrocarbons to which this name is applied: α cymene, obtained from Roman cumin-oil and from the oil of water-hemlock seed, in which it exists ready-formed; also produced, together with several of its homologues, by the dehydration of common camphor with fused zinc chloride, phosphoric oxide, P^2O^5 , or phosphoric sulphide, P^2S^5 ; and β cymene which occurs amongst the products of the destructive distillation of coal.

α Cymene.—The preparation of this modification from Roman cumin-oil and from the oil of *Cicuta virosa* is described in vol. ii, p. 296. The portion of the distillate obtained by treating camphor with fused zinc-chloride, which passes over between 173° and 176°, consists mainly of α cymene (Fittig, Köbrich a. Jilke, *Jahresb.* 1867, p. 701); and by distilling camphor with phosphoric sulphide, cymene is obtained without any admixture of other hydrocarbons:

This is therefore the best method of obtaining cymene from camphor: On mixing 1 mol. phosphoric sulphide in a capacious retort with 5 mol. coarsely comminuted camphor, and applying a gentle heat, the mass fuses to a brown liquid, which, when more strongly heated, yields a large quantity of cymene, to be purified by agitation with strong potash-ley, then with water, and drying over calcium chloride (R. Pott, *Zeitschr. f. Chem.* [2] v. 200). The same modification of cymene appears to be obtained by the distillation of cumin-oil with phosphoric oxide (Louguinine, *Jahresb.* 1867, p. 692), and of carvol (from cumin-oil) with zinc-powder (a mixture of metallic zinc, zinc oxide, and hydrate) (Arndt, *Zeitschr.* [2] iv. 730).

α Cymene from camphor boils at 175°–178° (Pott); at 177°–179° (Louguinine, p. 278); that from Roman cumin-oil at 177.5° (Kopp); at 179.6° (corr.) (Warren, *Jahresb.* 1865, p. 515); at 175°–176° (Louguinine). Sp. gr. of that from camphor 0.8768 and 0.8732 at 0° (Louguinine); sp. gr. of that from cumin-oil 0.8705 at 0° (Louguinine); 0.8660 at 15° (Mendelejeff, *Jahresb.* 1863, p. 7). Cymene from either

source is converted by oxidation with dilute nitric acid into toluic acid, $C^6H^4 \cdot \begin{Bmatrix} CH^3 \\ CO^2H \end{Bmatrix}$; by further oxidation with chromic acid mixture, into acetic acid and terephthalic acid, $C^6H^4 \cdot (CO^2H)^2$. Consequently a cymene contains two lateral chains (p. 200), one of which is methyl; that is to say, it has the constitution of propyl-methylbenzene, $C^6H^5 \cdot \begin{Bmatrix} C^2H^5 \\ CH^3 \end{Bmatrix}$.

Propyl-methylbenzene prepared by the action of sodium and propyl-iodide on bromotoluene boils at nearly the same temperature as a cymene (178°–179°); is also converted by oxidation into toluic and afterwards into terephthalic acid; yields a sulpho-acid whose barium salt agrees in crystalline form and amount of water with that of a cymene-sulphuric acid, and indeed appears to resemble a cymene in every respect excepting that its nitro-derivatives do not crystallise. From the analogy of cumene (p. 296), it is probable that the synthetically prepared compound may be normal propyl-toluene, and that a cymene may be isopropyl-toluene (Fittig, Schäffer a. König, *Ann. Ch. Pharm.* cxlix. 337).

α Cymene (from camphor) is converted by fuming sulphuric acid into cymene-sulphuric acid, $C^6H^5 \cdot SO^3H$, the barium salt of which, $(C^6H^5SO^3)^2Ba \cdot 6H^2O$, crystallises in easily soluble rhombic prisms (Fittig, Köbrich a. Jilke; Pott). When the potassium salt of this acid is fused with 2 pts. potassium hydrate, the fused mass dissolved in water, the solution acidulated with sulphuric acid, and the separated brown oil

distilled, a yellowish viscid oil is obtained boiling at 230° and having the composition of cymic phenol, $C^{10}H^{10}O$, isomeric with thymol. It is distinguished from the latter by not solidifying in a freezing mixture, and by being but slowly converted into a sulpho-acid, $C^{10}H^{10}O \cdot SO^2H$, by the action of fuming sulphuric acid (Fott).

According to Riche a. Bérard (*Bull. Soc. Chim.* [2] ii. 205), cymene from camphor left in contact with 4 at. bromine, forms crystallisable *dibromocymene*, $C^{10}H^{12}Br^2$, but that obtained from Roman cumin-oil does not yield this compound [?]; with an excess of bromine however it forms a small quantity of a more highly brominated crystalline compound. *Nitrocymene* (prepared from the cymene of Roman cumin-oil) is converted by sodium-amalgam into azocymene, $C^{10}H^{10}N^2$ (Werigo).

β Cymene is contained in coal-tar, chiefly in the heavy oil boiling above 170° . Mansfield (ii. 207) obtained it from the portion boiling between 170° and 180° . Berthelot (*Bull. Soc. Chim.* [2] viii. 226) separated by fractional distillation the portion of heavy coal-tar oil boiling between 175° and 190° ; then (after mixing the distillate with the liquid remaining in the retort and the portion saturated with naphthalene) collected by a second fractionation the portion distilling between 178° and 180° , and separated the naphthalene therefrom by means of an alcoholic solution of picric acid. The oil separated from the alcoholic mother-liquid by ammoniacal water yielded, after repeated rectification, a hydrocarbon $C^{10}H^{14}$, boiling between 179° and 180° , and yielding with nitric and sulphuric acids the usual reactions of the aromatic hydrocarbons. Heated with 80 times its weight of saturated aqueous hydriodic acid, it yielded decane or decyl-hydride, $C^{10}H^{22}$, together with a small quantity of a very volatile hydride, $[C^{10}H^{14}]?$. Rommier (*Compt. rend.* lxxiii. 1482), by treating the portion of coal-tar oil distilling between 200° and 220° with fuming nitric acid, obtained a small quantity of hard colourless crystals having approximately the composition of *dinitrocymene*, $C^{10}H^{12}(NO^2)^2$.

β cymene differs from α cymene in its boiling point. Its products of oxidation do not appear to have been examined; but as products of destructive distillation have hitherto been found to yield only methyl-derivatives of benzene, it most probably consists of tetramethylbenzene.

AZOCYME, $C^{10}H^{10}N^2$, is formed by the action of sodium-amalgam on nitrocymene (from the cymene of Roman cumin-oil), and crystallises in cherry-coloured plates melting at 86° (Werigo, *Zeitschr. Ch. Pharm.* 1864, p. 721).

Hydrocarbons $C^{11}H^{14}$.

Of the seven metameric forms of this hydrocarbon, viz. $C^6H^5 \cdot C^5H^9$; $C^6H^4 \cdot C^5H^8 \cdot CH^3$; $C^6H^4 \cdot C^4H^6 \cdot CH^3$; $C^6H^3 \cdot C^4H^5 \cdot (CH^3)^2$; $C^6H^3 \cdot (C^3H^3)^2 \cdot CH^3$; $C^6H^2 \cdot (C^3H^3)(CH^3)^2$; and $C^6H \cdot (CH^3)^4$, the three following are known:

1. **Amyl-benzene.** $C^6H^5 \cdot C^5H^9$.—Obtained by the action of sodium on a mixture of bromobenzene and amyl bromide diluted with an equal volume of ether (Tollens a. Fittig, *Ann. Ch. Pharm.* cxxxi. 303). It has a peculiar odour, not like that of benzene, a sp. gr. of 0.859 at 12° , and boils at 193° (Bigot a. Fittig, *ibid.* cxli. 160). By oxidation with chromic acid, it yields benzoic acid, together with other acids not yet investigated (Tollens a. Fittig). With 2 at. bromine it forms a liquid compound in which a few crystals gradually appear; on mixing the well-cooled hydrocarbon with 4 at. bromine, and heating the mixture to 100° till it is decolorised, the contents of the tube solidify to a crystalline pulp of *tribromamylbenzene*, $C^{11}H^{12}Br^3$. This compound crystallises from hot alcohol in silky needles, slightly soluble in cold, easily in hot alcohol, melting at 140° and decomposing at a slightly higher temperature. With chlorine and with fuming nitric acid, amylbenzene forms only liquid compounds. Concentrated sulphuric acid converts it into a very stable, crystallisable, deliquescent sulpho-acid, whose barium salt, $(C^{11}H^{12}SO^2)^2Ba$, crystallises readily in long needles very slightly soluble in cold water. The potassium salt $C^{11}H^{12}SO^2K$ is a radio-crystalline mass very soluble in water and in alcohol (Tollens a. Fittig).

2. **Diethyl-methyl-benzene or Diethyl-toluene.** $C^6H^5 \cdot \left\{ \begin{smallmatrix} (CH^2) \\ (C^2H^4) \end{smallmatrix} \right\}$. (Lippmann a. Louguinine, *Bull. Soc. Chim.* [2] viii. 426).—Produced by the action of zinc-ethyl on benzylene chloride:

To moderate the violence of the reaction, it is best to dilute the mixture with five times its weight of benzol, and gradually add the well-cooled solution of the benzylene chloride to the solution of the zinc-ethyl in excess. At the end of the reaction, the white solid product saturated with benzol is treated with hydrochloric acid, and the separated oily layer, after drying with calcium chloride, is freed from

benzol by distillation. The remaining hydrocarbon, after repeated heating with sodium to 200° for several days, and final rectification, yields, in the portion boiling between 175° and 180°, pure diethyl-toluene as a colourless aromatic liquid, of sp. gr. 0.8751 at 0°, boiling at 178° (i.e. 16° lower than amyl-benzene), and having a vapour-density of 5.1245, or by calculation 5.1107.

3. Propyl-dimethyl-benzene, Propyl-xylene, or Laurene. $C^6H^4 \left\{ \begin{smallmatrix} (CH^3)_2 \\ C^2H^7 \end{smallmatrix} \right\}$

(Fittig, Köbrich & Jilke, *Ann. Ch. Pharm.* cxlv. 129; *Jahresb.* 1867, p. 701).—Produced, together with several of its lower homologues, by distilling camphor with fused zinc chloride, passing over between 185° and 188°. It has a sp. gr. of 0.887 at 10°, and boils when pure at 188°. In contact with 6 at. bromine, it is gradually converted into tribromolaurene, $C^{11}H^{13}Br^3$, which crystallises from hot alcohol in long needles melting at 125°; not decomposed by alcoholic potash at the boiling heat. With a mixture of nitric and sulphuric acids laurene forms a nitro-compound melting at 84°. Dilute nitric acid oxidises it to lauroxylic acid, $C^6H^{10}O^2$, an acid isomeric with xylic acid:

By chromic acid it is further oxidised, acetic acid being produced, apparently as the ultimate product of its oxidation.

The hydrocarbon $C^{12}H^{18}$, of which ten modifications are possible, is known in only one, viz.,

Amyl-methyl-benzene or Amyl-toluene. $C^6H^4 \left\{ \begin{smallmatrix} CH^3 \\ C^5H^{11} \end{smallmatrix} \right\}$ (Bigot & Fittig,

Ann. Ch. Pharm. cxli. 160).—Prepared similarly to amyl-benzene (p. 303), excepting that the weighed quantity of sodium is added in the first place to the ether which serves as a diluent, and then, when all evolution of hydrogen has ceased, the thoroughly dried mixture of bromotoluene and amyl bromide is added. It is a colourless liquid, having an agreeable odour like that of ethyl-benzene, of sp. gr. 0.8643 at 9°, boiling at 213°, and not solidifying at -20°. By oxidation with chromic acid it yields acetic and terephthalic acids:

Heated with 8 at. bromine to 100°, it forms tribromamyl-toluene, $C^{12}H^{15}Br^3$, as a viscid ropy mass, which becomes mobile at 100°, and decomposes at a higher temperature. Fuming nitric acid converts it in the cold into dinitro-amyltoluene, $C^{12}H^{15}(NO^2)_2$, a viscid yellow transparent liquid, insoluble in water, easily soluble in alcohol, and not capable of distilling without decomposition. It does not appear to yield a solid trinitro-compound. It dissolves in fuming sulphuric acid, forming amyltoluene-sulphuric acid, $C^{12}H^{17}SO^3H$, the barium salt of which is very soluble in water and alcohol, and uncrystallisable; the potassium salt, $C^{12}H^{17}SO^3K$, likewise easily soluble and not obtainable in distinct crystals.

The hydrocarbon $C^{13}H^{20}$ is likewise known in only one modification, viz.,

Amyl-dimethyl-benzene or Amyl-xylene, $C^6H^4 \left\{ \begin{smallmatrix} (CH^3)_2 \\ C^5H^{11} \end{smallmatrix} \right\}$, which is prepared

similarly to amyl-toluene. It is a liquid smelling very much like amyl-benzene and amyl-toluene, boiling at 232°-233°, and having a sp. gr. of 0.8951 at 9°. It does not yield any well-characterised bromo- or nitro-derivatives. Fuming sulphuric acid dissolves it readily, forming amylxylene-sulphuric acid, $C^{13}H^{19}SO^3H$, the barium and potassium salts of which are very soluble and not crystallisable (Bigot & Fittig, *loc. cit.*).

BENZERYTHRENE. A solid hydrocarbon of unknown composition, formed, together with chrysene and other hydrocarbons, solid, liquid, and gaseous, when benzene vapour is passed through a porcelain tube heated to bright redness; occurring also amongst the solid hydrocarbons which pass over after the naphthalene in the distillation of coal-tar, the last portions of this distillate consisting of chrysene and benzerythrene. Still more abundantly do these two hydrocarbons occur in the reddish-yellow product obtained by the destructive distillation of the dry pitch of fir-wood.

Benzerythrene is at ordinary temperatures an orange-yellow resinous body of the consistence of colophony, and distilling at a red heat in yellow vapours. It dissolves but sparingly in alcohol, even at the boiling heat, forming a solution which gives no precipitate with picric acid, but when heated with this acid to the boiling point

deposits on cooling brownish-yellow flocks, consisting of benzerythrene picrate (Berthelot, *Jahresb.* 1866, p. 541; *ibid.* pp. 699, 695).

BENZUGENYL. Syn. with EUGENIO-BENZOIC ANHYDRIDE (ii. 605).

BENZHYDROL. $C^1H^{10}O$.—A monatomic alcohol produced by the action of nascent hydrogen on benzophenone or phenylbenzoyl, $C^6H^5 \cdot C^1H^5O$, under which it is described (iv. 478).

BENZIDINE or DIAMIDO-DIPHENYL. $C^{12}H^8(NH^2)^2$.—See i. 514; iv. 411. A base, $C^{12}H^{10}N^2$, homologous with benzidine, is produced by the action of hydrochloric acid on an alcoholic solution of hydrazotoluide. It crystallises in silvery laminae easily soluble in boiling water, soluble in alcohol and ether, melting at 128° – 129° , and decomposing at a higher temperature. It is a bi-acid base, forming a neutral and an acid sulphate; the latter, $C^{12}H^{10}N^2 \cdot 2H^2SO^4$, is a pulverulent salt partially decomposed by water. The *dihydrochloride*, $C^{12}H^{10}N^2 \cdot 2HCl$, crystallises in colourless laminae easily soluble in water, and forms a yellow crystalline precipitate with platonic chloride (Petrieff, *Zeitschr. f. Chem.* [2] vi. 265).

BENZILE or BENZILIC ANHYDRIDE. $C^{14}H^{10}O^2$ or $H^3C-C^1H^5=O \begin{smallmatrix} \diagup O \\ \diagdown O \end{smallmatrix}$

(see AROMATIC SERIES, p. 211).—This body, originally obtained by oxidation of benzoin, $C^{14}H^{12}O^2$, appears also to be produced by heating bromotoluylene with water to 150° (Limpricht a. Schwartz, *Jahresb.* 1867, p. 674):

The benzile thus obtained crystallises in four-sided needles melting at 95° (Zinin's benzile, i. 515, melts at 90° – 92° , and crystallises in six-sided prisms). The hexagonal crystals possess an optical rotatory power rather greater than that of quartz. All the crystals examined were dextrogyrate. Their double refraction is positive and very strong. For the line D, at 14° , $\omega = 1.6588$ and $\epsilon = 1.6784$. They expand by heat nine times as much as platinum in the direction of the axis, and five times as much in the direction perpendicular to the axis. Hence, contrary to what takes place in quartz, the original rhombohedron of $80^\circ 14'$ is rendered more acute by rise of temperature (Descloizeaux, *Compt. rend.* lxxiii. 308).

Chlorobenzile. $C^{14}H^9OCl^2$ (Zinin, *Ann. Ch. Pharm.* cxix. 177; *Zeitschr. f. Chem.* [2] iv. 718).—When benzile is heated to fusion with phosphorus pentachloride, 2 at. chlorine take the place, not of hydrogen, but of 1 at. oxygen, forming chlorobenzile:

On expelling the phosphorus oxychloride by heat, and washing the residue first with hot and then with cold water, it solidifies to a white crystalline mass of chlorobenzile. This substance dissolves easily in ether, and crystallises therefrom in short rhombic prisms or thin rhombic tables; it is less soluble in alcohol, insoluble in water; melts at 71° , and solidifies in the crystalline form (unless it has been too strongly heated or fused under water or alcohol, in which case it remains liquid at a lower temperature); it is decomposed by distillation, yielding a liquid containing benzoyl chloride. It dissolves with rise of temperature in strong *nitric acid*; and by boiling with this acid, or with an alcoholic solution of silver nitrate, it is converted, with evolution of red vapours, into benzile, which separates on addition of water. Heated with water in sealed tubes to 180° , it is completely resolved into benzile and hydrochloric acid:

Alcohol decomposes it at a lower temperature, yielding benzile, ethyl chloride, and hydrochloric acid:

Alcoholic potash acts on chlorobenzile in alcoholic solution, slowly in the cold, more quickly and completely when heated, forming potassium benzoate and benzoic aldehyde:

Aqueous *ammonia* does not act on chlorobenzile; alcoholic ammonia decomposes it in a more complex manner. Chlorobenzile heated to 200° with an equivalent quantity of *phosphorus pentachloride* is converted into a body $C^{14}H^9Cl^4$, which is insoluble in water, slightly soluble in alcohol and ether, and is slowly converted by nitric acid into a nitro-compound. In boiling alcoholic solution, it is easily converted by sodium-

Sup.

X

amalgam into a hydrocarbon C_6H_6 , identical with toluene. Chlorobenzene treated in alcoholic solution with zinc and hydrochloric acid is quickly converted into deoxybenzoin:

Nitrobenzile. $C^6H^5(NO^2)O^2$ (Zinin, *Ann. Ch. Pharm. Suppl.* iii. 153).—Produced, together with nitrobenzoic acid and a small quantity of benzile, by prolonged boiling of deoxybenzoin with nitric acid of sp. gr. 1.2; more advantageously prepared by adding benzoin (not more than 10 grms.) to nitric acid of sp. gr. 1.5 cooled to 0° , and immediately pouring the resulting solution into cold water. The colourless body thereby separated dissolves in an equal weight of ether, and separates therefrom in sulphur-yellow granules, composed of laminae and needles, which are now much less soluble in ether, still less in alcohol, and quite insoluble in water. The nitrobenzile, purified by recrystallisation, first from ether and alcohol, then from strong nitric acid, and lastly from pure alcohol, melts at 110° , distils with partial decomposition, dissolves in 30 pts. of boiling alcohol of 85 p. c., and in 27 pts. of 92 p. c. alcohol. When its hot saturated alcoholic solution is mixed with sufficient *alcoholic potash* to produce a faint alkaline reaction, potassium azobenzoate separates on cooling, and oxybenzoate remains in solution:

Hydrobenzile. $C^6H^{12}O$, produced by the action of ammonium sulphide on benzile, is described in vol. iii. p. 185.

This acid, originally obtained by oxidation of benzoin (i. 515), is also produced by boiling that substance with alcoholic potash:

the hydrogen being oxidised in contact with the air. If, however, the benzoin be heated with alcoholic potash to 120° – 160° in a sealed tube exhausted of air, it is converted into benzilic acid, hydrobenzoin, $C^6H^{14}O^2$, and a body crystallising in needles, which Claus obtained by the action of sodium-amalgam on an ethereal solution of bitter almond oil (Zinin, *Bull. Soc. Chim.* [2] vii. 260). According to Borodine (*Rép. Chim. pure*, iv. 433), benzilic acid is produced by the action of sodium amylate on benzile.

Pure benzilic acid melts at 150° . When heated for some time to 180° it yields, together with a red resin, a substance having the composition $C^{12}H^{22}O^4$, according to the equation $2C^6H^{12}O^2 - H^2O = C^{12}H^{22}O^4$. This substance crystallises in small needles melting at 196° , and is reconverted into benzilic acid by heating with water to 180° . Benzilic acid heated with *potassium chromate and dilute sulphuric acid* is resolved into water, carbon dioxide, and benzophenone:

Heated with *hydriodic acid* to 180° , it forms an acid which crystallises in beautiful needles, melts at 146° , and has the composition $C^6H^{12}O^2$ (A. Jena, *Berlin. Chem. Gesellsch.* 1889, p. 384).

BENZOIC ACID. $C^6H^5O^2 = C^6H^5.CO^2H$.—This acid has been produced synthetically by four different processes: 1. By passing benzene vapour mixed with carbonyl chloride (phosgene) through a heated retort exposed to the sun's rays, whereby benzoyl chloride, $C^6H^5.COCl$, is produced:

and decomposing the latter with water (Harnitz-Harnitzky, *Bull. Soc. Chim.* [2] i. 322). According to Berthelot, this reaction does not take place (p. 262). On the other hand, Schützenberger has obtained benzoic acid by treating benzene with a mixture of sulphuric anhydride and carbon tetrachloride (which produces carbonyl chloride); and Wurtz has formed it by the action of ethyl chlorocarbonate and sodium-amalgam on chlorobenzene (p. 206).

2. By adding sodium in small pieces to monobromobenzene diluted with benzene in a long-necked retort provided with an ascending condensing tube, heating the retort in the water-bath, and passing a current of dry carbonic acid gas into the mixture:

The product is treated with water which dissolves the sodium benzoate (Kekulé, *Ann.*

Ch. Pharm. cxxxvii. 159). This process is also applicable to the preparation of the homologues of benzoic acid (p. 306).

3. By distilling aniline with sulphuric acid, whereby, amongst other products, benzonitrile $C^6H^5.CN$, is obtained, and decomposing this compound with potash (Hofmann, *Proc. Roy. Soc.* xvi. 484). See AROMATIC SERIES (p. 206). V. Mers (*Zeitschr. f. Chem.* [2] iv. 38) obtains benzonitrile by heating potassium benzene-sulphate with potassium cyanide:

and converts the nitrile into benzoic acid by distillation with alcoholic potash.

4. By the action of a mixture of manganese dioxide and dilute sulphuric acid on benzene, the reaction consisting, first in the production of formic acid by oxidation of a portion of the benzene; secondly in the abstraction of an atom of hydrogen from the former and from the benzene residue by oxidation, and in the union of the residues CO^2H and C^6H^5 to form benzoic acid:

Part of the benzoic acid is, however, converted by a repetition of the same reaction into phthalic acid, $C^6H^4.(CO^2H)^2$ (Carius, *Ann. Ch. Pharm.* cxlviii. 50, 99).

The following modes of formation have also been observed; the fifth and sixth are applied to the industrial preparation of benzoic acid:

5. By heating phthalic acid with an equivalent quantity of calcium hydrate (slaked lime) to 330° – 350° for several hours, excluding the air as much as possible:

The phthalic acid required for this process is prepared from naphthalene (P. a. E. Depouilly, *Bull. Soc. Chim.* [2] iii. 163, 469).

6. By boiling benzoyl chloride, $C^6H^5.CO^2Cl$, with nitric acid for several hours in a flask connected with an inverted Liebig's condenser, whereby it is oxidised to benzoic acid and benzoic aldehyde, which may be separated by water. The benzoic acid thus obtained has a strong odour of bitter almond oil, which it partly loses on exposure to the air (Lauth a. Grimaux, *ibid.* vii. 105).

7. By exposing benzylene chloride, $C^6H^4Cl^2$, to the joint action of air and water (Carius, *Compt. rend.* lvi. 222).

8. By heating benzyl disulphide to 130° with bromine and water (Märcker, *Ann. Ch. Pharm.* cxl. 86):

9. By the oxidation of certain aromatic hydrocarbons, viz. those which contain a single lateral chain, e.g. methyl-benzene, ethyl-benzene, &c. See AROMATIC SERIES, p. 200.

10. By the action of sodium-amalgam and water on amidobenzoic acid (Hübner a. Petermann, *Zeitschr. f. Chem.* [2] iv. 548).

11. By boiling diazosalyl-nitric acid (prepared from anthranilic acid by the action of nitrous acid) in alcoholic solution (Griess, *ibid.* ii. 157):

12. By heating quinic acid with saturated hydriodic acid to 115° – 120° , or by distilling its syrupy solution with 4 mol. phosphorus diniodide. If the quinic acid be heated to 140° with hydriodic acid and phosphorus (the presence of which prevents the separation of iodine), an acid is formed containing more hydrogen than benzoic acid: hence the reduction appears to take place as follows:

and

(Lautemann, *Ann. Ch. Pharm.* cxx. 9).

13. By heating the aurochloride of cocaine or of atropine (Niemann, *Jahresb.* 1860, p. 367).

Decompositions.—1. A hot solution of benzoic acid acidulated with hydrochloric acid is decomposed by sodium-amalgam into benzyl alcohol, C^6H^5O , a neutral crystallising oil, $C^6H^{10}O^2$, and benzoic acid, $C^6H^5O^2$, a volatile acid heavier than water and

smelling like valerianic acid (Kolbe, *Ann. Ch. Pharm.* cxviii. 422; M. Hermann, *ibid.* cxxiii. 75).

2. Benzoic acid heated with 30 pts. of saturated *hydriodic acid* yields septane or heptyl hydride, C^7H^{14} , as normal product, and sextane, C^6H^{12} , resulting from the splitting up of the benzoic acid into benzene and carbon dioxide (Berthelot, *Jahresb.* 1867, p. 346).

3. Passed in vapour over heated zinc-dust, it is reduced to benzoic aldehyde (Bäyer, *Ann. Ch. Pharm.* cxl. 295).

4. When a solution of benzoic acid is boiled with *lead dioxide*, and *dilute sulphuric acid* is gradually added, the benzoic acid is oxidised to succinic acid. The same transformation takes place in the animal organism (Meissner a. Shepard, *Jahresb.* 1866, p. 397).

5. Iodine monochloride decomposes aqueous benzoic acid, with separation of iodine and formation of chlorinated benzoic acid (Stenhouse, *Chem. Soc. J.* [2] i. 327, 366).

6. Brown *chloride of sulphur*, (SCl^2) , acts violently on dry benzoic acid, forming benzoyl chloride, together with sulphurous oxide and hydrochloric acid. (See SULPHUR, CHLORIDES OF, v. 535).

Metallic Benzoates. The ammonium salt $C^7H^5O^2(NH^4)$ crystallises in tabular rhombic combinations, $\alpha P : P \infty$; angle $P : P$ (mncr.) = $24^\circ 28'$; $P : P$ (brach.) = $96^\circ 12'$; $P : P$ (basal.) = $143^\circ 56'$; $P \infty : P \infty$ (basal.) = $130^\circ 51'$ (Marignac, *Compt. rend.* xlv. 650). The potassium salt $C^7H^5O^2K$ is probably isomorphous with the ammonium salt, but it crystallises in laminae the form of which cannot be exactly defined (Marignac). Treated with cyanogen bromide, it yields large quantities of carbon dioxide and benzonitrile (together with a neutral solid azotized body):

(Cahours, *Ann. Ch. Phys.* [3] lii. 201). Subjected to electrolysis in neutral solution, it yields potash at the negative, benzoic anhydride and oxygen at the positive pole:

In a solution containing a slight excess of potash, $4C^7H^5O^2K + KHO$, the same decomposition takes place, but acetylene is also given off, part of the benzoic acid being decomposed as shown by the equation:

In a very alkaline solution, nothing is evolved at the positive pole but oxygen, with small quantities of carbon monoxide and dioxide (E. Bourgoin, *Zeitschr. f. Chem.* [2] iv. 566).

Sodium Benzoate, $C^7H^5O^2Na$, is decomposed by iodine monochloride at ordinary temperatures, forming iodine benzoate or benzo-iodic acid: $C^7H^5O^2Na + ICl = NaCl + C^7H^5IO^2$. On heating the product, carbon dioxide and iodine are evolved, together with an oily liquid which is resolved by fractional distillation into moniodobenzene, C^6H^5I , boiling at 185° , and di-iodobenzene, $C^6H^4I^2$, solidifying at ordinary temperatures, and boiling at 250° (Schützenberger, *Rép. Chim. pure*, iii. 145; iv. 268).

Cerous Benzoate, $(C^7H^5O^2)^2Ce \cdot 2H^2O$, obtained by precipitating cerous sulphate with ammonium benzoate, is a granular crystalline powder soluble in acids and in cerous sulphate, sparingly soluble in water (Czudnowicz, *Jahresb.* 1861, p. 190). The *lanthanum salt* $(C^7H^5O^2)^3La \cdot 2H^2O$ is a crystallo-granular precipitate, slightly soluble in water, becoming anhydrous at 100° (Czudnowicz, *ibid.* 1860, p. 129).

Chromic Benzoates.—Chromic salts mixed with potassium benzoate yield gradually at ordinary temperatures, immediately at 40° – 50° , a precipitate probably consisting of the normal salt $(Cr^2)^3(C^7H^5O^2)^6 \cdot \frac{1}{2}H^2O$. Boiled with water or alcohol, it gives up benzoic acid and yields the basic salt $\left. \begin{matrix} (C^7H^5O^2)^4 \\ (HO)^2 \end{matrix} \right\} O^2 \cdot H^2O$ (Schiff, *Ann. Ch. Pharm.* cxxiv. 157).

Alcoholic Benzoates. Benzoic Ethers. **Methyl Benzoate**, $C^7H^5O^2.CH^3$, has, according to Mendeleef (*Jahresb.* 1860, p. 7), a sp. gr. of 1.0921 at 12.3° . By prolonged digestion at 100° with potassium dichromate and dilute sulphuric acid, it is oxidised to benzoic acid, formic acid, and carbon dioxide (R. H. Smith, *Chem. Soc. J.* [2] v. 131).

Ethyl Benzoate, $C^7H^5O^2.C^2H^5$.—Sp. gr. 1.0517 at 14.1° (Mendeleef). By oxidation with chromic acid mixture it yields benzoic and acetic acids (Smith). Heated with

bromine, ultimately to 270°, it yields benzoic acid and ethylene bromide (A. Naumann, *Ann. Ch. Pharm.* cxxiii. 199):

According to Geuther (*Zeitschr. f. Chem.* [2] iv. 658), ethyl benzoate is not attacked by sodium ethylate at 120°; but at 160° sodium benzoate and ethyl oxide are formed, together with a colourless liquid, $C^1H^{10}O$, and a solid yellow mass, $C^1H^{10}O$.

Amyl Benzoate, $C^1H^1O^2.C^1H^{11}$, is formed by heating ethyl benzoate with amyl alcohol to 217°-240° for sixty hours, the ethyl and amyl changing places. A mixture of 1 mol. ethyl benzoate and 1 mol. amyl acetate heated for several hours to 300° yielded only small quantities of ethyl acetate and amyl benzoate (Friedel & Crafts, *Bull. Soc. Chim.* [2] ii. 100).

Cetyl Benzoate, $C^1H^1O^2.C^{18}H^{37}$ (i. 840).

Cholesteryl Benzoate, $C^1H^1O^2.C^{26}H^{43}$ (i. 926).

Sycoceryl Benzoate, $C^1H^1O^2.C^{18}H^{35}$ (v. 646).

Propylene or Tritylene Benzoate, $(C^1H^1O^2)^3.C^1H^4$, prepared by heating silver benzoate with propylene bromide, and treating the product with sodium carbonate and ether, forms large colourless crystals isomorphous with those of ethylene benzoate; insoluble in water and alkaline carbonates, soluble in ether and in alcohol, melting at 72°, and volatilising without decomposition at a temperature above 300°. *Amylene benzoate*, $(C^1H^1O^2)^2.C^1H^{10}$, prepared in like manner crystallises in long shining laminae melting at 123° (A. Mayer, *Bull. Soc. Chim.* [2] ii. 451).

Benzylene Benzoate, $(C^1H^1O^2)^2.C^1H^4$ (i. 578).

Cumylene Benzoate, $(C^1H^1O^2)^2.C^{10}H^{12}$ (ii. 184).

The chlorinated, brominated derivatives, &c., of benzoic acid exhibit isomeric modifications according to the relative positions occupied by the chlorine, bromine, &c., and the radicle CO^1H of the benzoic acid.

Bromobenzoic Acids.

Monobromobenzoic acid, $C^1H^1Br.CO^1H$, is produced by heating benzoic acid with bromine and water to 100° for several days. The acid thus obtained is slightly soluble in boiling water, dissolves easily in dilute alcohol, and crystallises in flat needles, melting at 152°-153°. Its *calcium salt*, $(C^1H^1BrO^2)^2Ca.3H^1O$, crystallises from water or alcohol in nodular groups of ill-defined needles. The *barium salt* $(C^1H^1BrO^2)^2Ba.4H^1O$ forms sparingly soluble flat needles. The acid is converted by *nitric acid* into two isomeric nitrobromobenzoic acids; by further treatment with *bromine*, into tribromobenzoic acid; by *potassium chlorate* and *hydrochloric acid*, into chlorobenzoic acid. Its silver salt exposed to the action of bromine-vapour yields a gas, probably O or Br^2O , together with bromobenzoic anhydride, which is converted by water into bromobenzoic acid:

(Reinecke, *Zeitschr. f. Chem.* [2] v. 109).

Bromobenzoic acid is also formed, together with hydrobromide of amidobenzoic acid, by the action of hydrobromic acid on diazobenzo-amidobenzoic acid (Griess, iv, 292):

The bromobenzoic acid thus produced appears to be identical with that obtained directly from benzoic acid. Diazobenzo-amidobenzoic acid treated with bromine and water yields a monobromobenzoic acid, which crystallises in laminae, and appears to be different from the preceding (Griess). Bromobenzoic acid identical with the first is also produced by oxidising orthobromotoluene with chromic acid mixture (Wroblewsky, *Zeitschr. f. Chem.* [2] v. 332); hence this modification consists of orthobromobenzoic acid. The same acid is obtained by decomposing with boiling alcohol the perbromide of diazobenzoic acid obtained by mixing nitrate of diazobenzoic acid with a solution of bromine in hydrobromic acid (Griess, *Jahresh.* 1865, p. 337):

and by the action of bromine-vapour on silver-benzoate (i. 314). Benzamide boiled with bromine and water is resolved, according to the equation,

into ammonium bromide and bromobenzoic acid, which, however, appears to be a

mixture of two isomeric acids, inasmuch as its melting point rises by recrystallisation from 149° to nearly 200° (Reinecke, *Zeitschr. f. Chem.* [2] ii. 367).

Bromobenzoic acid distilled with lime yields pure benzene; when distilled with pumice it passes over undecomposed (Riche, *Compt. rend.* liii. 586). The ammoniacal solution of the acid (prepared by Peligot's process, i. 554) is converted by heat into amidobenzoic acid: $C^6H^5BrO^2 + NH^3 = HBr + C^6H^5(NH^2)O^2$ (Alexeyeff, *Bull. Soc. Chim.* 1861, p. 71). Sodium bromobenzoate distilled with an equivalent quantity of iodine monochloride gives off carbon dioxide, iodine, bromobenzoic acid, and an oil containing iodobenzene and apparently phenyl bromobenzoate, $C^6H^5BrO^2 \cdot C^6H^5$ (Schützenberger a. Segenwald, *Jahresb.* 1862, p. 250).

Metabromobenzoic or *Bromosalicylic acid*, $C^6H^4BrH.CO^2H$, is said by v. Richter (*Zeitschr. f. Chem.* [2] v. 457) to be produced, together with the ortho-acid, by heating benzoic acid with water and bromine. It is said to be less soluble than the ortho-acid, and to separate out nearly pure, when the hot aqueous solution of the two is left to cool, in white flocks melting at 90° , and subliming at 89° in needles. These results, however, do not appear to be very well established (comp. Hübner, *ibid.* 514). Hübner a. Petermann (*Ann. Ch. Pharm.* cxlix. 131) find that only one monobromobenzoic acid is formed by the action of bromine on benzoic acid.

Parabromobenzoic or *Bromodracylic acid*, $C^6H^4BrH^2.CO^2H$, obtained by oxidising bromotoluene with chromic acid, crystallises from ether in small volatile needles, melting at 251° , slightly soluble in cold, more soluble in boiling water, easily in alcohol and ether. Its easily soluble *barium salt*, $(C^6H^4BrO^2)^2Ba$, crystallises in nacreous laminae; the *silver salt* $C^6H^4BrO^2Ag$ in white slightly soluble needles. The ethylic ether is a fragrant liquid (Hübner a. Ohly, *Jahresb.* 1866, p. 347).

Dibromobenzoic acid, $C^6H^2Br^2O^2 = C^6H^2Br^2.CO^2H$, is formed, together with other bromobenzoic acids, when benzoic acid is strongly heated with excess of bromine (Reinecke, *Jahresb.* 1865, p. 322; Hübner, *loc. cit.*). It crystallises in short needles melting at 223° - 227° , sparingly soluble in cold water, easily in alcohol and ether, not volatilising with aqueous vapour. The *barium salt* $(C^6H^2Br^2O^2)^2Ba \cdot 2H^2O$ forms short, transparent needles; the *calcium salt*, shining laminae; the *sodium salt* is difficult to crystallise (Hübner).

Dibromodracylic acid, which sublimes in needles, is produced by the action of nitrous acid on a hot alcoholic solution of dibromamidodracylic acid (Geitner a. Beilstein, *Jahresb.* 1865, p. 335).

Tribromobenzoic acid, $C^6H^3Br^3O^2 = C^6H^3Br^3.CO^2H$, is formed from the monobrominated acid when the mixture of benzoic acid with bromine and water is heated to 140° - 160° , part of it being, however, converted into pentabromobenzoic acid. The tribrominated acid may be partly separated by dissolving the mixture of acids which crystallises out, in a boiling solution of sodium acetate, the liquid on cooling yielding crystals of the tribrominated acid (Reinecke). It is also formed, together with monobromobenzoic acid, by the action of bromine and water on diazobenzo-amidobenzoic acid (Griess). It crystallises in tufts of slender needles having a strong silky lustre, and melting at 234° - 235° ; the admixture of another bromobenzoic acid, however, lowers the melting point to below 100° . The crystals are nearly insoluble in boiling water, more easily in dilute alcohol or boiling benzene. The metallic *tribromobenzoates* are sparingly soluble, and crystallise in needles. The calcium salt $(C^6H^3Br^3O^2)Ca \cdot 5H^2O$ easily gives off its water when heated.

Tribromobenzoic acid is the most stable of all the bromobenzoic acids, not being altered by boiling with nitric acid or by fusion with caustic potash. By prolonged heating in a sealed tube with potassium chlorate and hydrochloric acid it is completely converted into trichlorobenzoic acid. The silver salt $C^6H^3Br^3O^2Ag$, exposed to the action of bromine vapour [? moist], is ultimately reconverted into tribromobenzoic acid (Reinecke, *Zeitschr. f. Chem.* [2] v. 110).

Pentabromobenzoic acid, $C^6HCl^5O^2 = C^6Cl^5.CO^2H$, is formed by the long-continued action of bromine and water on tribromobenzoic acid at temperatures above 200° ; but a considerable portion of it is at the same time resolved into carbon dioxide and pentabromobenzene. The remainder treated with ammonia yields an ammonium salt which may be purified by crystallisation.

Pentabromobenzoic acid has the aspect of sublimed benzoic acid. It is nearly insoluble in boiling water; crystallises from dilute alcohol in thin laminae or long broad needles; from boiling benzene, in which it is but slightly soluble, it crystallises on cooling in thick, larger needles; melts at 234° - 235° , which is also the melting point of tribromobenzoic acid. Heated with a strong solution of sodium acetate to 149° - 160° in a sealed tube, it forms an acid which crystallises in needles and turns

iron salts blue, doubtless tetrabromosalicylic acid. At a higher temperature carbon dioxide is evolved, in consequence of the further decomposition of this acid.

The metallic *pentabromobenzoates* are all sparingly soluble. The ammonium salt $C^*Br(NH^4)O^2$ forms shining laminae very much like leucine; the potassium and sodium salts also crystallise in flat prisms. The calcium salt $(C^*BrO^2)Ca.6H^2O$ crystallises from dilute alcohol in scales having a strong lustre (Reinecke, *loc. cit.*).

Chlorobenzoic Acids.

Monochlorobenzoic acid, C^*H^3ClO , is known in the three modifications of ortho- (1 : 2), meta- (1 : 3), and para- (1 : 4).

Orthochlorobenzoic acid, $C^*H^4Cl.CO^2H$, is the modification which Limpricht a. von Uslar obtained by the action of water or alkalis on chlorobenzoyl chloride, $C^*H^4Cl.COCl$ (i. 566). It is also produced by the action of chlorine or hypochlorous acid on benzoic acid (i. 555); of hydrochloric acid on chloro-hippuric acid (Otto, *Jahresb.* 1862, p. 255); of hydrochloric acid on diazobenzo-amidobenzoic acid (Griess). Lastly it is produced by the oxidising action of chromic acid on orthochlorotoluene, $C^*H^4Cl.CH^3$ (Wroblewsky, p. 281). It forms a crystalline mass, slightly soluble in water, easily in alcohol, subliming in crystals, and melting at 151° (Wroblewsky); at 152.5° , not under water (Beilstein a. Schlun, *Jahresb.* 1865, p. 330). By fusion with potassium hydrate it is converted into oxybenzoic acid (Dembey, *Ann. Ch. Pharm.* cxlviii. 221). Its calcium salt, $(C^*H^4ClO^2)Ca.3H^2O$, crystallises well, and dissolves in 82.7 pts. water at 12° .

Metachlorobenzoic or Chlorosalicylic acid, $C^*H^3ClH.CO^2H$, discovered by Chiozza, and formerly called *parachlorobenzoic acid* (i. 555), is prepared by distilling 1 mol. of salicylic (meta-oxybenzoic) acid, or better of its sodium salt, with 2 mol. phosphorus pentachloride, whereby chlorosalicyl chloride, $C^*H^3OCl^2$, is obtained, together with salicyl chloride, $C^*H^3O^2Cl$, and chlorosalicyl trichloride, $C^*H^3Cl^3$; rectifying the distillate; and decomposing the portion which distils above 240° and consists mainly of chlorosalicyl chloride, $C^*H^3ClO.Cl$, with boiling water. The chlorosalicylic acid thus obtained may be freed from salicylic acid by once recrystallising it from water (Kolbe a. Lautemann, *Ann. Ch. Pharm.* cxv. 157; *Jahresb.* 1860, p. 288).

Chlorosalicylic acid is a crystalline mass composed of white silky needles, melting at 140° (Kolbe a. Lautemann); at 137° , and likewise under water (Beilstein a. Schlun). Dissolves in 881 pts. water at 0° . Like the ortho-acid, it gives with ferric chloride a yellow precipitate, but no violet coloration. It is not decomposed by boiling potash-ley, but is converted into salicylic acid by melting with potassium hydrate. In hot aqueous solution it is easily reduced to benzoic acid* by sodium-amalgam, whereas orthochlorobenzoic acid is scarcely affected by that reagent (Kolbe a. Lautemann). Its calcium salt, $(C^*H^3ClO^2)Ca.2H^2O$, is very soluble in water (Beilstein a. Schlun). The *ethylic ether*, $C^*H^3ClO^2.C^2H^5$, obtained by treating with alcohol the product of the action of phosphorus pentachloride on salicylic acid (i. 555), is a colourless fragrant liquid, insoluble in water, and boiling at $238^\circ-242^\circ$ (Kekulé, *Rép. Chim. pure*, 1861, p. 308).

Parachlorobenzoic or Chlorodracrylic acid, $C^*H^2ClH^2.CO^2H$, is produced: 1. By heating diazo-amidodracrylic acid (isomeric with diazo-amidobenzoic acid, iv. 292) with hydrochloric acid (Wilbrand a. Beilstein, *Ann. Ch. Pharm.* cxxviii. 257).—2. By oxidising mono-chlorobenzene with a mixture of dilute sulphuric acid and manganese dioxide. Part of the chlorobenzene then suffers complete decomposition, yielding formic acid, amongst other products, and the formic acid, together with free oxygen, converts the rest of the chlorobenzene into chlorodracrylic acid:

The chlorodracrylic acid, the greater part of which remains mixed with undecomposed chlorobenzene, may be extracted therefrom by soda-ley, precipitated by sulphuric acid, and purified by converting it into a barium salt, and decomposing this salt with hydrochloric acid (Carl Müller, *Zeitschr. f. Chem.* [2] v. 137).

Chlorodracrylic acid is easily soluble in alcohol and ether, sparingly in water, 1 pt. of the acid requiring for solution 5,288 pts. water. It melts at 235° , and sublimes in fine needle-shaped prisms and in laminae (Müller); melts at $236^\circ-237^\circ$, and sublimes in scales, but not in needles like the two preceding modifications (Beilstein a. Schlun). Its barium salt, $(C^*H^2ClO^2)Ba.4H^2O$, crystallises in prisms and laminae; the calcium salt has the composition $(C^*H^2ClO^2)Ca.3H^2O$.

* The benzoic acid thus obtained is impure, and was for some time regarded as a distinct acid, called by Kolbe a. Lautemann *salicylic acid*; but Beilstein a. Schlun have shown that, when purified by distillation in aqueous vapour, it exhibits all the properties of ordinary benzoic acid.

Dichlorobenzoic Acid. $C^6H^4Cl^2O^2 = C^6H^4Cl^2.CO^2H$ (Otto, *Ann. Ch. Pharm.* cxxii. 129; cxxiii. 216; *Jahresb.* 1862, 253, 255. Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] iv. 661; v. 180, 526; *Ann. Ch. Pharm.* clii. 224).—Produced: 1. By distilling chlorobenzene-sulphuric acid with phosphorus pentachloride, whereby chlorobenzoyl chloride, $C^6H^4ClO.Cl$, is produced, and decomposing this chloride with potash.—2. By prolonged boiling of dichlorhippuric acid with strong hydrochloric acid (Otto).—3. By oxidising dichlorotoluene with chromic acid:

4. By heating dichlorobenzene trichloride with water in a sealed tube:

5. By boiling benzoic acid with solution of chloride of lime, whereby calcium monochlorobenzoate appears to be formed in the first instance:

The chloride of lime solution acts very quickly on the free acid, but scarcely at all on the calcium salt; hence, as soon as the liquid becomes neutral, it is necessary to precipitate the monochlorinated acid by addition of hydrochloric acid, filter off the liquid, and again boil the crude acid with chloride of lime solution; the reaction then goes on further, and the calcium salt of dichlorobenzoic acid is produced:

The liquid is again acidulated, and the treatment with chloride of lime repeated a third, and sometimes even a fourth time; if, however, the treatment be too much prolonged, part of the product is converted into trichlorobenzoic acid. The crude dichlorinated acid is then combined with baryta, the barium salt purified by recrystallisation (1 pt. dissolves in 100 pts. of water), and the acid precipitated from it by hydrochloric acid (Beilstein a. Kuhlberg).

Dichlorobenzoic acid exhibits the same properties, by whichever of the preceding processes it may be prepared (Beilstein, *Zeitschr. f. Chem.* [2] v. 180). It is sparingly soluble in cold, more freely in hot water, easily soluble in alcohol, crystallises from water in slender needles, melts at 210° ,* and distils without decomposition. Fuming nitric acid converts it into monochloronitrobenzoic acid (Beilstein a. Kuhlberg). By sodium-amalgam it is reduced to benzoic acid (Otto).

The barium salt $(C^6H^4Cl^2O^2)^2Ba.4H^2O$ crystallises in slender shining needles, slightly soluble in water. The calcium salt $(C^6H^4Cl^2O^2)^2Ca.3H^2O$ crystallises in shining scales. The ethylic ether, a fragrant liquid, boiling at 262° – 263° , is obtained by heating dichlorotoluene-trichloride with absolute alcohol to 180° :

Dichlorobenzoyl chloride, $C^6H^4Cl^2O.Cl$, produced by the action of phosphorus pentachloride on dichlorobenzoic acid (B. and K.), or on chlorobenzene-sulphuric acid (Otto), is a liquid boiling without decomposition at 242° (B. and K.).

Dichlorobenzamide, $C^6H^4Cl^2O.NH^2$, is obtained by treating the chloride with ammonia, or directly by heating dichlorotoluene trichloride with an equivalent quantity of ammonia to 200° :

It forms beautiful silky, yellowish needles, melting at 133° , volatilising with vapour of water, more soluble in boiling than in cold water. Heated with excess of ammonia to 200° , it decomposes with elimination of chlorine (B. and K.).

Trichlorobenzoic Acid. $C^6H^3Cl^3O^2 = C^6H^3Cl^3.CO^2H$ (Janasch, *Zeitschr. f. Chem.* [2] iii. 404. Beilstein a. Kuhlberg, *ibid.* iv. 663; v. 526; *Ann. Ch. Pharm.* clii. 224).—Produced: 1. By oxidising trichlorotoluene with chromic acid mixture:

but the conversion is very slow.—2. By heating trichlorotoluene-trichloride with water to 260° in sealed tubes:

The reaction takes place quickly, and almost without formation of secondary products, the trichlorinated acid often crystallising in the tubes. It is extracted by repeated boiling with ammonia, and precipitated by hydrochloric acid (B. and

* Otto observed lower melting points for the acid obtained by the first and second processes; but his descriptions of the salts agree in all essential particulars with those given by Beilstein a. Kuhlberg.

K.).—3. By boiling the dichlorinated acid with strong solution of chloride of lime, precipitating the neutral solution with hydrochloric acid, and repeating the same treatment on the precipitated acid till the conversion is nearly complete. To purify the product from remains of the dichlorinated acid, it is converted into the ethylic ether, which, being solid, may be freed from adhering dichlorinated ether by pressure and recrystallisation from alcohol; when decomposed by strong potash-solution, it yields the pure acid. The three modes of preparation yield the acid with exactly the same properties; the second is the most expeditious (B. and K.).

Trichlorobenzoic acid crystallises in very slender needles melting at 163° (B. and K.); 160° (Janasch); scarcely soluble in cold, sparingly in boiling water, freely in alcohol and ether. The ammonium salt $C^3H^2Cl^3O^2(NH^4).H^2O$ is crystalline and very slightly soluble in cold water. The barium salt $(C^3H^2Cl^3O^2)^2Ba.7H^2O$ crystallises in slender silky needles, moderately soluble in hot water. The calcium salt $(C^3H^2Cl^3O^2)^2Ca.2H^2O$ forms small needles more soluble than the barium salt. The strontium salt $(C^3H^2Cl^3O^2)^2Sr.4H^2O$ is easily soluble in boiling water, and crystallises on cooling in small white needles. The magnesium salt is extremely soluble; the zinc salt forms slender needles; the lead salt is moderately soluble in hot water; the copper salt is a green insoluble precipitate. The ethylic ether $C^3H^2Cl^3O^2.C^2H^5$ crystallises from alcohol in long flat white needles, melts at 65° , and has a faint fruity odour.

Trichlorobenzoic chloride, $C^3H^2Cl^3.COCl$, boils almost without decomposition at 272° , melts at about 41° , and is extremely soluble in benzol, ether, and carbon bisulphide.

Trichlorobenzamide, $C^3H^2Cl^3.CONH^2$, produced by the action of ammonia on the chloride, is very sparingly soluble in water even at the boiling heat, easily soluble in alcohol, and crystallises from benzol in slender white needles melting at 167.6° (Beilstein a. Kuhlberg).

Tetrachlorobenzoic acid (para), $C^3H^2Cl^4O^2 = C^3HCl^4.CO^2H$, is prepared by heating tetrachlorobenzotrichloride, $C^3HCl^4.CCl^3$, with water to 270° – 280° . It melts at 187° . Its barium salt crystallises in slender needles (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 75, 528).

Iodobenzoic Acids.

Only the monoiodated acid is known, in two modifications.

Ortho-iodobenzoic acid, $C^6H^4I.CO^2H$, is produced by the action of hydriodic acid or of iodine on diazobenzamide-benzoic acid (Griess, *Jahresh.* 1859, p. 466; 1861, p. 411. Cunze a. Hübner, *ibid.* 1865, p. 331); also by the action of iodic acid on benzoic acid (Peltzer, *Ann. Ch. Pharm.* cxxvi. 194); and by oxidising ortho-iodotoluene (p. 284) with chromic acid mixture (Körner, *Zeitschr. f. Chem.* [2] v. 637). It crystallises in needles slightly soluble in water, easily soluble in alcohol, subliming without decomposition (Griess), melting at 187° (Cunze a. Hübner). According to Körner, it melts at 172.5° , and is converted by fusion with potash into oxybenzoic acid. Converted by ammonia into amidobenzoic acid; by strong nitric acid into nitro-iodobenzoic acid.

Barium iodobenzoate, $(C^6H^4IO^2)^2Ba.2H^2O$, forms needles soluble in alcohol; the calcium salt $(C^6H^4IO^2)^2Ca$ crystallises in hard anhydrous nodules and in shining scales containing 1 mol. of water. The magnesium salt $(C^6H^4IO^2)^2Mg.2H^2O$ forms easily soluble nodules; the sodium salt $C^6H^4IO^2Na.H^2O$ four-sided tables (Cunze a. Hübner). The silver salt $C^6H^4IO^2Ag$ is white, insoluble in water and in alcohol (Griess). The ethylic ether $C^6H^4IO^2.C^2H^5$ is a liquid, insoluble in water, not converted into iodobenzamide by contact with ammonia.

Para-iodobenzoic acid, $C^6H^4IH^2.CO^2H$, is formed by oxidising para-iodotoluene, $C^6H^4IH^2.CH^3$, with chromic acid mixture. When purified by conversion into a sodium salt, precipitation by hydrochloric acid, and recrystallisation from alcohol, it forms nacreous scales, nearly insoluble in boiling water, easily soluble in boiling alcohol; does not melt at 250° , but begins to sublime at 230° in white laminae having a strong lustre. Its sodium salt crystallises in long transparent needles. The acid is converted by melting potash into a crystalline acid, possessing the appearance and properties of para-oxybenzoic acid (W. Körner, *Zeitschr. f. Chem.* [2] iv. 327).

Nitrobenzoic Acids.

Mononitrobenzoic acid, $C^6H^4(NO^2).CO^2H$ is known with certainty only in two modifications, ortho- and para-

Orthonitrobenzoic acid is produced by the action of fuming nitric acid, or of a mixture of potassium nitrate and sulphuric acid on benzoic acid, and by several other processes already mentioned (i. 555); also, together with nitrodracrylic acid, in the oxidation of toluene by fuming nitric acid (Reichenbach a. Beilstein, *Ann. Ch. Pharm.* cxxxii. 137). This acid melts under water below 100°, but in the dry state, according to Mills (*Chem. Soc. J.* [2] iv. 563), at 128°. According to A. Naumann (*Jahresb.* 1865, p. 338), the acid separated from its ethylic ether by potash melts at 141°–142°. Its barium salt, $[C^6H^4(NO^2)O^2] \cdot Ba \cdot 4H^2O$, crystallises in thin flattened needles, mostly in radiate groups. It dissolves (reckoned as anhydrous) in 425 to 475 pts. water at 8°–10°; the acid separated from this salt after five recrystallisations, and heated for a few minutes to 137°, yielded a barium salt soluble in 328.5 pts. water (Mills). The acid treated with tin and hydrochloric acid is reduced to amidobenzoic acid, which forms a double salt with stannous chloride, $C^6H^4(NH^2)O^2 \cdot HCl \cdot SnCl^2$; with zinc and hydrochloric acid, it likewise yields amidobenzoic acid; with zinc and caustic soda, an intermediate product appears to be formed (Wilbrand a. Beilstein, *Jahresb.* 1863, p. 342). With alcoholic potash it yields azoxybenzoic acid and aldehyde (Griess, *Ann. Ch. Pharm.* cxxxi. 92):

Sodium nitrobenzoate strongly heated with iodine monochloride yields, together with sodium chloride and free iodine, an oily mixture of mono-iodonitrobenzene, $C^6H^4(NO^2)I$, with a small quantity of a crystalline body, probably di-iodonitrobenzene, $C^6H^4(NO^2)I^2$ (Schützenberger a. Sengenwald, *Jahresb.* 1862, p. 251). The ethylic ether heated with bromine to 170°–200° is resolved into nitrobenzoic acid (melting at 141°–142°) and ethylene bromide, sometimes mixed with a yellowish-white nitrogenous acid insoluble in ether, cold alcohol, and water:

(A. Naumann, *Ann. Ch. Pharm.* cxxxiii. 199).

Paranitrobenzoic or Nitrodracrylic acid. $C^6H^4(NO^2)H^2 \cdot CO^2H$.—Produced, together with the ortho-acid, by the action of fuming nitric acid on toluene (iv. 60), part of the toluene being oxidised to benzoic acid, which is then converted into nitrobenzoic acid, while the greater portion of the toluene is transformed into nitrotoluene, which is then oxidised to nitrodracrylic acid. Crystallised nitrotoluene is completely converted into nitrodracrylic acid by oxidation with chromic acid (Körner, *Zeitschr. f. Chem.* [2] v. 636; Rosenstiehl, *ibid.* 701). The oxidation of nitrotoluene with chromic acid affords a very convenient mode of obtaining pure nitrodracrylic acid. For this purpose a mixture of 10 pts. nitrotoluene, 40 pts. potassium dichromate, and 55 pts. sulphuric acid diluted with twice its volume of water, is heated in a flask provided with a condensing tube, and the nitrated acid is extracted from the filtered residue by sodium carbonate. By precipitating the alkaline solution with hydrochloric acid, and once recrystallising the precipitate, nitrodracrylic acid is obtained in the pure state (Beilstein a. Geitner, *Ann. Ch. Pharm.* cxxxix. 331). Nitrodracrylic acid is likewise obtained (together with nitrobenzoïn), by treating deoxybenzoïn with nitric acid (Zinin, *Ann. Ch. Pharm.* xxxvi. 218; *Zeitschr. f. Chem.* [2] iv. 563).

Nitrodracrylic acid melts at 236°–240°, not under boiling water; it is slightly soluble in cold water (1 pt. in 1327 pts. at 16°). Its zinc salt, $[C^6H^4(NO^2)O^2] \cdot 2Zn \cdot 2H^2O$, dissolves (anhydr.) in 152.7 pts. of water at 14° (Mills, *loc. cit.*). The calcium salt $[C^6H^4(NO^2)O^2] \cdot 2Ca \cdot 8H^2O$ forms large tabular efflorescent crystals, whereas the corresponding salt of orthonitrobenzoic acid contains only 2 mol. water, and crystallises in slender needles. Sodium nitrodracrylate, $C^6H^4(NO^2)O^2Na \cdot 3H^2O$, contains the same proportion of water as the nitrobenzoate; the crystals of both salts are triclinic prisms terminated by oblique faces; but those of the nitrodracrylate are cleavable parallel to one of the end-faces, whereas those of the nitrobenzoate do not exhibit this direction of cleavage (Billinger, *Jahresb.* 1865, p. 334).

The following comparison (p. 315) of the crystalline forms and solubilities of certain salts of ortho- and para-nitrobenzoic acid is given by Sokoloff (*Jahresb.* 1864, p. 343).

Mill describes two other modifications (γ and δ), obtained by treating benzoic acid with a mixture of nitric and sulphuric acids, the latter remaining in the mother-liquor after the former has crystallised out: they are both, however, very much like the ortho-acid, differing from it chiefly by a somewhat higher melting-point (136°–142°); moreover, the process by which they are formed is almost the same as that by which Gerland obtained the ordinary ortho-acid (i. 555).

Dinitrobenzoic acid is described in vol. i. p. 567.

Forms and Solubilities of Ortho- and Para-nitrobenzoic Acids [$\text{NO}^2 = \text{X}$].

	Formula	Crystalline Form	1 pt. salt dissolves in pts. of water	
			at 100°	at ordinary temp.

NITROBROMOBENZOIC ACID. $\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2 = \text{C}^6\text{H}^4\text{Br}(\text{NO}^2) \cdot \text{CO}^2\text{H}$ (Hübner a. Ohly, *Zeitschr. f. Chem.* [2] i. 547; ii. 241; *Ann. Ch. Pharm.* cxliii. 230).—Two modifications of this acid (α and β) are formed by the action of fuming nitric acid on bromobenzoic acid. If when the first violent action is over, the mixture be gently warmed till the whole of the bromobenzoic acid is dissolved, and then mixed with cold water, the less soluble modification (α -bromonitrobenzoic acid) separates out, while the more soluble (β -bromonitrobenzoic acid) remains in the liquid, and may be obtained in the solid state by evaporation. The latter when purified by recrystallisation or sublimation forms, according to O. Philipp, monoclinic combinations ($\infty\text{P}\infty$). ∞P . — P . oP, having the angle oP : ($\infty\text{P}\infty$) = $90^\circ 23'$; ($\infty\text{P}\infty$): ∞P = $140^\circ 11'$; no distinct cleavage. Melting point, 140° – 141° . The ammonium salt forms yellowish laminæ; the potassium salt $\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{K} \cdot 2\text{H}^2\text{O}$, transparent shining needles easily soluble in water, sparingly in alcohol. The sodium salt $2\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{Na} \cdot 6\text{H}^2\text{O}$ crystallises from a highly concentrated aqueous solution in yellowish pointed prisms gradually changing to four-sided tables; from the alcoholic solution also in tables. The silver salt is obtained by precipitation in anhydrous silky needles. The barium salt $[\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2]^2\text{Ba}$ forms white needles; the calcium salt separates from strong solutions in small white nodules containing $[\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2]^2\text{Ca} \cdot 2\text{H}^2\text{O}$, and the mother-liquor deposits asbestos-like needles of the anhydrous salt. The magnesium salt $[\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2]^2\text{Mg} \cdot 4\text{H}^2\text{O}$ forms yellowish elongated, apparently rhombic tables. The lead salt forms indistinct white crystals; the copper salt is obtained by precipitation in greenish crystals: both these salts are anhydrous. The ethylic ether $\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2 \cdot \text{C}^2\text{H}^5$ crystallises from alcohol in shining monoclinic prisms exhibiting the combination ($\infty\text{P}\infty$). ∞P . $\pm\text{P}\infty$. oP, with the clinopinacoid predominant, and the angle ∞P : ∞P (clinod.) = $115^\circ 8'$; cleaving distinctly parallel to oP, less distinctly parallel to ($\infty\text{P}\infty$). The crystals melt at 65° , and are easily soluble in ether.

α -Nitrobromobenzoic acid appears to be formed in greatest quantity when the process is so conducted as not to allow the mixture to get very hot, and remains undissolved when the product is treated with cold water. It is purified by repeated boiling with water, till the residue no longer melts under water, and crystallises from ether in large colourless shining octohedrons which are monoclinic combinations of $+\text{P}$ and $-\text{P}$ with ($\text{P}\infty$) very subordinate. Melting point, 246° – 248° . The sodium salt crystallises sometimes in small nodules, sometimes in rhombic tables; the silver salt in white, anhydrous, very soluble needles decomposing at 110° . The barium salt $[\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2]^2\text{Ba} \cdot 4\text{H}^2\text{O}$, and the calcium salt, form easily soluble laminæ; the magnesium salt, which is soluble even in cold water, forms long needles containing $6\text{H}^2\text{O}$; the lead salt forms small needles soluble in hot water. The ethylic ether crystallises from ether in colourless monoclinic prisms ∞P . $\infty\text{P}\infty$. — $\text{P}\infty$. oP, elongated in the direction of the prismatic axis, cleaving very distinctly parallel to oP, and having the angle ∞P : ∞P (clinod.) = $47^\circ 5'$. They melt at 80° , and dissolve very easily in alcohol and in ether.

The two varieties of nitrobromobenzoic acid just described differ also in their behaviour with reducing agents (p. 317).

Paranitrobromobenzoic or Nitrobromodracrylic acid, $\text{C}^6\text{H}^4\text{Br}(\text{NO}^2)\text{O}^2$, produced by the action of fuming nitric acid on bromodracrylic acid, forms a granulo-crystalline mass melting at 199° , subliming in slender needles, sparingly soluble in cold, more easily

in hot water, freely in alcohol. The *barium salt* forms slightly soluble needles containing $4\text{H}_2\text{O}$; the *magnesium salt*, with $6\text{H}_2\text{O}$, crystallises in spherical groups of small needles easily soluble in water. The *silver salt* $\text{C}^6\text{H}^3\text{Br}(\text{NO}^2)\text{O}^2\text{Ag}$ is a gelatinous precipitate composed of microscopic needles insoluble in hot water and in alcohol. The *ethylic ether* $\text{C}^6\text{H}^3\text{Br}(\text{NO}^2)\text{O}^2 \cdot \text{C}^2\text{H}^5$ crystallises in shining, faintly yellow, monoclinic prisms, $\infty\text{P} \cdot \text{oP}$, having the angle $\infty\text{P} : \infty\text{P}$ (clinod.) = $92^\circ 40'$, elongated in the direction of the principal axis, frequently hollow, cleavable parallel to oP ; melting at 74° .

Nitrobromodracrylic acid may also be prepared by oxidising liquid nitrobromotoluene (melting at 265°) with chromic acid mixture. The acid thus obtained crystallises in needles slightly soluble in water and melting at 195° . Its *barium salt* is easily soluble; the *ethylic ether* melts at 70° . In other respects it exactly resembles that above described.

It appears, then, that the nitrobromodracrylic acids prepared by these two processes do not differ from one another in any essential particular, but that they differ from the two nitrobromobenzoic acids above described, which also are different one from the other: that is to say, we are now acquainted with three modifications of the acid $\text{C}^6\text{H}^3\text{Br}(\text{NO}^2)\text{O}^2$ out of nine which are possible. (See AROMATIC SERIES, p. 197.)

The different arrangement of the atoms in the molecules of these compounds does not exert any essential influence on their crystalline forms, inasmuch as the crystals of the several acids and ethers, though exhibiting differences of development and angular magnitude, all belong to the monoclinic system.

NITROCHLOROBENZOIC ACID (Hübner, *Zeitschr. f. Chem.* [2] ii. 614).—Of the molecule $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{O}^2$ or $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2) \cdot \text{CO}^2\text{H}$ four modifications are known, viz. two produced by the action of fuming nitric acid on chlorobenzoic acid, one in like manner from chlorosalicylic, and one from chlorodracrylic acid.

Of the two (ortho) nitrochlorobenzoic acids, one is sparingly soluble in hot water, and melts at 225° – 230° . Its *barium salt*, $[\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{O}^2]_2\text{Ba} \cdot 4\text{H}_2\text{O}$, forms tufts of needles somewhat sparingly soluble in water; the *calcium salt*, stellate groups of slightly soluble crystals containing $2\text{H}_2\text{O}$; the *ethylic ether*, well-defined needles, melting, according to Cunze a. Hübner (*Jahresb.* 1865, p. 332), at 282° . The other modification of the acid is easily soluble, difficult to purify, and melts at 135° – 137° . (Compare i. 557 and iv. 601).

Nitrochlorosalicylic acid obtained as above, or by the action of phosphorus pentachloride on nitrosalicylic acid, crystallises in capillary or flat needles moderately soluble, and melting at 164° – 165° . Its *barium salt* forms moderately soluble needles containing $2\text{H}_2\text{O}$; the *calcium salt*, stellate groups of thick, pointed, rather sparingly soluble crystals, also containing $2\text{H}_2\text{O}$; the *magnesium salt*, with $8\text{H}_2\text{O}$, easily soluble rhombic tables; the *ethylic ether* melts at 28° – 29° and remains liquid for a long time.

Nitrochlorodracrylic acid, obtained by nitration of chlorodracrylic acid, or by oxidation of nitrochlorotoluene, dissolves sparingly in cold, more freely in hot water, and crystallises in needles melting at 178° – 180° . The *silver salt* forms colourless anhydrous needles; the *barium salt*, with 2 mol. water, small efflorescent, slightly soluble needles; the *magnesium salt*, with 5 mol. water, is easily soluble and crystallises with difficulty in needles. The *ethylic ether* melts at 58° , and likewise crystallises in needles.

NITRO-IODOBENZOIC ACID, $\text{C}^6\text{H}^3\text{I}(\text{NO}^2)\text{O}^2$, formed by the action of nitric acid on iodobenzoic acid, forms rhombic crystals melting at 220° . Its *barium salt*, $[\text{C}^6\text{H}^3\text{I}(\text{NO}^2)\text{O}^2]_2\text{Ba} \cdot 5\text{H}_2\text{O}$, crystallises in nodules. The acid is converted by ammonium sulphide into yellow nodules of amidiodobenzoic acid, $\text{C}^6\text{H}^3\text{I}(\text{NH}^2)\text{O}^2$ (Cunze a. Hübner, *Ann. Ch. Pharm.* cxxxv. 106).

Reduction-derivatives of the Nitrobenzoic Acids.

Amidobenzoic Acid. $\text{C}^6\text{H}^4\text{NO}^2 = \text{C}^6\text{H}^4(\text{NH}^2)\text{O}^2 = \text{C}^6\text{H}^4(\text{NH}^2) \cdot \text{CO}^2\text{H}$. *Oxybenzamic Acid* (iv. 290).—This acid is known in the three isomeric modifications, viz. ortho-amidobenzoic or ordinary amidobenzoic acid, meta-amidobenzoic, amidosalicylic or anthranilic acid, and para-amidobenzoic or amidodracrylic acid.

ORTHO-AMIDOBENZOIC ACID, originally prepared by reducing nitrobenzoic acid with ammonium sulphide, may also be obtained by treating that acid with hydrochloric acid and zinc, iron, or tin; in the last case the double salt $\text{C}^6\text{H}^4\text{NO}^2 \cdot \text{HCl} \cdot \text{SnCl}_2$ is produced, from which, by successive treatment with hydrogen sulphide, ammonia, and acetic acid, amidobenzoic acid is obtained (Wilbrand a. Beilstein, p. 314). It is likewise produced from bromobenzoic acid by the action of ammonia: $\text{C}^6\text{H}^3\text{BrO}^2 + \text{NH}_3 = \text{HBr} + \text{C}^6\text{H}^4(\text{NH}^2)\text{O}^2$ (Alexejeff, p. 314); and from the two modifications,

α and β , of nitrobromobenzoic acid, by converting them into the corresponding bromamidobenzoic acids, $C^6H^4Br(NH^2)O^2$, with tin and hydrochloric acid, and reducing these bromamidated acids by means of sodium-amalgam; in like manner from parachloronitrobenzoic acid and metachloronitrobenzoic or chloronitrosalylic acid. Further it is obtained by the action of tin and hydrochloric acid on nitrophthalic acid (A. Faust, *Zeitschr.* [2] v. 335):

and by boiling amidobenzamide (oxybenzodiamide, Chancel's carbanilide, Gerhardt's phenyl-urea, iv. 290, 294) with potash, being in fact identical with Chancel's carbanilide acid.

The amidobenzoic acids obtained from all these sources exhibit exactly the same properties, and form perfectly identical salts and ethers. The acid crystallises in warty groups of needles melting at 172° – 174° ; its compound with sulphuric acid, $(C^6H^4NO^2)^2.H^2SO^4$, crystallises with 1 mol. of water, and melts in the hydrated state at 225° , in the anhydrous state at 230° . The barium salt always has the composition $[C^6H^4(NH^2)O^2]^2Ba.8H^2O$ and is easily soluble; the copper salt $[C^6H^4(NH^2)O^2]^2Cu$ forms a bright green crystalline powder. The identity of the amidobenzoic acid obtained from the ortho-, meta-, and para-modifications of the chloro- and bromo-nitrated benzoic acids is a very remarkable fact, and promises to throw great light on the nature of the isomerism in these bodies (Hübner a. Biedermann, *Zeitschr. f. Chem.* [2] iii. 567; iv. 408).

Amidobenzoic acid unites directly with diazobenzene, forming diazobenzene-amidobenzoic acid, $C^{12}H^{11}NO^2$ (iv. 433). With dry hydrochloric acid gas at 200° it forms, besides the compound $C^6H^4NO^2.HCl$ (iv. 291), an insoluble compound which appears to be amidobenzoic anhydride, $(C^6H^4NO^2)^2O$ (Harbordt, *Ann. Ch. Pharm.* cxiii. 287). When amidobenzoic acid is heated with phosphorus pentachloride, and the product treated with boiling water, amidobenzoic phosphate, $C^6H^4NO^2.H^2PO^4$, dissolves and crystallises out in needles, whilst a resinous compound easily soluble in ammonia, and apparently consisting of $C^6H^4NO^2$, remains behind (Harbordt). Amidobenzoic acid treated with bromine is converted into tribromamidobenzoic acid and bromaniline. Fuming nitric acid converts it into trinitroxybenzoic acid, $C^6H^4(NO^2)^3O^2$ (Beilstein a. Geitner).

When a cold alcoholic solution of amidobenzoic acid is saturated with cyanogen gas, a deep yellow crystalline precipitate is formed, consisting of amidobenzoic cyanide, $C^6H^4NO^2.(CN)^2$, and the alcoholic mother-liquor after standing for some weeks deposits a crystalline mixture of homicyanamidobenzoic acid, $C^6H^4(CN)_2O^2$, or rather $C^6H^{12}(CN)O^4$, and cyanethylic amidobenzoate, $C^6H^4N^2O^2 = 2C^6H^4(C^2H^3CN)NO^2.5H^2O$, which may be separated by the former being the more soluble (Griess, *Zeitschr. f. Chem.* [2] iii. 567; *Jahresb.* 1867, p. 410). Amidobenzoic cyanide, $C^6H^4NO^2.Cy^2$, is insoluble in water, nearly insoluble in alcohol and ether, and forms salts with bases. It is decomposed by strong hydrochloric acid, with formation of a white sweet-tasting body, different from amidobenzoic acid (Griess a. Leibius, *Ann. Ch. Pharm.* cxiii. 232). The other two compounds will be described further on.

Bromamidobenzoic Acid. $C^6H^4Br(NH^2)O^2$.—This acid is known in two modifications, α and β , obtained by reducing the corresponding bromonitrobenzoic acids (p. 315) with tin and hydrochloric acid. α -Bromamidobenzoic acid forms small needles melting at 171° – 172° . β -Bromamidobenzoic acid crystallises in long very sparingly soluble needles melting at 208° . Both these acids, when treated with excess of tin and hydrochloric acid, or with sodium-amalgam, yield amidobenzoic acid melting at 142° – 145° , and exhibiting exactly the same properties in either case (Hübner a. Mecker, *Zeitschr. f. Chem.* [2] iii. 564; Hübner a. Petermann, *ibid.* iv. 548; *Ann. Ch. Pharm.* cxlix. 133). When cupric β -bromamidobenzoate in considerable quantity was shaken up with sodium-amalgam and water, and the mixture allowed to get hot, ammonia was evolved, and the alkaline liquid, on being neutralised with hydrochloric acid, yielded a large quantity of benzoic acid, resulting from the replacement of the NH^2 of the amidobenzoic acid by hydrogen: $C^6H^4(NH^2)O^2 + H^2 = NH^2 + C^6H^4O^2$.

Tribromamidobenzoic acid. $C^6H^4Br^3NO^2 = C^6HBr^3(NH^2).CO^2H$, prepared by treating amidobenzoic acid with bromine and water, is sparingly soluble in cold, moderately in hot water, and crystallises in colourless shining needles melting at 169° ; by dry distillation it is resolved into carbon dioxide and tribromaniline. Its hot solution in fuming nitric acid deposits on dilution with water white needles of tribromodiazobenzoic nitrate, $C^6HBr^3N^2O^2.HNO^2$ (Beilstein a. Geitner, *Zeitschr. f. Chem.* [2] i. 505).

Chloramidobenzoic Acid, $C^6H^4Cl(NH^2)O^2$, produced by the action of ammonium sulphide on nitrochlorobenzoic acid, crystallises in light yellow nodules slightly soluble in water, easily in alcohol and ether; it volatilises with partial decomposition and sublimes in tufts of needles which melt at 145° – 148° , turning brown at the same time. It is a stronger acid than amidobenzoic acid, and forms brown precipitates with solutions of those metals which are precipitable from acid solution by hydrogen sulphide, also with ferrous salts, white with uranium salts. Its potassium, sodium, and magnesium salts, also the slightly soluble barium salt, crystallise in nodules, the potassium salt with $2H^2O$, the barium salt with $6H^2O$, the calcium salt with $3H^2O$.

Chloramidobenzoic acid dissolved in alcohol and treated with a current of nitrous acid gas is converted into diazochlorobenzo-amidochlorobenzoic acid, $C^{14}H^9Cl^2N^2O^4$, which forms a yellowish-red crystalline powder. On heating chloramidobenzoic acid with dilute sulphuric acid, and adding barium carbonate to the solution, warty crystals are obtained consisting of the barium salt of sulphamidochlorobenzoic acid, $C^6H^4Cl(NH^2).SO^2H$ (Cunze a. Hübner, *Ann. Ch. Pharm.* cxxxv. 106).

Hemicyanamidobenzoic Acid. $C^6H^4(CN)NO^2$ or $C^{14}H^{11}(CN)N^2O^4$ (Griess, *Zeitschr. f. Chem.* [2] iii. 533; iv. 389, 650).—This acid, consisting of a double molecule of amidobenzoic acid having 1 at. H replaced by cyanogen, is contained, together with neutral cyanethyl amidobenzoate, in the alcoholic mother-liquor from which amidobenzoic cyanide (p. 317) has been deposited. The two compounds separate out together, after standing for several weeks, in the form of a white crystalline precipitate, and may be separated by treatment with hot water, in which the hemicyanamidobenzoic acid dissolves more readily than the neutral compound, and is deposited on cooling in white needles. For further purification it is dissolved in hot dilute hydrochloric acid; and the solution, after decolorisation with animal charcoal, is mixed with a quantity of ammonia sufficient to redissolve the precipitate, and afterwards with acetic acid. The hemicyanamidobenzoic acid then separates as an amorphous mass, which gradually becomes crystalline. It unites, like amidobenzoic acid, both with other acids and with bases. The barium salt $(C^{14}H^{12}N^2O^4)^2Ba$ crystallises in white needles moderately soluble in hot water. The hydrochloride $C^{14}H^{13}N^2O^4.HCl$ forms granular or needle-shaped crystals, easily soluble in water, very slightly soluble in hydrochloric acid. The platinochloride $2(C^{14}H^{13}N^2O^4.HCl).PtCl^4$ crystallises in slightly soluble nodules.

Cyanethyl Amidobenzoate. $C^{20}H^{20}N^2O^6 = 2C^6H^4(C^2H^5CN)NO^2.5H^2O$.—This compound, which may also be regarded as $2[C^6H^4(C^2H^5)(NH^2)O^2.CHNO].3H^2O$, that is, as ethylamidobenzoic cyanate with 3 mol. water, forms, after recrystallisation from boiling water, needle-shaped crystals easily soluble in alcohol and ether. Its solution in dilute acids or alkalis is decomposed by heat, with separation of an acid having the composition $C^6H^8N^2O^3$:

This acid, called uramidobenzoic acid by Griess, oxybenzuramic acid by Menschutkin (*Zeitschr. f. Chem.* [2] iv. 275), who obtained it by adding potassium cyanate to a boiling saturated solution of amidobenzoic sulphate:

is also prepared by fusing amidobenzoic acid with urea at a gentle heat, dissolving the mass in a large quantity of hot water, and supersaturating with hydrochloric acid (Griess, *Zeitschr. f. Chem.* [2] v. 312):

It crystallises in small prisms containing 1 mol. water, which they give off at about 100° ; dissolves very sparingly in boiling water, is slightly more soluble in alcohol, almost insoluble in ether. Its salts are all soluble in water and difficult to crystallise (Menschutkin). Heated to about 200° , it is resolved into urea and an acid, $C^{14}H^{11}N^2O^3$, homologous with asoxybenzoic acid, and resembling it in most of its properties:

The same decomposition takes place on repeatedly evaporating the aqueous solution of barium uramidobenzoate. From the solution of the resulting barium salt the acid $C^{14}H^{11}N^2O^3$ is separated by hydrochloric acid in microscopic needles. It is nearly insoluble in water, alcohol, and ether. Its ammoniacal solution forms white precipitates with barium chloride and silver nitrate (Griess).

Uramidobenzoic acid is converted by fuming nitric acid into a nitrated acid, $C^6H^4(NO^3)^2N^2O^3$, which is easily soluble in alcohol and especially in ether; dissolves

also without decomposition in a large quantity of moderately warm water, but is decomposed on boiling the solution, with evolution of gas, and formation of two isomeric acids, $C^6H^4N^2O^4$, one (α) very sparingly soluble in boiling water and separating out almost as soon as it is formed, while the other (β) remains in solution. The α -acid crystallises from boiling alcohol in tufts of yellowish-red shining laminae, subliming at a moderate heat in rhombic laminae, melting and afterwards decomposing at a higher temperature. The more soluble β -acid, purified by several recrystallisations from boiling water, forms thick yellow needles or prisms, sparingly soluble in cold water, easily soluble in alcohol and ether, fusing when heated and subsequently decomposing, with detonation and emission of yellow fumes. The α -barium salt, $(C^6H^4N^2O^4)_2Ba \cdot 2H^2O$, forms yellowish-red prisms which are very slightly soluble in water, and do not give off the whole of their crystallisation-water till heated to 190° . The β -barium salt, $(C^6H^4N^2O^4)_2Ba \cdot 7H^2O$, crystallises in needles, very soluble even in cold water. Both these acids are reduced by tin and hydrochloric acid, yielding amidated acids having the composition of diamidobenzoic acid, $C^6H^4N^2O^2$, both being very soluble in hot water and separating for the most part on cooling, the α -acid in yellowish laminae, the β -acid in needles, both quickly assuming a reddish colour on exposure to the air. The hydrochlorides of these amidated acids are quickly reduced by sodium nitrite to the corresponding azo-acids $C^6H^4N^2O^2$, crystallising in hydrated needles which give off their water of crystallisation at 100° (Griess, *Zeitschr. f. Chem.* [2] v. 699).

META-AMIDOBENZOIC, AMIDOSALYLIC, OR ANTHRANILIC ACID. $C^6H^4(NH^2)O^2$.—This acid, originally obtained by boiling indigo with potash (see PHENYL-CARBAMIC ACID, i. 751), has lately been formed by the action of sodium-amalgam on bromamidobenzoic acid (Hübner a. Petermann, *Zeitschr. f. Chem.* [2] iv. 205, 546; *Ann. Ch. Pharm.* cxlix. 129). The bromamidobenzoic acid (p. 317) having been shaken up for a considerable time with sodium-amalgam, the acidulated solution was precipitated with cupric acetate, the resulting cupric salt decomposed with hydrogen sulphide, the liberated amidobenzoic acid saturated with sulphuric acid, and the amidobenzoic sulphate crystallised out. To obtain the free amidobenzoic acid, the sulphate was neutralised with barium carbonate, the resulting barium salt decomposed with cupric acetate, and the precipitated copper salt decomposed with hydrogen sulphide and purified by recrystallisation.

The amidobenzoic acid thus prepared, whether from α - or β -bromamidobenzoic acid, forms long shining colourless needles, exactly resembling those of anthranilic acid from indigo, and melting at 144° , which is also the melting point of anthranilic acid (not 132° , as stated in vol. i.). Moreover, when treated with nitrous acid, not in excess, it is converted (like anthranilic acid) into meta-oxybenzoic or salicylic acid, distinguished from ortho- and para-oxybenzoic acids by the characteristic blue-red colour which it gives with ferric salts.

The amidobenzoic acid prepared as above is therefore meta-amidobenzoic or amidosalylic acid. This result is intelligible if we suppose that in bromamidobenzoic acid the radicals CO^2H , Br, and NH^2 occupy the places 1 : 2 : 3, thus, $C^6H^4(NH^2)Br.CO^2H$; so that when the bromine is replaced by hydrogen, the molecule $C^6H^4(NH^2)H.CO^2H$ is formed, in which the CO^2H and NH^2 occupy the positions 1, 3.

The salts of amidosalylic acid prepared from bromamidobenzoic acid (α or β) also exactly resemble those of anthranilic acid from indigo. The barium salt $(C^6H^4NO^2)_2Ba$ crystallises easily in shining flat needles; the ortho-amidobenzoate, on the other hand, forms needles which are not flattened and contain $8H^2O$. The copper salt $(C^6H^4NO^2)_2Cu$ forms a green precipitate much lighter and more bluish than the ortho-amidobenzoate. The silver salt $C^6H^4NO^2Ag$ forms slender needles which may be recrystallised without decomposition, and have when dry the aspect of metallic silver; the ortho-amidobenzoate is much less stable. The lead salt $(C^6H^4NO^2)_2Pb$ is either a dense white precipitate, or crystallises from aqueous or alcoholic solution in shining silver-white needles, which turn yellowish when exposed to light. *Amidosalylic sulphate*, $(C^6H^4NO^2)_2.H^2SO^4$, crystallises from water in thick obliquely truncated prisms containing $2H^2O$, which give off their water at 125° , and melt at 188° ; and from dilute alcohol, in long thin groups of needles containing 1 mol. of water (Hübner a. Petermann).

The action of cyanogen on anthranilic acid is very different from that which it exerts on ortho-amidobenzoic acid. When cyanogen gas is passed into an alcoholic solution of anthranilic acid, little or no precipitation of an additive product $(C^6H^4NO^2.Cy)^2$ takes place; but on leaving the saturated solution to itself for about a week, the anthranilic acid is almost wholly converted into the ethylic ether of cyan-anthranilic acid, $C^6H^4N^2O^2 = C^6H^4(CN)NO^2.C^2H^5$, while two other compounds, an acid and an indifferent substance (not isomeric with any of the bodies

obtained in like manner from amidobenzoic acid), are formed at the same time in small quantity. To separate the cyananthranilic ether, the alcoholic solution is evaporated at a gentle heat, and the crystalline residue is washed with dilute ammonium carbonate to remove the acid product, and further purified by recrystallisation from alcohol with addition of animal charcoal. It is thus obtained in white needle-shaped crystals, very slightly soluble in boiling water, freely soluble in boiling alcohol and ether. Its formation is represented by the equation:

Cyananthranilic ether dissolves without alteration in cold hydrochloric acid, but on boiling the solution, decomposition takes place, resulting in the formation of alcohol and cyananthranilic acid, $C^8H^7N^2O^2$ or $C^7H^4(CN)NO^2$, isomeric with azodioxindol (see ISATIN), the latter separating out:

Cyananthranilic acid dissolves very slightly in boiling water, alcohol, and ether, and crystallises in small white brilliant plates melting above 350° ; the solutions are neutral to test-paper. The acid dissolves in aqueous caustic alkalis, but is precipitated by carbonic acid; its aqueous or alcoholic solution gives a white precipitate with silver nitrate. Fuming nitric acid converts it into the nitro-compound $C^7H^2(NO^2)(CN)NO^2$, which is reduced by ammonium sulphide, or by tin and hydrochloric acid, to the corresponding amido-compound $C^7H^2(NH^2)(CN)NO^2$, which is basic, and crystallises in slightly yellowish needles difficultly soluble in all neutral liquids. Its compounds with acids generally crystallise well, but are for the most part sparingly soluble.

Cyananthranilic ether digested at 100° in sealed tubes with alcoholic ammonia is gradually converted into a base, $C^8H^7N^2O = C^7H^2(CN)(NH^2)NO$, which is almost insoluble in water, slightly soluble in boiling alcohol, and crystallises from the latter in brilliant nacreous plates:

This base is mono-acid. Its nitrate is almost insoluble in water and in alcohol, and separates from very dilute solutions of the base in small white plates on addition of nitric acid. Its platinum salt $2(C^8H^7N^2O.HCl).PtCl^4$ crystallises in thick yellow needles. The base may perhaps be regarded as the creatinine of the benzoic series, standing to anthranilic acid in the same relation as creatinine, $C^8H^7N^3O$, to sarcosine, $C^6H^5NO^2$ (Griess, *Proc. Roy. Soc.* xviii. 91).

PARA-AMIDOBENZOIC OR AMIDODRACYLIC ACID, $C^8H^2(NH^2)H^2.CO^2H$, produced by the action of ammonium sulphide or of tin and hydrochloric acid on nitrodracrylic acid, has already been described as **PARA-OXYBENZAMIC ACID** (iv. 343).

Its **barium salt** $(C^8H^2NO^2)^2Ba$ is easily soluble, and crystallises in small shining laminae. The **copper salt** produced by mixing the solution of the calcium salt with cupric acetate, is a dark-green precipitate insoluble in water, easily soluble in ammonia and in acetic acid; the **lead salt** forms pale yellow crystals having a vitreous lustre. **Amidodracrylic sulphate**, $2C^8H^2NO^2.H^2SO^4$, separates from water acidulated with sulphuric acid, in furcate tufts of crystals easily soluble in hot, sparingly in cold water (Geitner a. Boilestein, *Ann. Ch. Pharm.* cxxxix. 1; *Jahresb.* 1866, p. 350).

Dibromamidodracrylic acid, $C^8H^2Br^2(NH^2)O^2$, is produced by the action of bromine and water on an acidulated solution of amidodracrylic acid, as a flocculent precipitate, which, when freed from admixed tribromaniline by solution in ammonia and precipitation with hydrochloric acid, crystallises from hot alcohol in needles. Its **sodium salt** $C^8H^2Br^2(NH^2)O^2Na.5H^2O$ crystallises in silky needles; the **ammonium salt** in tufts of needles; the **barium salt** $[C^8H^2Br^2(NH^2)O^2]^2Ba.4H^2O$ is slightly soluble in cold water; the **calcium salt** $(C^8H^2Br^2NO^2)^2Ca.6H^2O$ and the **magnesium salt** are easily soluble in water; the **zinc, copper, and silver salts** are insoluble flocculent precipitates.

Dibromamidodracrylic acid is easily reduced by sodium-amalgam to amidodracrylic acid. With nitrous acid in hot alcoholic solution it yields dibromodracrylic acid, $C^8H^2Br^2O^2$, which sublimes in needles (Geitner a. Boilestein, *Zeitschr. f. Chem.* [2] i. 506).

Diamidobenzoic acid, $C^8H^4N^2O^2 = C^7H^4(NH^2)^2O^2$, is described in vol. iv. p. 294 as **DIOXYBENZAMIC ACID**.

Azobenzoic Acid, $C^8H^5N^2O^4$ (Strecker, *Ann. Ch. Pharm.* cxxix. 129).—The sodium salt of this acid is produced by treating a concentrated aqueous solution of sodium nitrobenzoate with sodium-amalgam, the reduction taking place without

evolution of hydrogen or formation of ammonia. It is also produced, together with glycocine, by the action of sodium-amalgam on nitrohippuric acid. On mixing the orange-yellow solution of the sodium salt with acetic or dilute sulphuric acid, azobenzoic acid separates as a light yellow gummy precipitate, which becomes pulverulent on boiling the liquid with addition of alcohol. After drying it is light yellow and amorphous; it does not lose weight when heated to 100° – 170° , but melts with decomposition at a higher temperature. When dried at 100° it contains $2C^6H^5N^2O^4 \cdot H^2O$. It is but slightly soluble in water, alcohol, and ether, dissolves with yellow colour in strong sulphuric acid, and is precipitated therefrom by water without alteration. Ammonia and the hydrates and carbonates of the alkali-metals dissolve it with lemon-yellow colour; the ammoniacal solution when evaporated leaves an acid ammoniacal salt.

Barium azobenzoate, $2C^6H^5N^2O^4 \cdot Ba \cdot 5H^2O$, is a lemon-yellow or orange-yellow granular precipitate, nearly insoluble in water and in alcohol, which gives off four-fifths of its water at 100° ; after drying at 140° it contains $2C^6H^5N^2O^4 \cdot K^2 \cdot H^2O$. The *calcium salt* dried at 140° , appears to have a similar composition. The *silver salt* $(C^6H^5N^2O^4 \cdot Ag)^2$ is a yellowish-white precipitate, insoluble in water, but easily soluble in ammonia.

Ethyl azobenzoate, $C^6H^5N^2O^4(C^2H^5)^2$, obtained by reducing ethylnitrobenzoate with sodium-amalgam in alcoholic solution containing a little free acetic acid, precipitating with water, washing the precipitate with aqueous ammonia, and crystallising it from boiling alcohol, forms long golden-yellow needles melting below 100° , solidifying again in the crystalline form, not volatile without decomposition. It is insoluble in water, but dissolves easily in alcohol and ether. With alcoholic potash it yields potassium azobenzoate; with alcoholic ammonia it forms yellowish laminae of the amide—probably azobenzamide—which is produced by treating nitrobenzamide with sodium-amalgam. The acid and its salts when ignited with soda-lime give off only half their hydrogen in the form of ammonia.

Para-azobenzoic or Azodracrylic acid, $C^6H^5N^2O^4$, is obtained by reducing sodium nitrodracrylate with sodium-amalgam, and separates on addition of hydrochloric acid to the yellow solution, as a bulky flesh-coloured precipitate. It melts at above 130° , is sparingly soluble in water, alcohol, and ether, easily in ammonia and fixed caustic alkalis, also in strong sulphuric acid, from which latter solution it is reprecipitated by water. Its *ammonium salt* $2C^6H^5N^2O^4(NH^4)^2 \cdot H^2O$ forms orange-yellow crystals less soluble in water than the azobenzoate; the *sodium salt* $C^6H^5N^2O^4Na^2$ crystallises with difficulty in needles or warty masses; the *barium salt* $C^6H^5N^2O^4Ba$, and the *calcium salt* $C^6H^5N^2O^4Ca \cdot 3H^2O$, are flesh-coloured precipitates; the *silver salt* $C^6H^5N^2O^4Ag^2$ is flesh-coloured and amorphous (Reichenbach u. Beilstein, *Ann. Ch. Pharm.* cxxxii. 137; Billinger, *ibid.* cxxv. 152).

The same modification of azobenzoic acid appears to be obtained by reducing an ammoniacal solution of paranitrobenzoic acid with zinc (Sokoloff, *Jahresb.* 1864, p. 344); also, together with oxybenzoic acid, by the action of alcoholic potash on nitrobenzile (Zinin, *ibid.* p. 356):

The descriptions of the acid thus obtained, and of its salts, do not quite agree with those of the azodracrylates above given; but the differences are unimportant, relating chiefly to shades of colour.

HYDRAZOBENZOIC ACID, $C^6H^5N^2O^4$, is produced by treating a boiling solution of azobenzoic acid in excess of soda-ley with ferrous sulphate, whereupon ferric hydrate is first precipitated, then black ferroso-ferric oxide, and the filtrate yields, on addition of acids, a yellowish-white precipitate of hydrazobenzoic acid. It is likewise easily produced by treating azobenzoic acid in ammoniacal (not in acid) solution with zinc, and (together with azo- and amido-benzoic acids) by treating nitrobenzoic acid with excess of sodium-amalgam. It is insoluble in water, sparingly soluble in hot alcohol, and is precipitated by water from the latter in yellowish-white flocks. With ammonia, potash, or soda it forms yellowish solutions, which absorb oxygen from the air, and are converted into azobenzoates. The warm concentrated ammoniacal solution gives with barium chloride orange-red crystals of the barium salt $C^6H^5BaN^2O^4$, and with silver nitrate a yellowish precipitate which blackens quickly, with formation of azobenzoic acid. Hydrazobenzoic acid boiled with strong hydrochloric acid is resolved into azobenzoic and amidobenzoic acids: $2C^6H^5N^2O^4 = C^6H^5NO^4 + 2C^6H^5NO^3$ (Strecker, *loc. cit.*).

Hydrazodracrylic acid, $C^6H^5N^2O^4$, is obtained in like manner by reduction of

Sup.

Y

azodraeylic acid, and precipitated by hydrochloric acid as a light flesh-coloured powder, nearly insoluble in water, soluble in hot alcohol, from which it separates on cooling in shining colourless crystals. Its reactions are similar to those of hydrazobenzoic acid. In alkaline solution it is easily oxidised to azodraeylic acid. It quickly reduces silver nitrate in presence of ammonia, and is decomposed by boiling hydrochloric acid, with separation of azodraeylic acid (Reichenbach a. Beilstein, *Ann. Ch. Pharm.* cxxii. 137; Bilsfinger, *ibid.* cxxv. 152).

AZO-AMIDOBENZOIC or DIAZOBENZO-AMIDOBENZOIC ACID, $C^4H^4N^2O^4$ = $C^4H^3N^2O^2 \cdot C^2H^2NO^2$, originally obtained by the action of nitrous acid on amidobenzoic acid (iv. 292), may also be produced by mixing the aqueous solutions of diazobenzoic nitrate and amidobenzoic acid:

By mixing the aqueous solutions of diazobenzoic nitrate and amidodraeylic acid, or of diazodraeylic nitrate and amidobenzoic (or amidodraeylic) acid, a number of double acids are produced, represented by the formula $C^4H^4N^2O^2 \cdot C^2H^2NO^2$, isomeric with the preceding, and very similar to it in their properties (Griess, *Jahresb.* 1864, p. 353).

Azoamidodraeylic acid is likewise produced by treating a cold saturated solution of amidodraeylic acid with nitrous ether (alcohol saturated with nitrous acid), as a yellow crystalline precipitate, which differs from azoamidobenzoic acid, by yielding, when warmed with strong hydrochloric acid, a red crystalline precipitate of chlorodraeylic acid (p. 311) and a solution of amidodraeylic hydrochloride:

Nitrous acid passed into a hot alcoholic solution of amidodraeylic acid forms benzoic acid and acetic aldehyde, with evolution of nitrogen:

(Wilbrand a. Boilstein, *Ann. Ch. Pharm.* cxxviii. 257; *Jahresb.* 1863, p. 343).

Azoxybenzoic acid, $C^4H^4N^2O^4$, is produced, together with aldehyde, by heating an alcoholic solution of nitrobenzoic acid with solid potassium hydrate:

The potassium salt separates from the resulting solution as a reddish crystalline mass, and the acid separated therefrom by hydrochloric acid forms (after treatment with animal charcoal) colourless microscopic needles or laminae, insoluble in water, slightly soluble in alcohol and ether. The acid is bibasic, its salts having the general formula $C^4H^4M^2N^2O^4$ or $C^4H^4M^2N^2O^4$. The barium and silver salts are white crystalline precipitates (Griess, *Ann. Ch. Pharm.* cxxxi. 92).

Respecting the general relations between the azo-derivatives of benzoic acid, see AROMATIC SERIES, p. 210.

Diazobenzoic Acid. $C^4H^4N^2O^2$ (iv. 294).—An aqueous solution of diazobenzoic nitrate or nitrate-diazobenzoic acid mixed with a solution of bromine in hydrobromic acid, deposits an oily precipitate quickly solidifying to yellow prisms of diazobenzoic perbromide, $C^4H^4N^2O^2 \cdot HBr \cdot Br^2$. This compound is decomposed by boiling alcohol, in the manner shown by the equation:

yielding bromobenzoic acid identical with that which is produced by the action of bromine on benzoic acid, or of hydrobromic acid on diazo-amidobenzoic acid. The same decomposition takes place, but with strong detonation, when the perbromide is simply heated (Griess, *Ann. Ch. Pharm.* cxxv. 121; see also Cunzio a. Hubner, *ibid.* 106).

Isomeric perbromides with similar properties are produced when the above-mentioned solution of bromine is made to act on the nitric acid compounds of diazodraeylic and diazosalylic acids. When boiled with alcohol they also yield the corresponding modifications of monobromobenzoic acid (Griess).

Sulpho-derivatives of Benzoic Acid.

Sulphobenzoic acid, or *Salicyl-sulphurous acid*, $\text{C}^7\text{H}^5\text{SO}^3 = \left(\text{C}^7\text{H}^4\text{O}^{\text{SO}^2} \right)^{\text{H}^2} \text{O}^2$, is described at p. 487, vol. v. Kämmerer u. Carius (*Ann. Ch. Pharm.* cxxxi. 153) have obtained a modification of this acid, which they designate as benzosulphuric acid and represent by the formula $\left(\text{C}^7\text{H}^4\text{O}^{\text{SO}^2} \right)^{\text{H}^2} \text{O}^2$, as follows: A mixture of silver sulphate with twice its bulk of pounded glass is heated with benzoyl chloride to $140^\circ\text{--}150^\circ$ for a few hours, till the resulting liquid solidifies on cooling to an amorphous transparent mass of benzosulphuric anhydride, $\text{C}^7\text{H}^4\text{SO}^2$:

This anhydride is resolved by solution in warm water into benzoic and benzo-sulphuric acids, the former of which crystallises out:

and on saturating the warm filtered solution with lead carbonate, decomposing the lead salt with hydrogen sulphide, and evaporating the filtrate at a temperature below 80° , benzosulphuric acid is obtained, as a white crystalline mass melting at 80° , solidifying again in the crystalline form, easily soluble in water and in alcohol, and resolved by boiling its aqueous solution into benzoic and sulphuric acids. From the isomeric compound, sulphobenzoic acid, it is distinguished by the fact that both the free acid and its salts, when treated with phosphorus pentachloride, yield benzo-sulphuric chloride, $\text{C}^7\text{H}^4\text{ClPSO}^2 = \left(\text{C}^7\text{H}^4\text{O}^{\text{SO}^2} \right)^{\text{Cl}^2}$, differing in its reactions from the isomeric chloride obtained from sulphobenzoic acid (*infra*).

The metallic benzosulphates are soluble in water, mostly crystallisable, and not decomposed by heating to 150° , or by the boiling of their aqueous solutions. The *ammonium salt* $\text{C}^7\text{H}^4\text{SO}^2(\text{NH}^4)^2$ crystallises in radiate groups of needles; the *acid potassium salt* $\text{C}^7\text{H}^4\text{SO}^2\text{K}$, in fibrous masses permanent in the air (the corresponding sulphobenzoate is efflorescent); the neutral *sodium salt* $\text{C}^7\text{H}^4\text{SO}^2\text{Na}^2$ crystallises in tufts of needles; the neutral *barium salt* $\text{C}^7\text{H}^4\text{SO}^2\text{Ba} \cdot 3\text{H}^2\text{O}$, in microscopic needles, which slowly give off 1 mol. water over sulphuric acid; the acid *barium salt* $\text{C}^7\text{H}^4\text{SO}^2\text{Ba} \cdot \text{C}^7\text{H}^5\text{SO}^2$ is more soluble than the corresponding sulphobenzoate, and forms apparently rhombic, often six-sided prisms. The *lead salt* $\text{C}^7\text{H}^4\text{SO}^2\text{Pb} \cdot 2\text{H}^2\text{O}$ crystallises in spherical groups of needles which give off one-fourth of their water at 100° .

Benzosulphuric anhydride, $\text{C}^7\text{H}^4\text{SO}^2$, is soluble in anhydrous ether, and remains, after evaporation of the solvent, as a light-brown amorphous mass melting at a gentle heat. By solution in water it is decomposed into benzoic and benzosulphuric acids. By excess of benzoyl chloride, it is resolved into benzosulphuric chloride and benzoic anhydride:

With a still larger excess of benzoyl chloride, it yields sulphuryl chloride, SO^2Cl^2 , together with other products.

Benzosulphuric chloride, $\text{C}^7\text{H}^4\text{SO}^2\text{Cl}^2$, obtained as above or by the action of phosphorus pentachloride on benzosulphuric acid, or by heating silver sulphate with excess of benzoyl chloride to 150° , is a viscid liquid having a pungent odour, especially when warmed. It distils without decomposition at about 300° (sulphobenzoic chloride decomposes at that temperature, v. 488), and is resolved by water into hydrochloric and benzosulphuric acids. Heated with 1 mol. phosphorus pentachloride, it is resolved into sulphuryl chloride and chlorobenzoyl chloride, together with phosphorus trichloride:

With excess of the pentachloride, it yields, instead of chlorobenzoyl chloride, the chloride $C^6H^5Cl^5$, isomeric with chlorosulphuryl trichloride; at about 180° the sulphuryl chloride is partly decomposed, yielding chloride of sulphur. The isomeric chloride obtained from sulphobenzoinic acid, heated with 1 mol. phosphorus pentachloride to 140° - 150° , yields sulphurous chloride, chlorobenzoyl chloride, and phosphorus oxychloride:

Thiobenzoic Acid. $C^6H^5OS = \begin{array}{c} C^6H^5O \\ H \end{array} \{ S = C^6H^5.COSH$ (Engelhardt, Latschinoff a. Malyscheff, *Zeitschr. f. Chem.* [2] iv. 353).—Produced: 1. By the action of benzoyl chloride on potassium monosulphide: $C^6H^5OCl + K^2S = KCl + C^6H^5KOS$.

2. By boiling ethyl or amyl thiobenzoate, thiobenzoic anhydride (benzoyl sulphide), phenyl benzoate, or benzoic anhydride, with an alkaline solution of potassium sulphhydrate:

3. By heating benzoyl sulphide with alcoholic potash or with aqueous ammonia:

4. By heating benzoyl bisulphide with an alcoholic solution of potassium hydrate or sulphhydrate.

Thiobenzoic acid is precipitated from the aqueous solution of its potassium salt by hydrochloric acid, as a yellow oil which, when cooled by snow, solidifies to a white radio-crystalline mass, and may be purified by washing with water and drying in the air. It melts at the heat of the hand (about 24°), and has a peculiar sulphurous odour. When exposed to the air it volatilises slightly, apparently with partial decomposition. It may be distilled with vapour of water, but is decomposed by dry distillation, giving off benzoic acid and other products, and leaving a carbonaceous residue. It dissolves easily in alcohol, and in all proportions in ether and in carbon bisulphide, and does not crystallise from solution in a small quantity of either of the two latter liquids, even when cooled by a freezing mixture; but the solution when left to evaporate in contact with the air, deposits a yellowish oil, which gradually solidifies to crystals of benzoyl bisulphide.

A crystalline modification of thiobenzoic acid was obtained by Fleischer (*Ann. Ch. Pharm.* cxl. 234) by prolonged boiling of thiobenzoic aldehyde, C^6H^5S (p. 329), with nitric acid of sp. gr. 1.3. To separate it from the benzoic acid formed at the same time, the liquid was saturated with sodium carbonate, then mixed with hydrochloric acid as long as a yellowish precipitate was produced, and this precipitate after being heated to 160° in a stream of carbonic acid gas was recrystallised from hot water. The thiobenzoic acid thus obtained is more soluble in water than benzoic acid, and separates therefrom as a yellowish crystalline powder; from alcohol or benzol, in tufts of white needles. The crystallised acid $2C^6H^5OS.H^2O$ gives off its water (6.1 p. c.) at 110° , and then becomes less soluble in water. When strongly heated it blackens without melting (Fleischer).

The thiobenzoic acid described by Cloez (v. 775) as a crystalline solid melting at 120° was, according to Engelhardt, Latschinoff a. Malyscheff, nothing but benzoyl bisulphide, $(C^6H^5O)^2S^2$, into which thiobenzoic acid is easily converted by atmospheric oxidation while in the liquid state.

Thiobenzoic acid heated with nitric acid is oxidised to benzoyl bisulphide and benzoic acid. It dissolves in baryta-water and in aqueous sodium carbonate, expelling

carbonic acid in the latter case. It dissolves in aqueous ammonia, and on evaporating the solution on the water-bath, the ammonium salt is partially decomposed, with formation of ammonium sulphide.

Potassium thiobenzoate, C^7H^5OSK , prepared as above is very soluble in water, dissolves also in hot alcohol, and crystallises on cooling in large transparent tables and prisms, having a faint yellowish colour. Its aqueous solution mixed with a solution of iodine in potassium iodide deposits benzoyl bisulphide:

The aqueous solution forms with *cupric sulphate* a greenish-yellow precipitate, which in contact with excess of the reagent gradually acquires a bright red colour; from this red precipitate, carbon bisulphide extracts benzoyl bisulphide. An aqueous solution of the potassium salt forms with *ferric chloride* a violet-brown precipitate, turning yellow when warmed. An alcoholic solution of the potassium salt mixed with ferric chloride acquires a transient violet-brown colour, and soon deposits a white precipitate of benzoyl bisulphide, the ferric chloride being at the same time reduced to ferrous chloride.

The *sodium salt* C^7H^5OSNa , obtained by dissolving the acid in sodium carbonate, is very soluble in alcohol, and separates therefrom on evaporation as an indistinctly crystalline mass. The *barium salt* $(C^7H^5O)_2Ba$ (at 120°) is also very soluble in alcohol, and separates on evaporation in hydrated laminae which easily give off their water of crystallisation. The barium salt of *Fleischer's thiobenzoic acid* is easily soluble in water, sparingly in alcohol, and forms hard crusts made of small nodules containing $(C^7H^5O)_2Ba \cdot 2H_2O$, which easily give off their water over sulphuric acid. The *lead salt* $(C^7H^5O)_2Pb$ is a white precipitate insoluble in water, but slightly soluble in boiling carbon bisulphide, and separates on cooling in small slender needles. When warmed it turns black, from formation of lead sulphide. The *silver salt* C^7H^5OSAg is a yellowish-white precipitate insoluble in water. It is but very little decomposed by boiling with water, but if an aqueous solution of the potassium salt be boiled with excess of silver nitrate, and the solution boiled together with the precipitate, the latter soon turns black, being converted into silver sulphide and benzoic acid.

Ethyl thiobenzoate, $C^7H^5OS \cdot C^2H_5$, first obtained by Tütsehoff (*Petersb. Acad. Bull.* v. 295) by the action of benzoyl chloride on lead mercaptide, $(C^7H^5S)_2Pb + 2C^7H^5OCl = PbCl_2 + 2(C^7H^5OS \cdot C^2H_5)$, is likewise produced by boiling silver thiobenzoate with ethyl iodide. It is a transparent colourless oily liquid smelling like ethyl benzoate and mercaptan; boils at 243° , is insoluble in water, soluble in alcohol and ether. Boiled with alcoholic solutions of potassium hydrate and sulphhydrate, it yields mercaptan, together with benzoate and thiobenzoate of potassium. When boiled with nitric acid, it yields, according to the strength of the acid, benzoic or nitrobenzoic acid, together with ethylsulphurous acid. *Amyl thiobenzoate*, $C^7H^5OS \cdot C^5H_{11}$, obtained by heating amyl mercaptan with benzoyl chloride, is an oily liquid insoluble in water, easily soluble in alcohol and ether; boiling with partial decomposition at 271° . Its reactions are exactly analogous to those of ethyl thiobenzoate.

BENZOYL SULPHIDE OF THIOBENZOIC ANHYDRIDE, $(C^7H^5O)^2S$, is produced by the action of benzoyl chloride on potassium thiobenzoate: $C^7H^5OSK + C^7H^5OCl = KCl + (C^7H^5O)^2S$. The product washed with water and sodium carbonate leaves an oil soluble in ether; and on evaporating the ethereal solution, benzoyl sulphide separates as an oil which solidifies at low temperatures to a crystalline mass, and may be purified by recrystallisation from ether. It is insoluble in water, easily soluble in ether, and separates therefrom by evaporation at low temperatures in large prismatic crystals having a waxy lustre; boils at 48° , and is decomposed by dry distillation, leaving a residue of charcoal, and yielding various oily and crystalline products not yet examined. It dissolves easily in warm aqueous ammonia, forming benzamide and ammonium thiobenzoate; also in alcoholic solution of potassium sulphhydrate, with formation of thiobenzoic acid.

BENZOYL BISULPHIDE, $(C^7H^5O)^2S_2$, is obtained by atmospheric oxidation of thiobenzoic acid dissolved in carbon bisulphide or in ether; by oxidising thiobenzoic acid with nitric acid; and by the oxidising action of iodine, cupric sulphate, or ferric chloride on potassium thiobenzoate in aqueous solution. It is also produced, together with the monosulphide $(C^7H^5O)_2S$, by gently heating lead sulphide with benzoyl chloride diluted with ether. Moelling (*Ann. Ch. Pharm.* cxviii. 304) obtained it by the action of hydrogen sulphide on benzoic anhydride. It is conveniently prepared by pouring a solution of iodine in potassium iodide into an aqueous solution of

potassium thiobenzoate, dissolving the dried precipitate in boiling carbon bisulphide, from which it separates, by slow cooling or evaporation in a warm place, in large shining prisms or six-sided tables, and by rapid cooling or evaporation in six-sided or rhombic tables. It dissolves with difficulty in boiling ether or alcohol, melts at 128° , and assumes a violet colour when heated a few degrees above its melting point. It is insoluble in water and in aqueous ammonia, not acted upon by nitric acid; dissolves in alcoholic solution of potassium hydrate, with formation of benzoic and thiobenzoic acids; easily in alcoholic solution of potassium sulphhydrate, with evolution of hydrogen sulphide and formation of thiobenzoic acid (Engelhardt, Latschneff, u. Malyschew).

THIOBENZOYL SULPHYDRATE OR DITHIOBENZOIC ACID. $C^6H^5S^2 = C^6H^5S \left\{ \begin{matrix} S \\ H \end{matrix} \right\} S = C^6H^5 \cdot CS^2H$ (Engelhardt u. Latschinoff, *Zeitschr. f. Chem.* [2] iv. 455).—

Produced by the action of benzotrichloride (p. 282) on potassium monosulphide:

1 mol. benzotrichloride is added to an alcoholic solution of 2 mol. potassium sulphide diluted with a large quantity of alcohol, to moderate the otherwise violent reaction. Chloride of potassium then separates out; the mixture is finally heated over the water-bath to complete the reaction; the red alcoholic solution is filtered, the potassium chloride washed with alcohol; and the united liquids are mixed with water, which throws down a small quantity of resinous substance. The aqueous solution filtered therefrom contains sulphide, dithiobenzoate, and a small quantity of chloride of potassium. On mixing it with lead acetate, a black precipitate of lead sulphide is first formed; and the liquid filtered from this precipitate yields with lead acetate a red precipitate of nearly pure lead dithionate, which may be completely purified by crystallisation from boiling commercial benzol boiling at 122° – 130° . The lead salt treated with aqueous solution of potassium or ammonium sulphide yields a precipitate of lead sulphide, and a red solution of potassium or ammonium dithiobenzoate.

Dithiobenzoic acid is also formed as a lead salt, $(C^6H^5S^2)^2Pb$, by treating lead sulphide with benzoyl chloride at a high temperature, whereas if the temperature be kept low, the products of this reaction are benzoyl monosulphide and bisulphide (p. 325); and Fleischer appears to have obtained it as a potassium salt, together with benzylene sulphide, C^6H^5S , by heating benzylene chloride with an alcoholic solution of potassium sulphhydrate (p. 281).

Dithiobenzoic acid, $C^6H^5S^2$, is obtained by treating the ammonium or lead salt with hydrochloric acid. It is unstable, quickly decomposing in contact with the air; insoluble in water, easily soluble in ether and in alcohol. A small quantity of it dissolved in ether colours the liquid a splendid carmine-red. When the oily acid, separated from the aqueous solution of the potassium or ammonium salt, is exposed to the air for some time under water, it is converted into a resin insoluble in dilute ammonia, and apparently consisting of a mixture of the compounds $(C^6H^5S^2)^2$ and $(C^6H^5S^2)^3$.

Ammonium dithiobenzoate in aqueous solution has a fine dark orange-red colour, gives with lead acetate a minium-coloured precipitate, with silver nitrate a brown-red, with mercuric chloride a brownish yellow, with bismuth nitrate a red, and with cupric sulphate a black-brown precipitate. The aqueous solution evaporated in contact with the air, decomposes, with separation of a resin similar to that deposited from the solution of the free acid. The potassium salt is easily soluble in water, alcohol, and ether, insoluble in carbon bisulphide; the aqueous solution decomposes on evaporation like that of the ammonium salt. The lead salt $(C^6H^5S^2)^2Pb$ is insoluble in water, slightly soluble in boiling ether and alcohol, and crystallises from these solutions in very thin orange-red needles; more soluble in boiling carbon bisulphide, and still more in boiling benzol (B. P. 122° – 130°), and separates from either of these solutions in beautiful red needles. Boiled with strong hydrochloric acid, it yields dithiobenzoic acid, which may be extracted by ether. Nitric acid oxidises it, with formation of lead sulphate. The mercuric salt $C^6H^5S^2Hg$, obtained by precipitation, is insoluble in water, soluble in boiling alcohol, ether, and benzol; crystallises from alcohol in shining laminae of a reddish golden-yellow colour, like mosaic gold; from benzol in tufts of laminae having a golden lustre. The silver salt $C^6H^5S^2Ag$ is a brown precipitate insoluble in water and in benzol.

Chlorodithiobenzoic acid, $C^6H^5Cl \cdot CS^2H$, is obtained by treating monochlorobenzotrichloride (p. 283) with alcoholic solution of potassium sulphide, the process being

conducted similarly to that for the preparation of dithiobenzoic acid. The *lead salt* $(C^6H^4ClS^2)^2Pb$ is a minium-coloured precipitate, which dissolves in boiling benzol and carbon bisulphide, and crystallises therefrom in beautiful red slender needles. When heated with strong hydrochloric acid, it yields the free acid $C^6H^4ClS^2$ as a violet-red oil. The *mercuric salt* $(C^6H^4ClS^2)^2Hg$, obtained by precipitating an ethero-alcoholic solution of the acid with mercuric chloride, is somewhat less soluble in boiling alcohol than the dithiobenzoate, and crystallises on cooling in small shining laminae of a greenish-gold colour.

BENZOIC ALDEHYDE. *Benzaldehyde. Benzoyl Hydride. Bitter Almond Oil.* $C^6H^5O = C^6H^5.COH$.—The following modes of formation of this compound have been observed, in addition to those already given (i. 568):

1. By the action of alcoholic potash on benzylene chloride: $C^6H^4Cl^2 + H^2O = 2HCl + C^6H^5O$ (Calours, *Compt. rend.* lvi. 222).—2. By treating benzylene chloride at ordinary temperatures with strong sulphuric acid, adding water to the mixture and distilling. The reaction is:

(Oppenheim, *Zeitschr. f. Chem.* [2] v. 441).

3. By heating benzyl chloride to 100° with an equal weight of nitric acid of 27° Bm. diluted with 10 vol. water:

A large quantity of benzoic acid is formed at the same time. Benzoic aldehyde is obtained in greater quantity by heating the benzyl chloride (10 grms.) with lead nitrate (14 grms.) and water (100 grms.) to the boiling point for an hour in an atmosphere of carbon dioxide.

4. From benzoic and phthalic acids, by passing their vapours over heated zinc-dust (Bayer, *Jahresh.* 1866, p. 263); from benzoic acid also by reduction with stannous chloride (Dusart, *ibid.* 1862, p. 263).

5. In small quantity, together with benzene and an unknown substance, by heating a mixture of 1 pt. sodium phthalate and 4 pts. calcium oxalate with 4 pts. calcium hydrate (Dusart).—6. Together with glycocone, by the action of nascent hydrogen on hippuric acid.

7. By heating the silver-compound of diosindol, $C^6H^4AgNO^2$, the silver being at the same time reduced (Bayer a. Knop, *Jahresh.* 1866, p. 639).—8. In the germination of the seeds of *Lepidium sativum* (M. Schulze, *ibid.* 1862, 502).

Preparation from Bitter Almonds.—Michael Puttenkofer (*Ann. Ch. Pharm.* cxxii. 77; *Jahresh.* 1862, p. 261) attributes the variation in the yield of oil from the same material to the fact that too little attention is generally paid to ensure the complete dissolution of the amygdalin contained in the almonds, and to prevent the premature decomposition of the emulsion. To obtain a uniform and maximum product, he recommends the following process: 12 pts. of the coarsely pulverised press-cake of bitter almonds (i. 598) are stirred up with 100 to 120 pts. of boiling water; the pasty mass, after being kept at the same temperature for a quarter to half an hour, and then left to cool, is mixed with 1 pt. of the same pulverised press-cake stirred up with 6 to 7 pts. of water; and the mixture, after 12 hours' maceration, is subjected to a moderately rapid distillation. The distillate contains all the volatile oil and prussic acid that can be formed from the amygdalin present: 48 oz. of press-cake yield 7 drms. (nearly 2 p. c.) of bitter almond oil. For the methods of purifying the bitter almond oil from prussic acid, see vol. i. p. 568.

Reactions.—1. Bitter almond oil made up into a paste with *phosphoric anhydride*, in such a manner as not to allow the mixture to get hot, hardens after a few days, and the portion of the mass which is insoluble in warm water dries up on the water-bath to an inodorous resin, resembling colophony, and having, when purified by precipitation of its alcoholic solution with water containing hydrochloric acid, nearly the same composition as the a resin of gum-benzoin: it yields by dry distillation a thick brownish oil, together with a large quantity of benzoic acid, and by fusion with potash, benzoic and paraoxybenzoic acids (Hlasiwetz a. Barth, *Ann. Ch. Pharm.* cxxxix. 83; *Jahresh.* 1866, p. 632).

2. Bitter almond oil carefully mixed with *sulphuric anhydride* is converted into an acid $C^6H^5SO^4$, whose barium salt $(C^6H^5SO^4)^2Ba$ crystallises in hydrated nodules which give off their water at 170° (Engelhardt, *Jahresh.* 1864, p. 360).

3. Gaseous *hydriodic acid* converts benzoic aldehyde into the compound $C^6H^5I^5O$

(Geuther & Cartmell, i. 572); but by heating with 20 pts. of saturated aqueous hydriodic acid, benzoic aldehyde is mainly converted into toluene:

together with smaller quantities of benzene and carbon dioxide (Berthelot, *Jahresb.* 1867, p. 346).

4. Benzoic aldehyde diluted with coal-tar naphtha (boiling at about 100°) rapidly dissolves sodium, producing a compound which separates in gelatinous flocks, and is decomposed by water into benzyl alcohol, C^7H^6O , benzoic aldehyde, and sodium hydrate (Church, *Phil. Mag.* [4] xxv. 522; *Jahresb.* 1863, p. 337). Friedel (*Bull. Soc. Chim.* 1862, p. 18), by treating benzoic aldehyde with sodium-amalgam and water for four or five days, obtained a quantity of benzyl alcohol equal to half the benzoic aldehyde employed. By treating benzoic aldehyde with sodium-amalgam and water in an atmosphere of hydrogen, Church obtained, besides benzyl alcohol, a body which he represents by the formula $C^{11}H^{10}O^2$, and designates as *dicrosol*. Claus (*Ann. Ch. Pharm.* cxxxvii. 92), by treating an ethereal solution of benzoic aldehyde with pasty sodium-amalgam for 12 hours, obtained a body having the composition $C^{11}H^{10}O^2$, isomeric with hydrobenzoin; and Zinin (*ibid.* cxxiii. 125) has obtained hydrobenzoin by treating benzoic aldehyde with an alcoholic solution of hydrochloric acid and granulated zinc. Claus, in a subsequent paper (*Zeitschr. f. Chem.* [2] iv. 127), regards the body $C^{11}H^{10}O^2$, obtained by the use of sodium-amalgam (with which Church's so-called dicrosol is in all probability identical), as *oxybenzylic ether*, $C^6H^5-CH(OH)-O-CH^2-C^6H^5$, a compound intermediate in constitution between benzyl alcohol and benzoic aldehyde—inasmuch as it may be converted into benzyl alcohol by further treatment with sodium-amalgam, and is easily oxidised to benzoic aldehyde by treatment with chromic acid, even in the cold. This body is also related to benzoic aldehyde, C^7H^6O , in the same manner as pinacone, $C^6H^{10}O$, to acetone, C^3H^6O . When benzoic aldehyde is heated with sodium-amalgam, and a stream of carbonic acid gas is passed into the liquid, sodium benzoate is formed, together with an oily liquid, $C^{11}H^{10}O^2$, boiling at 314° (Alexeyoff, *Ann. Ch. Pharm.* cxxix. 317). According to Groville Williams (*Chem. News*, xv. 211), benzoic aldehyde repeatedly treated with sodium at a high temperature is converted into toluylene (stilbene), $C^{11}H^{12}$, together with other products:

5. Benzoic aldehyde heated to 100° with *succinyl chloride*, is converted into benzylene chloride and succinic anhydride (Rembold, *Ann. Ch. Pharm.* cxxxviii. 189):

6. When benzoic aldehyde is left in contact with *ammonium carbamate* in a flask (under an exsiccator), the whole solidifies after some time; and on heating the mass with ether, water, and again with ether, then leaving it for some days between filtering paper, and drying, a colourless, apparently amorphous body is obtained, having the composition of ammonium carbamate with 4 at. H replaced by 2 mol. C^7H^6 ; thus:

On heating this body with alcohol and filtering, crystals of hydrobenzamide are obtained (E. Mulder, *Zeitschr. f. Chem.* [2] v. 58).

7. A precisely similar action takes place with ammonium oxysulphocarbamate,

$\left(\begin{array}{c} H^2 \\ (CS)^N \\ NH^4 \end{array} \right) O$ (produced by passing carbon-oxy-sulphide, COS, through alcohol saturated with ammonia), resulting in the formation of the body $\left(\begin{array}{c} H^2 \\ (CS)^N \\ N(C^7H^6)^2 \end{array} \right) O$, which is

also colourless and apparently amorphous, but when heated with alcohol yields a crystallised body different from hydrobenzamide (Mulder, *loc. cit.*).

8. A warm aqueous solution of *amylamine bisulphite*, saturated with benzoic aldehyde, deposits on slow cooling, crystals of hydrated amylamine benzoyl bisulphite, $C^7H^6N.SH^2O^2.C^7H^6 + H^2O$, which give off their water in a vacuum over sulphuric acid (H. Schiff, *Zeitschr. f. Chem.* [2] iv. 12).

9. Benzoic aldehyde heated with *acetic anhydride* to 150° for several hours, unites with it, forming the compound $C^{11}H^{12}O^4 = C^7H^5(C^7H^6O^2)^2$, identical with benzylene biacetate (i. 578). When purified by distilling the product, and washing the

portion which passes over above the boiling point of benzoic aldehyde with aqueous sodium bisulphite, it remains as an oil, which quickly solidifies to a crystalline mass, melting at 45° , very easily soluble in alcohol and ether, and distinguished by its great tendency to crystallise (Geuther, *Ann. Ch. Pharm.* cvi. 249; Hübner, *Bull. Soc. Chim.* [2] viii. 459; Perkin, *Chem. Soc. J.* [2] v. 586).

10. With *acetyl chloride*, benzoic aldehyde forms cinnamic (phenyl-acrylic) acid :

(Bertagnini, *Ann. Ch. Pharm.* c. 125). With *butyryl chloride*, in like manner, it forms phenyl-angelic acid (Fittig a. Bieber, *Z. itschr. f. Chem.* [2] v. 333):

11. When bitter almond oil containing *prussic acid* is left in contact in a closed flask for two hours with aqueous *hydrochloric acid* saturated at 8° , the watery and oily liquids then shaken together, while the vessel is kept cool by immersion in cold water, the whole again left to itself for 24 hours, and once more shaken up, the liquids solidify together to a mass of crystals consisting of dibenzoyl-hydrocyanide, $(\text{C}^6\text{H}^5\text{O})^2\text{CNH}$. This compound is nearly insoluble in boiling water, slightly soluble in boiling alcohol, ether, and benzol, and crystallises from alcohol or glacial acetic acid in small prisms melting at 195° , and decomposing when volatilised into an oil and charcoal. Heated with aqueous hydrochloric acid to 120° , it decomposes, with formation of benzoic aldehyde, mandelic acid (?), and sal-ammoniac. Heated with water or alcohol to 180° , it is entirely resolved into benzoic aldehyde and mandelamide, $\text{C}^6\text{H}^5\text{NO}^2$:

which crystallises from water in rhombic or hexagonal tables (Zinin, *Zeitschr. f. Chem.* [2] iv. 709).

12. The yellow resinous body produced by prolonged contact of *ammonia* with bitter almond oil containing prussic acid was examined by Laurent and by Gohardt, who obtained from it various products, according to the circumstances of its formation (i. 599). Th. Müller a. H. Limpricht (*Ann. Ch. Pharm.* cxi. 136) have examined the product obtained by the action of ammonia on that portion of crude bitter almond oil which remains in the retort after distillation at 184° . The yellow resin thus formed is resolved by ether into an insoluble portion containing hydrobenzamide and other bodies, and a solution which, on addition of alcohol, deposits a large quantity of a crystalline substance, not exhibiting a constant composition, even after repeated crystallisation from alcohol. Its alcoholic solution mixed with hydrochloric acid gives off hydrocyanic acid, and yields needle-shaped crystals of a hydrochloride $\text{C}^6\text{H}^5\text{N}^2\cdot 2\text{HCl}$, from which potash separates a base, $\text{C}^6\text{H}^5\text{N}^2$, crystallising from dilute alcohol in shining laminae melting at 122° . The sulphate $\text{C}^6\text{H}^5\text{N}^2\cdot \text{H}_2\text{SO}_4$ crystallises in needles; the *platinum salt* $\text{C}^6\text{H}^5\text{N}^2\cdot 2\text{HCl}\cdot \text{PtCl}_4$ is a yellow precipitate.

Parachlorobenzoic aldehyde, $\text{C}^6\text{H}^4\text{Cl}\cdot \text{COH}$, is produced by prolonged boiling of chlorobenzyl chloride, $\text{C}^6\text{H}^4\text{Cl}\cdot \text{CH}_2\text{Cl}$, with lead nitrate and water; more easily by heating chlorobenzylene chloride, $\text{C}^6\text{H}^4\text{Cl}\cdot \text{CHCl}_2$, with water in a sealed tube. When separated from its compound with sodium bisulphite, it is an oil which boils without decomposition, smells like bitter almond oil when cold, and when heated gives off a strongly tear-exciting vapour (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] iii. 467). The same compound is obtained by distilling chlorotribenzylamine, $(\text{C}^6\text{H}^4\text{Cl})^3\text{N}$, with bromine and water. (See BENZYLAMINES.) It passes over with the aqueous vapour, and when purified as above, boils between 210° and 220° . When exposed to the air it quickly absorbs oxygen, and is converted into parachlorobenzoic acid (Berlin, *Ann. Ch. Pharm.* cli. 140).

Tetrachlorobenzoic aldehyde, $\text{C}^6\text{HCl}_4\cdot \text{COH}$, appears to be produced by heating the chloride $\text{C}^6\text{HCl}_4\cdot \text{CH}_2\text{Cl}$ with water to 280° (Beilstein a. Kuhlberg, *Zeitschr.* [2] v. 528).

THIOBENZOIC ALDEHYDE or *THIOBENZYL HYDRIDE*, $\text{C}^6\text{H}_5\text{S} = \text{C}^6\text{H}_5\cdot \text{CSH}$, the compound which Laurent obtained by the action of ammonium sulphide on an alcoholic solution of bitter almond oil (i. 571), is probably identical with the benzylene sulphide or sulphobenzol which Cahours obtained by treating benzylene chloride, $\text{C}^6\text{H}_5\text{Cl}_2$, in alcoholic solution with potassium sulphhydrate (i. 577), although Laurent's product is described as a white powder softening at 90° - 95° , whereas that obtained by Cahours crystallised in micaceous scales melting at 64° . The latter product has been further examined by Fleischer (*Ann. Ch. Pharm.* cxl. 234), who finds that it melts at 68° - 70° , and decomposes at a higher temperature, yielding toluylene or stilbene, $\text{C}^{10}\text{H}_{12}$, thionessal, $\text{C}^{10}\text{H}^8\text{S}$ (the products of decomposition

obtained by Laurent), together with toluyl sulphide, C^6H^5S . It dissolves easily in ether and benzol, less easily in alcohol, and crystallises from the latter in white shining laminae, from ether in transparent prisms. The alcoholic solution does not unite with mercuric oxide; with *mercuric chloride* and *lead acetate*, it forms precipitates which quickly decompose. *Bromine* produces in the ethereal solution a brown oil, which strongly attacks the mucous membranes. *Nitric acid* of sp. gr. 1.3 converts it into a yellowish oil, and, after prolonged boiling, forms, together with sulphuric and benzoic acids, a peculiar modification of thiobenzoic acid, C^6H^5OS (p. 324).

In preparing the compound C^6H^5S by the action of potassium sulphhydrate on benzylene chloride, Fleischer likewise obtained dithiobenzoic acid, $C^6H^5S^2 = C^6H^5S.HS$ (p. 320), perhaps in consequence of the presence of potassium bisulphide in the sulphhydrate. It remained in solution after the monosulphide had been thrown down by water, and was separated therefrom by hydrochloric acid as a red non-crystallising oil having a fetid odour.

Parachlorothiobenzoic aldehyde, $C^6H^4Cl.CSH$, separates on passing dry sulphydric acid gas into the alcoholic solution of parachlorobenzoic aldehyde, as a pale rose-coloured flocculent precipitate, insoluble in alcohol, but easily soluble in benzol, and remaining on evaporation of that solvent as a transparent varnish (Beilstein u. Kuhlberg).

BENZOIC CHLORIDE or **BENZOYL CHLORIDE**. $C^6H^5OCl = C^6H^5.COCl$ (i. 566).—This compound is produced synthetically by the action of carbonyl chloride on benzene in sunshine: $C^6H^6 + COCl^2 = HCl + C^6H^5OCl$ (Harnitz-Harnitzky, *Bull. Soc. Chim.* [2] iii. 322). It is formed also by the action of sulphur dichloride, S^2Cl^2 , on sodium benzoate, or at a high temperature on benzoic acid (Carius, *Ann. Ch. Pharm.* cvi. 291). Red chloride of sulphur likewise converts sodium benzoate into benzoyl chloride (Heintz). Bkettoff (*ibid.* cix. 256) obtained benzoyl chloride in small quantity by heating a mixture of benzoic acid, sodium chloride, and sodium anhydrosulphate to 200° :

Lastly, benzoyl chloride is formed, together with other products, by the action of phosphorus pentachloride on hippuric acid (Schwanert, iii. 158).

Reactions.—1. Benzoyl chloride is not acted upon by *chlorine*, even at the boiling heat (Grimaux u. Vogt, *Dict. de Chimie*, i. 569).—2. By treating benzoyl chloride with *phosphorus pentachloride*, Lippich (*Ann. Ch. Pharm.* xcix. 171) has obtained the compounds $C^6H^4Cl^2$ and $C^6H^3Cl^3$, in addition to the trichloride $C^6H^3Cl^3$ previously obtained by Schischkoff u. Rosing (i. 567).

3. Benzoyl chloride treated with *potassium monosulphide* in alcoholic solution, is converted into thiobenzoic acid, and by heating with lead sulphide into benzoyl bisulphide (p. 325).—4. With *sulphuric anhydride* it unites directly, forming *sulphobenzoic chlorhydrate*, $C^6H^5ClSO^2$ (v. 488) (Engelhardt, *Jahresb.* 1864, p. 919).—5. Heated to 140° – 150° with caustic baryte, it yields benzoic anhydride, the reaction doubtless consisting in the first instance in the formation of barium chloride and barium benzoate, from which the benzoic anhydride is formed by the action of the benzoyl chloride (H. Gal, *Jahresb.* 1863, p. 337). A similar reaction, but less complete, takes place with lead oxide.—6. With *barium dioxide*, BaO^2 , benzoyl chloride yields benzoyl peroxide, $(C^6H^5O)^2O^2$ (Brodie, iv. 310).

7. Benzoyl chloride is not attacked by *potassium* or *sodium* at ordinary temperatures; but when its solution in anhydrous ether is heated with sodium for 24 hours in the water-bath, the ether deposits small crystals of dibenzoyl, $(C^6H^5O)^2$ (Briegel, *Bull. Soc. Chim.* [2] v. 278).—8. When dry *hydrochloric acid gas* is slowly passed through liquid *sodium amalgam* (containing but little sodium) covered with a layer of benzoyl chloride, benzoic aldehyde is first produced, and this by further addition of hydrogen is converted into benzyl alcohol (Lippmann, *ibid.* iv. 249).

9. *Potassamide* introduced into a solution of benzoyl chloride in anhydrous ether forms benzamide and dibenzamide (Baumert u. Landolt, *Ann. Ch. Pharm.* cxi. 1):

10. With *argentammonium sulphate* (an ammoniacal solution of silver-oxide mixed with sulphuric acid) benzoyl chloride forms ammonium sulphate, silver chloride, and benzamide (Engelhardt, *Ann. Ch. Pharm.* cviii. 386):

11. Benzoyl chloride heated with *potassium cyanate* gives off a small quantity of

benzonitrile, C^6H^5N , and leaves cyaphenine, $C^{10}H^{11}N^2$ (a solid substance polymeric therewith), mixed with potassium chloride (Cloeze, *Bull. Soc. Chim.* 1859, p. 100).—12. With *zinc ethyl* it forms benzoyl-ethyl, $C^7H^5O.C^2H^5$, which separates on addition of water as a fragrant liquid boiling at 117° (Frouard, *Ann. Ch. Pharm.* cxviii. 1).—13. With the zinc-salt of *amidobenzoic acid* it forms benzo-amidobenzoic acid, $C^{11}H^4(C^7H^5O)NO^2$ (Poster, *iv.* 292).—14. Heated to 200° in a sealed tube with *ethyl succinate*, it yields succinic anhydride, ethyl benzoate, and ethyl chloride (Kraut, *Ann. Ch. Pharm.* cxxxvii. 254):

15. *Isethionates* are converted by benzoyl chloride into benzoyl-isethionates, e.g.,

With *ethyl sulphates* a totally different reaction takes place, resulting in the formation of ethyl chloride. With *sulphanilic acid*, in like manner, it forms benzoylsulphanilic acid, $C^6H^4(ISO^2)(C^7H^5O)N$ (Engelhardt a. Latschinoff, *Zeitschr. f. Chem.* [2] iv. 234, 266.)

16. Benzoyl chloride unites directly with *nicotine*, forming the compound $(C^{10}H^{11}N^2.2C^7H^5OCl)$, which may be regarded as hydrochloride of benzoyl-nicotine, $\begin{pmatrix} C^{10}H^{12}N^2 \\ (C^7H^5O)^2 \end{pmatrix} N^2.2HCl$, or chloride of benzoyl-nicotammonium, $\begin{pmatrix} C^{10}H^{14}N^2 \\ (C^7H^5O)^2 \end{pmatrix} N^2.Cl^2$ (H. Will, *Ann. Ch. Pharm.* cxviii. 206).—17. With *hydroxylamine*, $NH^2(OH)$, it forms dibenzylhydroxamide, $N(C^7H^5O)^2OH$ (C. A. Heintz, *Zeitschr. f. Chem.* [2] v. 733).

Chlorobenzoyl chloride, $C^7H^5ClO.Cl$, is produced by the action of 1 mol. phosphorus pentachloride on benzosulphuric chloride, $C^7H^5SO^2Cl^2$ (Kämmerer a. Carius, p. 323); or by gently heating 1 mol. quinic acid, $C^7H^{12}O^8$, with 5 mol. phosphorus pentachloride (Gruebe, *Ann. Ch. Pharm.* cxxxviii. 197):

Metachlorobenzoyl chloride, or *Chlorosalyl chloride*, $C^7H^4ClO.Cl$, is isomeric with the preceding, is the compound which Chiozza obtained by the action of phosphorus pentachloride on salicylic acid (i. 568: there called *chloride of parachlorobenzoyl*). It is transformed by water into metachlorobenzoic or chlorosalicylic acid; by ammonia into chlorosalylamide; by aniline into chlorosalylanilide. According to Kekulé (*Ann. Ch. Pharm.* cxvii. 145), it is partly decomposed at each distillation, becoming richer in chlorine the oftener it is rectified.

BENZOIC OXIDE or ANHYDRIDE. $(C^7H^5O)^2O$.—This compound is produced, according to Gal (p. 330), by heating benzoyl chloride with barium oxide to 140° – 150° for twenty hours. Its specific gravity in the liquid state is 1.227 at 27° and 1.206 at 25.8° (Mendelejef, *Jahresb.* 1858, p. 274). Heated in dry hydrochloric acid gas, it is resolved into benzoic acid and benzoyl chloride:

By prolonged heating in dry sulphydric acid gas it yields a distillate of benzoic acid, mixed with oily drops apparently consisting of benzoic aldehyde and a residue of benzoyl bisulphide (Mösling, *Ann. Ch. Pharm.* cxviii. 303):

Benzo-iodic oxide or Iodine benzoate, $C^7H^5IO^2 = \begin{matrix} C^7H^5O \\ I \end{matrix} O$, has not been obtained pure, but appears to be formed, together with sodium chloride, by the action of iodine chloride on sodium benzoate: $C^7H^5NaO^2 + ICl = NaCl + C^7H^5IO^2$. On heating the product of this reaction, carbon dioxide and iodine are given off, and a liquid distils over which is resolved by fractional distillation into iodobenzene, C^6H^5I , and a solid body resembling naphthalene (Schützenberger, *Compt. rend.* lii. 135; *Jahresb.* 1861, p. 349).

Benzoic Peroxide, $(C^7H^5O)^2O^2$, is described in vol iv. p. 310.

BENZOIC SULPHYDRATE, $C^7H^5O.8H$, **SULPHIDE**, $(C^7H^5O)^2S$, and **BISULPHIDE**, $(C^7H^5O)^2S^2$, have already been described among the **SULPHUR-DERIVATIVES OF BENZOIC ACID** (pp. 324–326).

BENZOIN. $C^8H^7O^2$.—This body, polymeric with benzoic aldehyde, is easily prepared from benzils, $C^{14}H^{13}O^2$, by the action of reducing agents, as when a solution of 1 pt. benzils in 6 pts. acetic acid of sp. gr. 1.065 is boiled with 1 or 2 pts. of metallic iron. The liquid then coagulates to a pulp of needle-shaped crystals of benzoïn, and by decanting these crystals from the residual iron, washing them, after

cooling, with water, and crystallising from alcohol, benzoïn is obtained perfectly pure. A warm alcoholic solution of benzile is also converted into benzoïn by treatment with finely granulated zinc and hydrochloric acid. By further continuance of the reducing action in this latter case, the benzoïn is converted into a body richer in hydrogen (iii. 185) (Zinin, *Ann. Ch. Pharm.* cxix. 177; cxxiii. 125).

Benzoïn boiled with alcoholic potash is almost wholly converted into potassium benzilate: $C^{12}H^{10}O^2 + KHO = C^{12}H^{11}KO^2 + H^2$ (the hydrogen being oxidised in contact with the air); but when heated with alcoholic potash to 150° – 160° in a sealed and exhausted tube, it yields benzilic acid, hydrobenzoïn, and the body isomeric (? identical) therewith which Claus obtained by the action of sodium-amalgam on an ethereal solution of benzoic aldehyde (Zinin, *Bull. Soc. Chim.* [2] vii. 260). Heated to 100° with alcoholic ammonia, it is resolved into benzoïniam, $C^{12}H^{12}N^2O$, lophine, $C^{12}H^{11}N^2$, and a resinous body, accompanied by small quantities of benzoïnimide, $C^{12}H^{11}N$, and a granular substance (J. Erdmann, *Ann. Ch. Pharm.* cxxv. 181). Heated with aniline to 200° , it is converted into a crystalline substance apparently identical with the so-called benzoyl-anilide, $C^{12}H^{11}N$, which Laurent a. Gerhardt obtained by the action of aniline on benzoic aldehyde. This body is probably ditoluidene-diphenamine, $C^{24}H^{22}N^2 = (C^6H^5)_2(C^6H_5)_2N^2$ (Schiff, *Jahresb.* 1866, p. 413).

Benzoïn heated for seven or eight hours to 130° with $1\frac{1}{2}$ pts. of hydrochloric acid saturated at 8° , is converted into an oily body, which floats on the acid, and on opening the tube solidifies to a laminar mass, separable by the action of solvents into lepidene, $C^{24}H^{20}O$, which remains for the most part undissolved on treating the product with ether; benzyl, $C^{12}H^{14}$, which crystallises from the ethereal solution, and a thick oil insoluble in water, easily soluble in alcohol and ether (Zinin, *Bull. Soc. Chim.* [2] viii. 271).

Deoxybenzoïn. $C^{12}H^{12}O$ (Zinin, *Ann. Ch. Pharm.* cxix. 179; cxxvi. 218; *Zeitschr. f. Chem.* [2] iv. 718).—Produced from benzoïn by the action of nascent hydrogen evolved by zinc and hydrochloric acid; more easily by similar treatment of chlorobenzile dissolved in alcohol:

Deoxybenzoïn, purified by crystallisation from ether and alcohol, is white, easily soluble in alcohol and in ether, slightly soluble in boiling water, from which it separates as an oil, or in needles and laminae resembling benzoic acid. It melts in capillary tubes at 45° , but in larger masses at a higher temperature, and then solidifies at 53° to a crystalline broadly laminar mass. It is not altered by potash, either in aqueous or in alcoholic solution, or by benzoyl chloride.

Deoxybenzoïn is strongly attacked by bromine, forming the compound $C^{12}H^{10}Br^2O$, analogous to chlorobenzile (p. 305), and crystallising in rhombic prisms melting at 87° , decomposing at a higher temperature. This compound treated with silver nitrate or fuming nitric acid yields benzile; with alcoholic potash, it yields potassium benzoate and benzoic aldehyde.

The action of chlorine on deoxybenzoïn is not so definite as that of bromine. The product, which does not resemble chlorobenzile, is dissolved by alcoholic potash, with formation of benzoic or benzilic acid.

With phosphorus pentachloride, deoxybenzoïn forms an oily body, $C^{12}H^{11}Cl$, insoluble in water, soluble in alcohol and ether:

and this substance treated with sodium-amalgam and water yields toluylene or stilbene:

The same substance distilled or merely heated to boiling with caustic potash yields crystals of toluene, $C^{12}H^{10} = C^{12}H^{11}Cl + HCl$.

Deoxybenzoïn heated with nitric acid of sp. gr. 1.2 is converted into paranitrobenzoic acid (p. 314).

Deoxybenzoïn may be regarded as the anhydride of hydrobenzoïn, $C^{12}H^{14}O^2 - H^2O = C^{12}H^{12}O$, it appears to be identical with hydrobenzile produced by the action of ammonium sulphide on benzile (iii. 185), and with oxide of toluylene or stilbene, which, according to Limpricht a. Schwanert (*Jahresb.* 1867, p. 675), is produced by heating toluylene acetate with alcoholic potash, and crystallises in needles melting at 58° .

Hydrobenzoïn. $C^{12}H^{14}O^2$, originally obtained by treating pure benzoic aldehyde with zinc and hydrochloric acid (iii. 185), and subsequently by heating benzoïn with alcoholic potash in sealed tubes (*supra*), is identical with toluylene or stilbene alcohol:

produced from toluylene bromide, C^6H^5Br , by heating that compound with silver acetate or oxalate, whereby it is converted into the corresponding acetate or oxalate, and treating either of these ethers with alcoholic potash (Limpricht a. Schwanert, *Zeitschr. f. Chem.* [2] iii. 684); probably also with the compound of the same composition obtained by the action of sodium-amalgam on benzoic aldehyde (Claus; Church, p. 328), or on benzoic acid (Hermann, *Ann. Ch. Pharm.* cxxxii. 75). It is true that the melting points of these several products do not quite agree, Zinin's hydrobenzoin melting at 130° , Church's so-called dieresol at 129° , Claus's product at 100° , and Hermann's at 116° , and the toluylene alcohol of Limpricht a. Schwanert at 122° ; but these differences may be due to the various degrees of purity of the several products. Claus, as already observed, regards his product as *oxybenzyl ether*:

and as different from hydrobenzoin, because it gives different reactions (not specified) with nitric acid, and because it reacts like a body intermediate between an alcohol and an aldehyde, being converted into benzyl alcohol by nascent hydrogen, and into benzoic aldehyde by oxidation with chromic acid. But hydrobenzoin exhibits very similar characters, being also converted by nascent hydrogen into benzyl-alcohol, which, indeed, is always formed simultaneously with it, and by oxidation with nitric acid into benzoin, polymeric with benzoic aldehyde.

BENZOLEIC ACID. $C^6H^5O^2$. *Hydrobenzoic Acid* (Hermann, *Ann. Ch. Pharm.* cxxxii. 75; Otto, *ibid.* cxxxiv. 303).—This acid, intermediate between benzoic and cinnanthylic acids, is obtained: 1. By the action of nascent hydrogen on benzoic acid. When this acid is boiled with a little water, sodium-amalgam added, and a current of hydrochloric acid gas directed into the mixture, sodium benzoate is produced, together with benzyl alcohol, and a compound containing $C^6H^5O^2$ (? hydrobenzoin). The benzyl alcohol is separated by distillation; the residue is agitated with ether to remove the compound $C^6H^5O^2$; and the remaining sodium benzoate is decomposed by hydrochloric acid. Benzoleic acid then separates as an oil which does not solidify in the cold, provided all the benzoic acid has been converted into benzoleic acid; in the contrary case, the treatment with nascent hydrogen must be repeated (Hermann).—2. By heating hydrobenzyluric acid, $C^6H^5NO^4$ (produced by the action of nascent hydrogen on hippuric acid), with a strong solution of caustic alkali:

Benzoleic acid is a rather mobile, volatile, acid oil, having a disagreeable odour somewhat like that of valerianic acid; heavier than water, insoluble therein, very soluble in alcohol and ether. It does not unite readily with bases; nevertheless when heated with alkaline carbonates it expels the carbonic acid. It is very unstable.

The *benzoates* of sodium and calcium are deliquescent, alterable on exposure to the air, slightly soluble in boiling alcohol, separating out as the solution cools. According to Otto, the calcium salt is converted by repeated crystallisation, into benzoate, with loss of 4 at. hydrogen. *Ethyl benzoate*, $C^6H^5(C^2H^5)O^2$, obtained by passing hydrochloric acid gas into an alcoholic solution of benzoic acid, is a transparent colourless liquid, smelling like ethyl valerate, and decomposing when exposed to the air (Hermann).

BENZONE or BENZOPHENONE. Syn. with *Phenyl benzoate* (iv. 478).

BENZONITRILE or *Phenyl Cyanide*. See **CYANIDES**.

BENZOPINACONE. See **PINACONE** (iv. 648).

BENZOYL. C^6H^5O .—The radicle of the benzoic series. In the free state, as $C^6H^5O^2$, sometimes called *Dibenzoyl*, it is obtained by treating benzoic chloride dissolved in ether with sodium-amalgam, the action being assisted towards the end by the heat of a water-bath. The solution, filtered after 24 hours, shaken up with water to decompose the remaining portion of benzoic chloride, then freed from the greater part of the ether by distillation, and left to stand in a closed vessel, gradually deposits small crystals of benzoyl, which may be purified by recrystallisation from water. Benzoyl forms small colourless prisms having a vitreous lustre, melting at 166° , subliming without decomposition, and only slightly soluble in alcohol and ether. It dissolves

in strong sulphuric acid, and separates on addition of water, apparently without alteration, in long slender needles. When boiled with alcoholic potash, it decomposes, with formation of benzoic acid, and an oily body precipitable by water, which is probably benzyl alcohol, this latter body being formed by a secondary reaction from benzoic aldehyde, which is probably formed in the first instance, together with benzoic acid :

This behaviour, together with the melting point and solubility, distinguish benzoyl from benzole (melting at about 90°), with which it is isomeric (Briguel, *Ann. Ch. Pharm.* cxxxv. 171).

BENZOYL CHLORIDE. See BENZOIC CHLORIDE.

BENZOYL HYDRIDE. See BENZOIC ALDEHYDE.

BENZYL, C^6H^5 ; in the free state, C^6H^{11} (dibenzyl).—The preparation and properties of this radicle are described in vol. v. p. 870, where the name *benzyl* is used as synonymous with *tolyl*. Fittig, however, has shown (*Ann. Ch. Pharm.* cxxxix. 178) that tolyl, C^6H^{11} , obtained by heating bromotoluene with sodium, is isomeric, not identical, with benzyl produced in like manner from benzyl chloride, tolyl being a liquid, whereas benzyl is a crystalline solid. The isomerism between benzyl and tolyl is exhibited by the following formulæ :

Benzyl is also produced by heating toluylene, C^6H^{12} , to 140° – 150° with concentrated hydriodic acid, and may be separated by washing the product with soda-ley and water, and recrystallising from alcohol. It melts at 48° – 50° (Limpricht a. Schwanert, *Ann. Ch. Pharm.* cxlv. 330).

When passed in the state of vapour through a red-hot tube filled with fragments of pumice, it is resolved into toluene and toluylene: $2\text{C}^6\text{H}^{11} = 2\text{C}^6\text{H}^8 + \text{C}^6\text{H}^{12}$ (R. Otto, *Zeitschr. f. Chem.* [2] vi. 22).

Benzyl bromide, $\text{C}^6\text{H}^5 \cdot \text{CH}^2\text{Br}$, *Benzyl chloride*, $\text{C}^6\text{H}^5 \cdot \text{CH}^2\text{Cl}$, and their substitution derivatives, are described in association with their isomerides, the bromo- and chloro- toluenes (v. 853–856, and pp. 280–284 of this volume).

Brominated substitution products of Dibenzyl were obtained by Stelling and Fittig (v. 871) by the action of bromine on benzyl suspended in water. Limpricht a. Marquart (*Zeitschr. f. Chem.* [2] v. 337) have obtained compounds isomeric with these by treating benzyl with dry bromine. *Monobromodibenzyl*, $\text{C}^6\text{H}^{11}\text{Br}$, thus obtained, is an oil, which when heated with alcoholic potash yields toluylene: $\text{C}^6\text{H}^{11}\text{Br} - \text{HBr} = \text{C}^6\text{H}^{12}$. The *dibromodibenzyl*, $\text{C}^6\text{H}^{12}\text{Br}_2$, produced in like manner, is identical with toluylene bromide, and like that compound is converted by alcoholic potash into toluene, C^6H^{10} . The *tribromodibenzyl* could not be separated completely from the preceding compound; but it is essentially different from the tribrominated compound produced by treating dibenzyl with bromine in presence of water.

Benzyl, therefore, exhibits the same tendency as toluene, xylene, &c., to yield, with bromine or chlorine, different products accordingly as the reaction takes place at low or at high temperatures, the substitution of the bromine in dibenzyl as well as in toluene taking place within the phenyl molecule at low temperatures, and in the methyl molecule (the lateral chain) at high temperatures.

BENZYL ALCOHOL. $\text{C}^6\text{H}^5\text{O} = \text{C}^6\text{H}^5 \cdot \text{CH}^2\text{OH}$.—Isomeric with cresol. Described in vol. i. p. 578. Produced also: 1. Together with hydrobenzoin and ethyl benzoate, by the action of sodium-amalgam on benzoic acid (Hermann, p. 328).—2. Together with glycoic acid, hydrobenzoin, and a nitrogenous acid, by the action of sodium-amalgam on hippuric acid (Hermann, *Ann. Ch. Pharm.* cxxiii. 355; *Jahresb.* 1865, p. 354).—3. By boiling hydrobenzyluric acid (produced by adding sodium-amalgam to a concentrated alkaline solution of hippuric acid) with alkalis:

and in like manner from hydroxybenzyluric acid:

(Otto, *Ann. Ch. Pharm.* cxxxiv. 303; *Jahresh.* 1866, p. 356).—4. By passing a slow stream of dry hydrochloric acid gas through liquid sodium-amalgam covered with a layer of benzoyl chloride, $\text{C}^6\text{H}^5\text{OCl}$, this compound being thereby converted into benzoic aldehyde, and the latter, by further addition of hydrogen, into benzyl alcohol (Lippmann, *Bull. Soc. Chim.* [2] iv. 249).—5. By heating benzyl chloride with 3 pts. of recently precipitated lead oxide and 10 pts. water:

(Lauth a. Grimaux, *ibid.* [2] vii. 106).

6. By the action of alcoholic potash on the portions of Peru-balsam oil boiling at 200° , and about the boiling point of mercury, the former consisting of benzyl benzoate, the latter of benzyl cinnamate. The benzyl alcohol thus obtained boils at 206.2° (corr.), has a sp. gr. of 1.0465 at 19° , and does not solidify at -18° (Kraut, *Ann. Ch. Pharm.* clii. 134).

Chlorinated Benzyl Alcohols (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] iii. 467; iv. 26, 528; v. 526).—*Parachlorobenzyl alcohol*, $\text{C}^6\text{H}^4\text{Cl}.\text{CH}^2\text{OH}$, obtained by heating parachlorobenzyl acetate (p. 336) with ammonia to 160° , and recrystallising the product from water, forms spicular crystals often several inches long; melts at 66° ; boils without decomposition; is nearly insoluble in cold, and but slightly soluble in boiling water; yields parachlorobenzoic acid by oxidation.

Paradichlorobenzyl alcohol, $\text{C}^6\text{H}^2\text{Cl}^2.\text{CH}^2\text{OH}$, is prepared by heating the corresponding acetate with ammonia to 180° , distilling the oily product to separate the more volatile portions, and recrystallising the portion which solidifies on cooling, from water. It forms white shining needles, very slightly soluble in water, melting at 77° , and partially decomposed by boiling.

Trichlorobenzyl alcohol, $\text{C}^6\text{H}^3\text{Cl}^3.\text{CH}^2\text{OH}$, is obtained by heating trichlorotoluene chloride, $\text{C}^6\text{H}^3\text{Cl}^3$, with potassium acetate to 150° in sealed tubes. The corresponding acetate is then formed, but decomposes partially on distilling the filtered solution, so that trichlorobenzyl alcohol distils over, and on mixing the distillate with water, separates as an oil, which solidifies after a while, and may be purified by recrystallisation from water. By oxidation with chromic acid, it is converted into trichlorobenzoic acid.

Tetrachlorobenzyl alcohol, $\text{C}^6\text{HCl}^4.\text{CH}^2\text{OH}$, is obtained by heating tetrachlorotoluene chloride, C^6HCl^4 , with absolute alcohol and potassium acetate to 180° , and purified by crystallisation from boiling water.

Pentachlorobenzyl alcohol, $\text{C}^6\text{Cl}^5.\text{CH}^2\text{OH}$, prepared in like manner by heating $\text{C}^6\text{Cl}^5.\text{CH}^2\text{Cl}$ with absolute alcohol and potassium acetate to 200° , and purified by recrystallisation from a mixture of benzol and absolute alcohol, forms short white needles, melting at 193° , insoluble in water and in cold absolute alcohol, slightly soluble in boiling alcohol. It does not appear to yield any organic acid by oxidation with chromic acid.

Nitrobenzyl Alcohols. *Mononitrobenzyl alcohol*, $\text{C}^6\text{H}^4(\text{NO}^2).\text{CH}^2\text{OH}$, is produced, together with potassium nitrobenzoate, by heating nitrobenzoic aldehyde with alcoholic potash:

On adding water to the product, the nitrobenzyl alcohol separates as a viscid, uncrystallisable oil, which is decomposed by distillation under ordinary atmospheric pressure, but distils under a pressure of 3 millim. at 170° – 189° , as an amber-coloured oil, which is converted by phosphorus pentachloride into a yellow chlorinated non-volatile liquid (Grimaux, *Bull. Soc. Chim.* [2] viii. 433).

Paranitrobenzyl alcohol, $\text{C}^6\text{H}^3(\text{NO}^2).\text{CH}^2\text{OH}$, is formed, together with acetamide, by heating paranitrobenzyl acetate with aqueous ammonia to 100° , till the oily layer disappears, and purified by recrystallisation from hot water. Colourless, slender needles, which become coloured on exposure to light, melt at 93° , dissolve easily in hot water or in water containing ammonia. Converted by oxidation into paranitrobenzoic acid (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] iii. 467).

Paradinonitrobenzyl alcohol, $\text{C}^6\text{H}^2(\text{NO}^2)^2.\text{CH}^2\text{OH}$, formed by dissolving the preceding compound in fuming nitric acid, is precipitated from the solution by water, and crystallises in needles melting at 71° (Beilstein a. Kuhlberg, *ibid.*).

BENZYL OXYGEN-ETHERS. *Parachlorobenzyl acetate*, $\text{C}_6\text{H}_4\text{Cl} \cdot \text{CH}_2\text{C}(\text{H}^1)(\text{O}^2)$, is prepared by prolonged boiling of a solution of chlorobenzyl chloride with a solution of potassium acetate in absolute alcohol, and rectifying the oil separated by water. Colourless aromatic liquid boiling at 240° . Converted by heating with ammonia into parachlorobenzyl alcohol (Neuhof, *Zeitschr. f. Chem.* [2] iii. 467). *Paradichlorobenzyl acetate*, $\text{C}_6\text{H}_2\text{Cl}_2 \cdot \text{CH}_2\text{C}(\text{H}^1)(\text{O}^2)$, prepared in like manner from dichlorobenzyl chloride, is an aromatic liquid boiling at 259° (Beilstein a. Kuhlberg).

Paranitrobenzyl acetate, $\text{C}_6\text{H}_4(\text{NO}^2) \cdot \text{CH}_2\text{C}(\text{H}^1)(\text{O}^2)$, is produced on dropping pure benzyl acetate (i. 21) into cooled fuming nitric acid. Separated by water and crystallised from alcohol, it forms long pale yellow needles, which become coloured on exposure to light, melt at 78° , dissolve sparingly in cold, freely in hot alcohol.

Parachlorobenzyl-ethyl oxide, $\text{C}_6\text{H}_4\text{Cl} \cdot \text{CH}_2\text{O} \cdot \text{C}_2\text{H}_5$, was obtained by Naquet (*Jahresb.* 1862, p. 420; 1863, p. 563) by decomposing chlorobenzyl chloride, $\text{C}_6\text{H}_4\text{Cl} \cdot \text{Cl}$, with alcoholic potash, and is likewise formed by boiling parachlorobenzyl acetate with alcoholic potash. Heavy liquid, having an agreeably sweet odour, insoluble in water, boiling at 215° – 220° (Beilstein a. Kuhlberg).

Benzyl oxalate, $(\text{C}_6\text{H}_5)_2\text{C}^1\text{O}^4$, produced by gently heating dry silver oxalate with an equivalent quantity of benzyl chloride, and purified by boiling the solidified product with alcohol, then melting, distilling, and recrystallising, forms dazzling white crystalline scales melting at 80.5° . It distils without decomposition, is insoluble in water, nearly insoluble in cold alcohol, but dissolves easily in boiling alcohol, also in ether and in benzol. With ammonia it yields benzyl alcohol and oxamide. *Paranitrobenzyl oxalate*, $[\text{C}_6\text{H}_4(\text{NO}^2)]_2\text{C}^1\text{O}^4$, is produced by dissolving benzyl oxalate in fuming nitric acid, and is decomposed by ammonia, with formation of paranitrobenzyl alcohol (Beilstein a. Kuhlberg, *loc. cit.*).

BENZYL SULPHYDRATE, SULPHIDE, and BISULPHIDE. The following reactions of these compounds have been observed by Märcker (*Ann. Ch. Pharm.* cxl. 86; *Jahresb.* 1866, p. 599), in addition to those already described (v. 858).

Benzyl sulphhydrate mixed with an ethereal solution of bromine, till the colour of the latter disappears, is completely converted, with rapid evolution of hydrobromic acid, into benzyl bisulphide:

Metabenzyl sulphhydrate is converted in like manner into metabenzyl bisulphide.

Benzyl sulphide, $(\text{C}_6\text{H}_5)_2\text{S}$, deliquesces in an atmosphere of bromine to a red-brown liquid, which strongly attacks the eyes, and consists of a mixture of sulphur bromide and benzyl bromide. *Benzyl bisulphide* is decomposed by bromine at 130° , and in presence of water benzoic acid is produced, together with a brown resin:

Ethyl-benzyl sulphide, $(\text{C}_6\text{H}_5)(\text{C}_2\text{H}_5)\text{S}$, is obtained by dissolving sodium in benzyl sulphhydrate (mixed with ether to moderate the action), and treating the product with ethyl iodide. On adding water the ethyl-benzyl sulphide separates as an oil, which, after dehydration, may be distilled at 214° – 216° , as a limpid liquid having an extremely pungent odour.

Benzyl-mercuric sulphide, $(\text{C}_6\text{H}_5)_2\text{HgS}^2$, heated to 130° with ethyl iodide, deliquesces to a lemon-yellow liquid, which solidifies to a crystalline mass on cooling.

BENZYL SULPHOCYANATE. $\text{C}_6\text{H}_5 \cdot \text{CNS}$.—When benzylamine is dissolved in carbon bisulphide, heat is evolved, and a colourless crystalline compound is formed, which, when mixed with alcohol and mercuric chloride, yields by distillation a liquid having a very powerful odour. On adding water to the alcoholic distillate, the benzyl sulphocyanate separates in transparent drops which sink in water. It smells like watercress and boils at 243° (Hofmann, *Zeitschr. f. Chem.* [2] iv. 690).

BENZYLAMINES. These bases, $(\text{C}_6\text{H}_5)_2\text{H}^1\text{N}$, $(\text{C}_6\text{H}_5)_3\text{H}^1\text{N}$, and $(\text{C}_6\text{H}_5)_3\text{N}$, discovered by Cannizzaro (i. 575; v. 867), have been further examined by Limpricht (*Ann. Ch. Pharm.* cxliv. 304; *Jahresb.* 1867, p. 508). They are formed by heating 1 vol. benzyl chloride (boiling at 170° – 190°) and 2 vol. alcoholic ammonia to 100° for 24 hours, and separated by the different solubilities of their hydrochlorides in alcohol, the monobenzylamine salt being the most, and the tribenzylamine salt the least soluble. The crystalline pulp formed by heating the benzyl chloride with ammonia is freed from alcohol and ammonia by distillation, and then mixed with water; the resulting precipitate is dissolved in hot alcohol; and the solution mixed

with hydrochloric acid is left to cool. Tribenzylamine hydrochloride then usually separates at first in prisms or needles, and the filtrate, after concentration, yields first a mixture of this salt with dibenzylamine hydrochloride, then pure crystals of the latter, and finally the hydrochloride of monobenzylamine, which is present in small quantity only.

Benzylamine, $(C^6H^5)H^2N = C^6H^5 \cdot CH^2NH^2$, is isomeric with *toluidine*. Separated from the hydrochloride by dilute caustic soda, it forms a transparent colourless liquid, which does not become coloured on exposure to light, has a faint peculiar odour, a sp. gr. of 0.990 at 14° , and boils at 183° . It dissolves in all proportions in water, alcohol, and ether, is separated from the aqueous solution by strong soda-ley, and when exposed to the air is quickly converted into *carbonate*. The *hydrochloride* and *hydrobromide* crystallise in easily soluble laminæ; the *platinocloride*, $2(C^6H^5N \cdot HCl) \cdot PtCl_4$, is a yellow granular crystalline precipitate. With *fuming sulphuric acid*, benzylamine forms a sulpho-acid, whose calcium salt $(C^6H^5NSO_3)^2Ca$ is easily soluble in water, and separates on addition of alcohol in small warty crystals.

Dibenzylamine $C^6H^5N = (C^6H^5)^2HN = C^6H^5 \cdot CH^2NH(C^6H^5)$, separated from the hydrochloride by dilute soda-ley, is a colourless viscid liquid of sp. gr. 1.033 at 14° , insoluble in water, easily soluble in alcohol and ether, decomposing when heated, and easily converted into tribenzylamine by the action of benzyl chloride. The *hydrochloride*, $C^6H^5N \cdot HCl$, crystallises in flat prisms or thin laminæ, melting at 250° ; the *platinocloride*, $2(C^6H^5N \cdot HCl) \cdot PtCl_4$, in orange-coloured concentrically grouped needles; the *hydrobromide*, $C^6H^5N \cdot HBr$, in large nacreous laminæ, melting at 266° ; the *hydriodide*, $C^6H^5N \cdot HI$, in long white prisms melting at 224° ; the *nitrate*, $C^6H^5N \cdot HNO_3$, in somewhat sparingly soluble flat prisms or needles, melting at 186° . Dibenzylamine is converted into monobenzylamine by reactions exactly analogous to those by which it is itself produced from tribenzylamine (*vid. inf.*), but more slowly and less completely. With *fuming sulphuric acid*, dibenzylamine forms a non-crystallisable bilasic sulpho-acid, whose barium salt $C^6H^5NS^2O^3Ba$ crystallises in small nodular masses easily soluble in water. Dibenzylamine heated with *aniline* and *arsenic acid* yields an amorphous violet colouring matter.

Cyan-dibenzylamine, $C^6H^5(CN)N$, is formed, together with dibenzylamine hydrochloride, which separates out, when gaseous cyanogen chloride is passed into an alcoholic solution of dibenzylamine. It is insoluble in water, easily soluble in alcohol and ether, and separates therefrom in laminar crystals melting at 53° – 54° .

Ethyl-dibenzylamine, $(C^6H^5)^2(C^2H^5)N$, is produced by heating dibenzylamine with ethyl iodide and alcohol to 110° , and is separated from its hydrochloride by silver oxide as a yellowish oil; the hydrochloride crystallises in nodular groups.

Tribenzylamine, $C^6H^5N = (C^6H^5)^3N = C^6H^5 \cdot CH^2N(C^6H^5)^2$, separated from the hot alcoholic solution of its hydrochloride by dilute soda-ley, and recrystallised from alcohol, forms large white laminæ or needles, easily soluble in ether and in hot alcohol, sparingly in cold alcohol, insoluble in water. It melts at 91° , may be distilled in small quantities without alteration; but in larger quantities it is decomposed, when heated above 300° , into toluene and several other products. The solution of tribenzylamine in *fuming sulphuric acid* contains a sulpho-acid (perhaps $C^6H^5NS^2O^3$), which appears to be resolved by water into two other acids, $C^6H^5NS^2O^3$ and $C^6H^5SO^3$, whose barium salts crystallise indistinctly and cannot be separated. Heated with *aniline* and *arsenic acid*, they yield an amorphous colouring matter which dissolves in alcohol or in hydrochloric acid with deep violet colour.

Tribenzylamine hydrochloride heated to 250° in a stream of hydrochloric acid gas is resolved into benzyl chloride and hydrochloride of dibenzylamine:

The *nitrate*, $(C^6H^5)^3N \cdot HNO_3$, separates by spontaneous evaporation in transparent crystals melting at 124° . Tribenzylamine heated with *bromine* and *water* is resolved into hydrobromic acid, benzoic aldehyde, and hydrobromide of dibenzylamine:

With *iodine* and *water* an analogous decomposition takes place at 120° . Dry *bromine* added to the ethereal solution of tribenzylamine throws down a yellow amorphous compound, $[(C^6H^5)^3N]^2Br^2$, which, when distilled with water, is resolved into benzoic aldehyde, dibenzylamine hydrobromide, hydrobromic acid, and free bromine.

Decomposition of Di- and Tri-benzylamine by Heat.—These bases, when slowly distilled in small retorts, yield a number of volatile products, together with a black-brown residue amounting to about half the original substance. The volatile products consist of ammonia, and a liquid which deposits crystals and yields by fractional

distillation toluene, boiling at 112° . The crystalline deposit may be separated by repeated crystallisation from alcohol into dibenzyl, $(C^6H^5)_2CH_2$, toluylene, $C^6H_5CH_2$, and small quantities of crystalline azotised bodies. The black-brown residue of the distillate, when boiled with alcohol, yields lophine, $C^9H^9N^2$, in colourless silky needles. The same alcoholic extract mixed with hydrochloric acid deposits concentrically grouped quadratic prisms of tetrabenzylammonium chloride, $(C^6H^5)_4NCl$, and afterwards small white nodules of the hydrochloride of tribenzylene-triamine, $(C^6H^5)_3H^3N^3 \cdot HCl$ (Brunner, *Ann. Ch. Pharm.* cli. 133).

Chlorinated Benzylamines (Berlin, *ibid.* 137).—When chlorobenzyl chloride (p. 281) is heated in sealed tubes with alcoholic ammonia, there are formed, together with sal-ammoniac, the three bases $(C^6H^4Cl)H^2N$, $(C^6H^4Cl)_2HN$, and $(C^6H^4Cl)_3N$, the second being the most abundant. The separation of these bases is much more difficult than that of the three benzylamines (p. 336), partly because their salts differ but little in solubility, partly in consequence of the existence of isomeric modifications. The contents of the tubes were washed on a filter with alcohol; and the filtrate, after removal of the ammonia and the greater part of the alcohol by distillation with water, was mixed with the sal-ammoniac remaining on the filter, which still retained a considerable quantity of oil. The oily liquid thus obtained was a mixture of the three chlorinated bases with unaltered chlorobenzyl chloride. When mixed with alcohol and hydrochloric acid, it gradually deposited a considerable quantity (A) of the hydrochlorides of these bases, the crystallisation of the remainder being, however, prevented by the chlorobenzyl chloride still present. To complete the separation, the mother-liquor was mixed with potash; the precipitated oil distilled with water as long as chlorobenzyl chloride continued to pass over; and the residue, to facilitate the separation of the bases, was finally mixed with bromine, whereby the chlorotribenzylamine was resolved into chlorobenzoic aldehyde and dibenzylamine, the former passing over on distillation, and leaving a residue (B) consisting only of chlorinated mono- and di-benzylamine.

Chlorotribenzylamine. $(C^6H^4Cl)_3N$.—The oily mixture of the three bases (A) mixed with alcohol and hydrochloric acid first deposits the hydrochloride of chlorodibenzylamine, and the mother-liquor gradually yields transparent crystals of the hydrochloride of chlorotribenzylamine, from the alcoholic solution of which the base may be precipitated by potash and water. It crystallises from alcohol in beautiful rhombic prisms melting at 88° – 89° . The hydrochloride, $(C^6H^4Cl)_3N \cdot HCl + 2H^2O$, forms large transparent rhombohedrons, moderately soluble in alcohol, insoluble in water, melting at 170° – 175° , giving off part of their water on exposure to the air, and the whole over sulphuric acid. At 100° they decompose, apparently thus:

The same decomposition appears to take place on distilling the hydrochloride with water or alcohol; and hence it is that, in the preparation of these bases, the residue left after distilling off the alcohol contains only a small quantity of chlorotribenzylamine, but considerable quantities of chlorodibenzylamine and chlorobenzyl chloride. Chlorotribenzylamine is resolved by distillation with water and bromine into hydrobromide of chlorodibenzylamine and chlorobenzoic aldehyde:

Chlorodibenzylamine. $(C^6H^4Cl)_2HN$.—This base exhibits four isomeric modifications, which may be distinguished by the prefixes α , β , γ , δ . They are non-volatile oils, having a faint yellowish colour, insoluble in water, easily soluble in alcohol and ether. The differences between them are exhibited chiefly in their salts. The hydrobromides differ in solubility sufficiently to admit of separation by fractional crystallisation, the α salt being the least soluble, then the β , then the γ , and the δ salt the most soluble in water; and from these salts the bases may be separated by potash and combined with other acids. Most of the salts crystallise in needles. Their melting points are given in the following table:

	α	β	γ	δ
Hydrochlorides . . .	288° – 289°	225° – 228°	218° – 220°	221° – 222°
Hydrobromides . . .	283° – 290°	224°	210° – 212°	198° – 199°
	(solidifying at 230°)			
Hydriodides		215°	187°	216° – 218°
Nitrates		204° – 205°	193°	177° – 179°

Chlorobenzylamine. $(C^6H^4Cl)H^2N$.—The hydrobromide of this base remains in the mother-liquor of the mixture B after the chlorodibenzylamine salt has crystallised.

one. By distilling it with potash, the base is obtained as a colourless liquid, easily soluble in alcohol and ether, insoluble in water, and converted into a solid salt by absorption of carbonic acid from the air. The hydrochloride $(C^6H^5Cl)H^+N^+ \cdot HCl$ forms small white needles easily soluble in water and in alcohol and melting at 197° . Platonic chloride forms in the concentrated alcoholic solution a yellow precipitate formed of microscopic rhombic laminae moderately soluble in water and in alcohol.

BENZYLENE. C^6H^6 .—The bromide and chloride of this diatomic radicle, together with the substitution-derivatives of the latter, $C^6H^5Cl \cdot Cl^+$, $C^6H^4Cl_2 \cdot Cl^+$, $C^6H^3Cl_3 \cdot Cl^+$, &c., are described amongst the bromo- and chloro-toluenes (pp. 281, 282). The oxygen-ethers of the same radicle are described in vol. i. pp. 577, 578.

BENZYL-SULPHUROUS ACID. Syn. with TOLUENE-SULPHURIC or SULPHO-TOLUIC ACID (v. 553, and p. 286 of this volume).

BERBERINE. $C^{20}H^{17}NO^4$ (i. 579 and APPENDIX v. 1088).—This base has been found in *Leontice thalictrifolius* (F. F. Mayer, *J. Pharm.* [3] xlvii. 496). According to Daniel (*Ann. Ch. Pharm.* cv. 360), the yellow bark of Abocouta, in which Stenhouse found berberine, belongs to *Celastrum polycarpa* (Dec.). Berberine is identical with xanthopicro from *Xanthoxylon Clava Herculis*, and with juncifoline from the bark of *Geoffroya inermis* (Gastell, *Jahresb.* 1866, p. 480).

Preparation.—The following method is given by Stenhouse (*Chem. Soc. J.* [2] v. 187) for preparing berberine from the columbo-wood of Ceylon (*Menispermum fenestratum*, *Coccinium fenestratum*): 20 pts. of the finely ground wood are boiled for three hours with a solution of basic lead acetate (prepared by heating 1 pt. of the neutral acetate with 1 pt. litharge and 3 pts. water, and afterwards adding 100 pts. water), and the liquid, strained through a linen filter, is concentrated (with addition of a little litharge) till the berberine crystallises out. The mother-liquor decanted from the crystals and acidulated with nitric acid yields the rest of the base, as a nitrate slightly soluble in the excess of acid. To purify the crude berberine, the hot aqueous solution is precipitated with basic lead acetate; the crystalline mass which separates from the filtrate on cooling is pressed, and redissolved in hot water; and, after the lead has been precipitated by hydrogen sulphide, the filtrate is acidulated with acetic acid and left to crystallise. The nitrate may be converted into the free base by heating the aqueous solution with ammonia, or better with calcium hydrate.

Procter (*Chem. News*, ix. 112) recommends a process given by W. A. Merrill (*Ann. J. Pharm.* xxxv. 97) for preparing berberine from the root of *Berberis vulgaris* or of *Hydrastis canadensis*. The evaporated aqueous extract of the root is treated with strong alcohol; the alcoholic liquid mixed with $\frac{1}{2}$ vol. water; $\frac{2}{3}$ of the alcohol distilled off; and the hot aqueous residue acidulated with dilute sulphuric acid. On cooling, it deposits berberine sulphate, which may be purified by recrystallisation. To obtain the free base, the hot aqueous solution of the sulphate is digested with recently precipitated lead oxide till the supernatant liquid is free from sulphuric acid. The filtrate left to evaporate deposits crystals of berberine.

Reactions.—Berberine heated with water to 190° – 200° for several days in sealed tubes is gradually converted into a substance resembling chlorophyll (Hlasiwetz, *Jahresb.* 1860, p. 533). By nascent hydrogen (zinc and dilute acids), it is converted into hydroberberine, $C^{20}H^{21}NO^4$ (iii. 185). By fusion with potassium hydrate, berberine is converted into two acids, $C^{18}H^{15}O^4$ and $C^{18}H^{13}O^4$ (?), the former homologous with protocatechuic, the latter probably with opianic acid (Hlasiwetz & Gilm, *Jahresb.* 1864, p. 406). Berberine distilled with sodium hypochlorite, yields propylamine (trimethylamine), and a yellow resinous substance not containing nitrogen (Kletzensky, *ibid.* 1865, p. 456).

An aqueous solution of berberine acetate forms with sodium sulpharsenate, a brown amorphous precipitate which decomposes in a few days (Mosing, *Zeitschr. f. Chem.* [2] v. 350).

The salts of berberine have been analysed by Fleitmann (*Ann. Ch. Pharm.* lix. 160), L. Henry (*ibid.* cxv. 132), and Perrins (*Chem. Soc. J.* xv. 389). The formulae, calculated by Fleitmann and Henry according to the old formula of berberine, have been corrected by Hlasiwetz & Gilm (*Ann. Ch. Pharm. Suppl.* ii. 191).

Hydrochloride,	$C^{20}H^{17}NO^4 \cdot HCl$,	yellow needles.
Aurochloride,	$C^{20}H^{17}NO^4 \cdot HCl \cdot AuCl^+$,	maroon-coloured needles soluble in alcohol.
Platinochloride,	$2(C^{20}H^{17}NO^4 \cdot HCl) \cdot PtCl^+$,	small needles.
Hydrobromide,	$C^{20}H^{17}NO^4 \cdot HBr \cdot 3aq.$,	yellow needles.
Hydriodide,	$C^{20}H^{17}NO^4 \cdot HI$,	yellow, slightly soluble needles.

Nitrate,	$C^{20}H^{11}NO^4.HNO^3$,	yellow, very slightly soluble in dilute nitric acid.
Chlorate,	$C^{20}H^{11}NO^4.HClO^3$,	yellow precipitate.
Sulphate,	$C^{20}H^{11}NO^4.H^2SO^4$,	small yellow crystals.
Argento-berberine } Hyposulphite, }	$(C^{20}H^{11}NO^4)_2.H^2S^2O^3.Ag^2S^2O^3$,	yellow amorphous precipitate.
Dichromate,	$CrO_2 \begin{cases} OHC^{20}H^{11}NO^4 \\ O \end{cases}$ $CrO_2 \begin{cases} OHC^{20}H^{11}NO^4 \\ O \end{cases}$	orange-yellow needles.
Hydrocyanide,	$C^{20}H^{11}NO^4.CNH.\frac{1}{2}aq.$,	brownish-yellow scales.
Nitro-berberine } Hydrocyanide, }	$C^{20}H^{11}(NO^2)NO^4.CNH$,	microscopic needles.
Sulphocyanate,	$C^{20}H^{11}NO^4.CNHS.\frac{1}{2}aq.$,	yellow needles.
Oxalate,	$C^{20}H^{11}NO^4.C^2H^2O^4.\frac{1}{2}aq.$,	nodular groups of needles.
Succinate,	$C^{20}H^{11}NO^4.C^2H^2O^4.\frac{1}{2}aq.$,	brownish needles.
Tartrate,	$C^{20}H^{11}NO^4.C^2H^2O^4.\frac{1}{2}aq.$,	siskin-yellow needles.
Picrate,	$C^{20}H^{11}NO^4.C^2H^2(NO^2)^2O$,	golden-yellow shining scales.
Ethyl-berberine } Hydriodide, }	$C^{20}H^{11}(C^2H^5)HO^4.HI$,	radiate needles.

Tartrate of Antimony and Berberine, $C^{20}H^{11}NO^4.HSbO.C^2H^2O^4$, crystallises in wavelitic groups, very slightly soluble in cold water, and recrystallisable without decomposition from alcohol (Stenhouse, *Proc. Roy. Soc.* xii. 491).

A solution of a berberine salt mixed with a slight excess of iodine yields the *periodide* $C^{20}H^{11}NO^4.HI^2$, which dissolves but sparingly in water and in cold alcohol, and crystallises from hot alcohol in translucent red-brown prisms, from which silver nitrate immediately abstracts the whole of the iodine. A hot alcoholic solution of a berberine salt mixed with a dilute solution of iodine in potassium iodide, carefully avoiding excess of iodine, deposits green shining spangles of a salt resembling sulphate of iodoquinine (v. 25), and exhibiting the peculiar polarising properties of that compound; they are always, however, mixed with the salt last described, and with berberine hydriodide. The formation of this green salt affords a very delicate test for the presence of berberine. It may be obtained in crystals $\frac{1}{2}$ inch long and half as broad by heating a solution of berberine in 90 p. c. alcohol mixed with ethyl iodide to 100° , leaving it to cool, and exposing the separated crystals of berberine hydriodide to the sun's rays for two hours, or to diffused daylight for a few days. It is probably identical in composition with the red salt, into which, indeed, it is very easily transformed (Ferrins).

BENZELIANITE. This mineral, occurring at Skrikerum in Sweden, as a black-blue crystalline powder of sp. gr. 6.71, has been analysed by A. Nordenskjöld (*Ann. Ch. Pharm.* cxlv. 127), with the following results:

Cu	Ag	Fe	Fl	So
53.14	4.73	0.54	0.38	39.85 = 98.64,
52.15	8.60	0.35	trace	38.74 = 99.74.

BETAINE. $C^9H^{11}NO^2$ (C. Scheibler, *Zeitschr. f. Chem.* [2] y. 539).—A base occurring in the juice of mangold-wurzel. To prepare it, the freshly expressed juice, strongly acidulated with hydrochloric acid, is mixed with a solution of sodium phosphotungstate; * the resulting precipitate, containing albumin, colouring matter, woody fibre, and a small quantity of the base, is filtered as quickly as possible; and the filtrate, mixed with a fresh quantity of the precipitant, is left to itself for 8 or 10 days. It then gradually deposits on the bottom and sides of the vessel a crystalline precipitate, which is rinsed with a little water and treated with milk of lime, whereby insoluble calcium phosphotungstate is produced, while the betaine remains in solution. The filtered liquid, freed from lime by carbonic acid and evaporated, leaves impure betaine, which may be purified by recrystallisation from alcohol with help of animal charcoal.

Betaine may also be obtained from the molasses of the beet, in which it exists in larger proportion than in the fresh juice. The solution of the molasses, diluted with twice its bulk of water, and strongly acidulated with hydrochloric acid, is mixed with a small quantity of the phosphotungstate solution, which throws down chiefly colouring matter and impurities, and the filtrate is mixed with a larger quantity of the same reagent, which throws down a second precipitate, to be treated as above.

Betaine crystallises from strong alcohol in large shining hydrated crystals,

* This reagent is prepared by dissolving sodium bitungstate in ordinary phosphoric acid, adding hydrochloric acid, and decanting the clear solution from the precipitate thereby produced.

$C^4H^{11}NO^2 \cdot H^2O$, which on exposure to the air quickly deliquesce to a colourless syrup. At 100° , or over sulphuric acid, they effloresce and give off all their water. They are extremely soluble in water; a solution saturated at 25° has a sp. gr. of 1.1177, and contains 61.8 p. c. of the anhydrous base. Betaine is inodorous, has a sweetish cooling taste, is neutral to vegetable colours, and optically inactive. When heated it swells up, emitting an odour first of trimethylamine, then of burnt sugar, and leaves a bulky cinder, which burns away slowly but completely.

Betaine hydrochloride, $C^4H^{11}NO^2 \cdot HCl$, and the *sulphate*, form splendid crystals permanent in the air; the *nitrate* crystallises in deliquescent needles. The *aurochloride*, $C^4H^{11}NO^2 \cdot HCl \cdot AuCl^3$, crystallises in beautiful thin needles or plates, sparingly soluble in cold, easily in hot water. With *platinic chloride*, betaine hydrochloride forms two compounds, which perhaps differ from one another only in their amount of crystallisation-water. It also forms well-crystallised double salts with the chlorides of mercury, cadmium, and zinc.

Betaine is not oxidised by chromic acid, or reduced by hydriodic acid, even when heated with it in sealed tubes. When boiled with potassium hydrate and a small quantity of water, it gives off trimethylamine, and forms at least two fixed bases, one of which yields an aurochloride containing $C^4H^{11}NO^2 \cdot HCl \cdot AuCl^3$.

Betaine is isomeric or polymeric with trimethylated glycollamide, with butalanine, lactamethane, &c., also with oxyneurine.

BEUSTITE. A shining mineral, containing lime, potash, and soda, from Mount Sforzella, near Predazzo. Sp. gr. 2.18 (Breithaupt, *Jahresh.* 1863, p. 846).

BILE. In applying Pottenkofer's test for bile (i. 586), the following method is recommended by J. Neukomm (*Ann. Ch. Pharm.* cxvi 30; *Jahresh.* 1862, p. 584), as affording the most delicate indications. The biliary acids are precipitated with basic lead acetate; the washed precipitate is mixed with sodium carbonate and evaporated to dryness; the sodium salts of the biliary acids are dissolved out by absolute alcohol; the residue left on evaporating the alcoholic solution is dissolved in water; and a drop of the aqueous solution is mixed in a porcelain capsule with a drop of dilute sulphuric acid (4 pts. water to 1 pt. of the concentrated acid) and a very small quantity of sugar solution. On evaporating the solution at a gentle heat, a splendid purple-violet coloration is obtained, even with only 0.06 milligram of biliary acids; 0.005 gram. cholic acid may in this manner be detected with certainty in a litre of water; in the same quantity of liquid, 0.01 gram. glycocholic acid gives only a faint, 0.02 gram. a deep purple-red coloration.

In applying the test to the detection of bile in urine, it is necessary to remove the inorganic salts as completely as possible before precipitating with basic lead acetate. For this purpose, the urine, evaporated to a thick syrup, is treated with alcohol of ordinary strength; the residue left on evaporating the solution is exhausted with absolute alcohol; the evaporated residue, which now contains but a small quantity of inorganic salts, is dissolved in a little water; the solution is precipitated with basic lead acetate; and the precipitate is collected after twelve hours. To remove other substances still adhering to the lead precipitate, it is digested with boiling alcohol, and the residue is converted into sodium salt. If the latter, as sometimes happens, still contains a small quantity of resinous substance, which would mask the reaction with sulphuric acid and sugar, its aqueous solution must be again precipitated with basic lead acetate, and the lead precipitate reconverted into sodium salt. In this manner, a quantity of glycocholic acid not exceeding 0.001 p. c. may be detected in urine (Neukomm).

Huppert (*Jahresh.* 1867, p. 880) points out that the indications of Pottenkofer's bile test may be masked by the presence of oxidising substances, such as nitrates and chlorates. It is scarcely necessary, however, to observe that such salts could not be present in the lead precipitate obtained as above.

Noel (*J. Pharm.* [3] xli. 354) recommends, as a test for bile, to immerse a strip of filtering paper for a few minutes in the liquid, then dry it, and moisten it with a drop of nitric acid, either pure or containing nitrous acid: it will then assume a violet colour, changing to red and yellow.

The biliary acids and their products of decomposition are optically dextrogyrate. Their rotatory powers, as determined by Hoppe-Seyler (*J. pr. Chem.* lxxxix. 267; *Bull. Soc. Chim.* v. 622), are given in the following table:

Optical Rotatory Power of Bile-constituents	Formula	Molecular Weight m	Specific Rotation for the line D (α) D	Molecular Rotatory Power (α) D m	(α) D $\frac{m}{408}$
<i>a. Dissolved in Alcohol :</i>					
Sodium Glycocholate . . .	$C^{22}H^{42}NO^2Na$	487	25.7°	12516	31.5°
Sodium Taurocholate . . .	$C^{22}H^{44}NSO^2Na$	537	24.5	13157	31.9
Glyccholic Acid . . .	$C^{22}H^{42}NO^2$	465	29.0	13485	33.0
Sodium Cholata . . .	$C^{24}H^{50}O^2Na$	430	31.4	13502	33.1
Potassium Cholate . . .	$C^{24}H^{50}O^2K$	446.2	30.8	13743	33.7
Methyl Cholate . . .	$C^{24}H^{50}O^2 \cdot CH^3$	422	31.9	13462	33.0
Ethyl Cholate . . .	$C^{24}H^{50}O^2 \cdot C^2H^5$	436	32.4	14126	34.7
Cholic Acid + aq. . .	$C^{24}H^{48}O^2 \cdot \frac{5}{2}H^2O$	447	31.2	13946	34.7
Cholic Acid	$C^{24}H^{46}O^2$	408	50.2	20482	50.2
<i>b. Dissolved in Water :</i>					
Sodium Glycocholate . . .	$C^{22}H^{42}NO^2Na$	487	20.8	10130	24.8
Sodium Taurocholate . . .	$C^{22}H^{44}NSO^2Na$	537	21.5	11546	28.2
Potassium Cholate . . .	$C^{24}H^{50}O^2K$	446.2	25.0	11151	27.3
Sodium Cholate	$C^{24}H^{50}O^2Na$	430	26.0	11188	27.4

The expression (α) D $\frac{m}{408}$ gives the value of the rotation reduced to the (active) atomic group of cholic acid, $C^{24}H^{46}O^2$, which exists in all these bile-constituents and determines the dextro-gyration. From the last two columns of the table, it appears that the highest molecular rotatory power is exhibited by cholic acid, and that in general the rotation diminishes as the complexity of the molecule increases, although the decrease does not bear any definite proportion to the increase of molecular weight. As the rotatory power of the several substances is less in aqueous than in alcoholic solution, it may be concluded that the water exerts a chemical action upon them, resulting in an increase of molecular weight. The differences of rotatory power of the several groups of atoms do not (excepting in the case of anhydrous cholic acid) exceed 3°, that is to say, about $\frac{1}{10}$ of the total rotation.

The optical rotatory power of the bile-constituents may be made available for verifying the analysis of a mixture of glycocholic and taurocholic acids, such as exists in the bile of man and of vegetable-feeders. The mixture (after precipitation from alcohol by ether) is dissolved in alcohol; the rotation is determined for yellow light; a measured volume of the solution, not too small, is evaporated; and the residue, dried at 120° and weighed, is heated to 100° with strong potash-ley in a glass tube for twenty-four to thirty hours. The contents of the tube (containing all the cholic acid that can be formed as product of decomposition) are mixed with a little ether and hydrochloric acid; the separated cholic acid is collected after twenty-four hours on a filter, washed with water, and redissolved in hot alcohol; and the evaporated residue is weighed after drying at 120°. In the liquid filtered from the cholic acid the sulphur is determined by fusion with carbonate and nitrate of potassium. Since 100 pts. barium sulphate correspond to 220.8 pts. taurocholic acid, $C^{22}H^{44}NSO^2$, and 100 pts. of the latter to 79.2 pts. cholic acid, $C^{24}H^{46}O^2$, the amount of taurocholic acid present in the mixture may be calculated, also the quantity of cholic acid produced therefrom, and (since 100 pts. cholic acid correspond to 113.9 pts. glycocholic acid) likewise the amount of glycocholic acid present. The correctness of these estimations may be tested by the rotatory power of the mixture. If the observed rotation in degrees for yellow light in a tube 1 decim. long be denoted by α , and the calculated quantity of taurocholic acid in the liquid by m , then, since the specific rotation of taurocholic acid (as sodium salt in alcoholic solution) is 25.3°, and that of glycocholic acid under similar circumstances = 27.6 for yellow light, the quantity of glycocholic acid is $\frac{100\alpha - 25.3m}{27.6}$. If the rotation gives a lower value than the cholic acid

estimation, the presence of inactive fatty acids may be inferred; if, on the other hand, the value is too high, cholic acid itself must have been present. An examination of dog's bile by this method showed, in accordance with Strecker's results, that this bile contains only taurocholic acid (Hoppe-Seyler, *J. pr. Chem.* lxxxix. 221; *Jahresb.* 1863, p. 717).

For Fröhde's view of the origin of the biliary acids, see *Zeitschr. Ch. Pharm.* 1864, p. 464; *Jahresh.* 1864, p. 656.

Pig-bile contains—besides fats and cholesterin—a non-soluble substance, lecithin, resolvable by baryta-water into glycerophosphoric acid and fatty acids (iii. 566); also sarcolactic acid and choline, $C^2H^{12}NO$. This base is also contained in the bile of the ox, and probably also in that of many other animals (Strecker, *Rép. Chim. pure*, iii. 345; *Ann. Ch. Pharm.* cxxiii. 353). See CHOLINE. According to J. Dogiel (*J. pr. Chem.* ci. 298), fresh ox-bile contains acetic and propionic acids, partly as metallic salts, partly as glycerides.

Goose-bile contains, according to R. Otto (*Zeitschr. f. Chem.* [2] iv. 633), 3.1 p. c. mucus, 0.3 fat, cholesterin, and colouring matter, 19.0 biliary acids and inorganic salts, and 77.6 water. Otto has confirmed the results obtained by Marrson and by Hointz a. Wislicenus, to the effect that the sulphuretted acid of goose-bile, taurochenocholic acid, differs in composition from the taurocholic acid of human bile, dog-bile, &c. Otto finds that the sodium salt of taurochenocholic acid, dried at 100° – 110° , has the composition $C^{22}H^{32}NaNSO^7$, or rather $C^{22}H^{32}NaNSO^7 \cdot H^2O$, and gives off a molecule of water at 140° , leaving the anhydrous salt $C^{22}H^{30}NaNSO^6$, whence the acid has the constitution $C^{22}H^{32}NSO^{6*}$, and is resolved by boiling with baryta-water into taurine and chenocholic acid:

Goose-bile appears also to contain another sulphuretted acid, less soluble in water than taurochenocholic acid, and crystallising in small mucronous scales; but it has not been obtained pure. No acid analogous to glycocholic acid has yet been found in goose-bile.

The bile of the horn-fish (*Bellone vulgaris*), like that of other fresh-water fish (i. 686), consists essentially of sodium taurocholate (Otto, *Ann. Ch. Pharm.* cxlv. 352).

Bile-constituents in Excrementitious Matters.—Cow-dung contains cholic and glycocholic acids; that of the dog contains cholic acid; pigeons' dung also contains a biliary substance. Peruvian guano contains a not inconsiderable quantity of an uncrystallisable, optically inactive biliary acid, insoluble in water, easily soluble in alkalis, and converted by boiling with concentrated hydrochloric acid into products analogous to choloidic acid and dyslysin, dissolving in strong sulphuric acid, and forming green fluorescent solutions, which, like the original acid, give the purple-violet coloration with sulphuric acid and sugar. The acid does not contain sulphur, and is probably also free from nitrogen. Peruvian guano also contains cholesterin, but no bile-pigments (Hoppe-Seyler, *Jahresh.* 1863, p. 654).

BILE-PIGMENTS. The colouring matters of bile are described in the article CHOLACHROME (i. 927) chiefly according to the results obtained by Thudichum in 1860. Since that time they have been further examined by several chemists, whose results, though differing in minor details, agree in showing that the brown and green pigments of bile may be separated by means of chloroform, in which the former is soluble, the latter insoluble, and that the pigment soluble in chloroform exhibits two modifications, one red (*bilirubin*), the other brown (*biliphaein* or *cholophaein*).

When bile is shaken up with chloroform, and the chloroform separated and evaporated, a crystalline substance is obtained, which, after washing with alcohol and ether, remains as a brick-red powder, soluble in ammonia; and the ammoniacal solution mixed with hydrochloric acid yields yellowish-brown flocks of cholophaein (E. Brücke, *J. pr. Chem.* lxxvii. 72; *Jahresh.* 1859, p. 637).

Thudichum (*Zeitschr. f. Chem.* [2] iv. 554) prepares bilirubin and cholophaein from gall-stones, by exhausting the pulverised calculi with hot water, alcohol, and cold dilute hydrochloric acid in succession, then again with alcohol; boiling the dried powder with water and chloroform free from hydrochloric acid; and mixing the concentrated dark green solution thereby obtained with alcohol. Bilirubin is then precipitated of a red colour as bright as that of mercuric oxide, and the mother-liquor yields brown rhombic crystals of cholophaein. The red and brown pigments thus obtained are identical in composition, and are represented by the formula $C^{22}H^{32}NO^6$. The red modification may be converted into the brown by repeated crystallisation. The red (or brown) pigment is insoluble in water, nearly insoluble in boiling alcohol and in ether, more soluble in benzol and carbon bisulphide, still more in chloroform (1 pt. in 586). When the chloroform solution is exposed to sunshine, the colouring matter is decomposed, probably owing to the formation of hydrochloric acid. Saturated aqueous ammonia converts bilirubin into a dark red bulky mass, probably $C^{22}H^{32}(NH^4)NO^6 \cdot H^2O$, which gives off all its ammonia in a stream of dry air. Bilirubin

* In the formula of taurochenocholic acid given at p. 700, vol. v., there is a misprint of O^6 for O^7 .

dissolves in dilute ammonia, and is reprecipitated unaltered by hydrochloric acid. It dissolves in the *fixed caustic alkalis* with brown-red colour, and the solution, if immediately mixed with hydrochloric acid, deposits brown flocks which redissolve in chloroform; but on exposing the alkaline solution to the air, biliverdin is produced. The potassium and sodium compounds of bilirubin are insoluble in chloroform. A neutral ammoniacal solution of cholephæin, obtained by digesting the pigment with weak aqueous ammonia, yields with *silver nitrate* a red-brown precipitate of the compound $C^{10}H^{10}AgNO^2$ (or perhaps $C^{10}H^9AgNO^2 \cdot H^2O$); but if the solution contains excess of ammonia, it yields, on addition of silver nitrate and subsequent neutralisation with nitric acid, a precipitate of the diargentate salt $C^{10}H^9Ag^2NO^2$. In an ammoniacal solution of the pigment containing excess of ammonia, *barium chloride* forms a precipitate containing $(C^{10}H^{10}NO^2)^2Ba$ (at 100°); but a neutral solution yields a precipitate containing excess of bilirubin; *calcium chloride* yields similar precipitates. *Neutral lead acetate* added in excess to an ammoniacal solution of bilirubin forms a precipitate consisting of $C^{10}H^7PbNO^2$ (Thudichum). See also Maly (*Zeitschr. f. Chem.* [2] v. 394), who, however, assigns to the red or brown pigment (which he calls *cholepyrrhin*) the formula $C^{10}H^{10}N^2O^2$.

Städeler (*Ann. Ch. Pharm.* cxxxii. 323; *Jahresh.* 1864, p. 657) has also examined the colouring matters of bile, but with somewhat different results. By exhausting strongly coloured pulverised gall-stones with ether, hot water, chloroform, and dilute hydrochloric acid, he obtains a brownish-green residue, from which boiling chloroform extracts a brown pigment (*bilifuscin*), together with a portion of the red pigment (*bilirubin*), whilst the undissolved portion yields to alcohol a green pigment (*biliprasin*), and then to hot chloroform the rest of the bilirubin. Städeler represents bilirubin by the formula $C^{10}H^{10}N^2O^2$, bilifuscin by $C^{16}H^{20}N^2O^4$ (bilirubin + H^2O), and biliprasin by $C^{16}H^{22}N^2O^4$. The residue left after exhausting the gall-stones successively with water, alcohol, ether, chloroform, and dilute acid, and forming a considerable portion of the whole, is a humus-like substance, designated by Städeler as *bilithumin* [? impure biliverdin]; it has not been analysed.

Biliverdin or *Cholochlorin* is formed when an alkaline solution of bilirubin is exposed to the air; the oxidation may be accelerated by passing a current of air through the heated liquid. The green solution thus formed yields with hydrochloric acid, green flocks, which appear black when dry, are quite amorphous, insoluble in water, ether, and chloroform, but easily soluble in alcohol (Thudichum); easily soluble in benzol and carbon bisulphide, very slightly soluble in amyl alcohol and ethyl iodide, but easily soluble in these last-mentioned liquids on addition of ethylic or methylic alcohol (Maly).

Biliverdin consists, according to Thudichum, of $C^{10}H^9NO^2$, and is formed from bilirubin in the manner represented by the equation:

Städeler, on the other hand, represents it by the formula $C^{10}H^{10}N^2O^2$ [= $2C^{10}H^{10}NO^2 + H^2O$], and finds that it may be formed by boiling an alkaline solution of bilirubin even when the access of air is completely prevented. He represents its formation by the first or second of the following equations, accordingly as the air has access to the solution or not:

The latter equation supposes the simultaneous formation of a second body, perhaps identical with that which is formed from biliverdin by reduction with sodium-amalgam.

Biliverdin dissolves in potash, soda, and ammonia, and is not precipitated from the solutions of calcium or barium chloride: but in alcoholic solution it forms dark green precipitates with *baryta-water*, *lime-water*, and with the *acetates of lead, mercury, and silver*. The barium and calcium compounds are soluble in water, the rest insoluble (Thudichum; Maly).

Reducing agents, such as hydrogen sulphide, zinc in acid solution, and sodium-amalgam, act upon biliverdin, but do not reconvert it into bilirubin. With *iodine* and *chlorine* it forms resinous products. An alcoholic solution of biliverdin treated with *silver oxide* forms a purple compound, *bilipurpin*, which, however, remains combined with the silver oxide, forming a compound which dissolves in ammonia, and yields *bilipurpin* on adding hydrochloric acid to the solution. The presence of bile-pigments may accordingly be detected by boiling the substance under examination with an ammoniacal solution of silver oxide, and acidulating the filtrate with hydrochloric

acid, whereupon, if bile-pigments are present, even in very small quantity, a purple colour will be produced. By prolonged action of silver-oxide, bilipurpin is converted into a yellow substance, biliflavin. Mercuric oxide does not act perceptibly on biliverdin; peroxides act like silver oxide. The alcoholic solution of biliverdin gradually mixed with *nitric acid* assumes a bluish-violet, then red, and ultimately yellow colour (Thudichum).

These colours, which are also produced by the action of nitric acid on crude bile-pigment,* correspond, according to Jaffe (*Zeitschr. f. Chem.* [2] v. 666), to characteristic alterations of the spectrum. The blue-violet solution exhibits in the spectrum a broad absorption-band between the lines C and D, which on dilution is resolved into two bands (α and β) separated by a bright band near D. Another absorption-band, γ , occurs between the lines b and F. As the action of the nitric acid progresses, the bands α and β gradually disappear, while γ becomes more distinct, and when the solution exhibits a red colour, γ likewise disappears.

The pigment contained in the blue-violet solution above mentioned may be obtained in the separate state by treating an alcoholic solution of biliverdin, or an ammoniacal solution of bilirubin mixed with alcohol, with a mixture of ordinary concentrated nitric acid and the fuming acid, till a sample exhibits the absorption-bands α and β , then mixing the solution with chloroform, and shaking it up with water. The water is then removed; the chloroform layer containing the blue pigment is filtered from biliverdin, and evaporated to dryness; and the residue is purified by repeated solution in chloroform. The substance thus obtained is of a deep violet colour, insoluble in water, easily soluble in alcohol, ether, and chloroform, forming violet solutions. Alkalis dissolve it with brown-violet colour; acids with a fine blue colour. The neutral and alkaline solutions exhibit no absorption-bands; but the smallest trace of acid brings to light the bands α , β , and γ . The blue pigment dissolves in strong sulphuric acid, forming a dark green solution, which on addition of water deposits green flocks. The liquid filtered from these flocks is blue by reflected, violet by transmitted light, becomes brown when mixed with sodium carbonate, and is not decolorised by glucose: hence it does not contain indigo. If in the preparation of the blue substance the action of the nitric acid has been carried too far, the acid solutions have a violet colour. On agitating the sulphuric acid solution with ether, the latter becomes red, and the acid liquid again blue.

The pigment corresponding to the absorption-band γ may be obtained in exactly the same way as the blue pigment, excepting that the action of the nitric acid must be carried so far as to cause the bands α and β to disappear completely. The substance thus obtained is brown-red, and dissolves in alcohol, ether, and chloroform with a fine red colour, not altered by alkalis or acids. It is only the acid solution that exhibits the band γ (Jaffe).

When human bile or dog-bile is treated with hydrochloric acid, a red solution is obtained which exhibits very distinctly the absorption-band γ . On adding an alkali the solution acquires a yellow colour (least distinct with ammonia), and then exhibits an absorption-band δ , also between C and F, but nearer to C. The colouring matter may be extracted from the solution by chloroform, and on evaporating the latter, there remains a red residue, which is soluble in water, alcohol, and chloroform, and is precipitated from the aqueous solution by lead acetate or calcium chloride. The same red pigment is found in normal human urine (Jaffe).

A solution of cholephæin in chloroform obliterates the entire blue and violet end of the spectrum as far as the line 70 of Bunsen's scale. Very dilute but still yellow solutions absorb only the violet. Solutions of cholephæin in aqueous ammonia produce similar phenomena. If their colour is equal to that of a strong solution of potassium dichromate, the field of view appears perfectly black from the violet end to near the sodium line (50), and somewhat sharply defined. On diluting the solution, the colour gradually becomes yellow and green, but somewhat dull. Biliverdin in alcoholic solution exhibits absorption at both ends of the spectrum. In strongly coloured layers, it transmits only green light; in somewhat more dilute layers, first yellow, orange, and part of the red, afterwards blue and violet. Very dilute solutions absorb only the very extreme red (Maly, *Zeitschr. f. Chem.* [2] v. 365).

BILIFUSCIN. } See the preceding article.
BILIVERMIN. }
BILIVERMIN. See NEURINE.

* Hoppert remarks that similar colours are produced on covering nitric acid with other alcoholic extracts, and especially with alcohol alone (*Chem. Centr.* 1863, p. 364).

BILIPHEIN, BILIPRASIN, BILIRUBIN, BILIVERDIN. See **BILIGMENTS**.

BISMUTH. According to determinations by F. Field and J. Abel (*Chem. Soc. J.* xvi. 304), bismuth occurs in most sulphuretted copper ores, in about the same proportion as silver in galena.

The following process, devised by R. Vogel (*Dingl. pol. J.* clxvii. 187), is now adopted in Joachimsthal for extracting bismuth from ores not containing lead. The stamped ores are mixed with 58 p. c. wrought-iron turnings, and, according to their richness and composition, with 15 to 50 p. c. soda, 5 p. c. lime, and 5 p. c. fluor-spar, and fused in Hessian or plumbago crucibles. Arsenic and sulphur then separate, in combination with cobalt, nickel, and a small quantity of iron, in the form of speiss, and nearly the whole of the bismuth is obtained in the metallic state. A similar process (fusion with limestone and quicklime in proportion to the amount of silica, with addition of scraps of iron) is employed by Paterna (*Jahresb.* 1862, p. 646) for the extraction of bismuth from refinery residues.

Estimation and Separation.—J. Löwo (*Jahresb.* 1859, p. 624) finds that basic bismuth nitrate, obtained by evaporating the nitric acid solution to a syrup, repeatedly mixing the residue with warm water, and evaporating over the water-bath, may be washed with a cold solution of ammonium nitrate (1 pt. in 500), without a trace of bismuth passing into the filtrate. He accordingly recommends this process for the quantitative estimation of bismuth and for separating this metal from lead, the nitrate of which is soluble in the dilute solution of ammonium nitrate. To separate bismuth from lead, copper, and cadmium together, the concentrated nitric acid solution is heated over the water-bath till the copper is wholly converted into insoluble basic nitrate, and the cooled residue is washed with ammonium nitrate, whereby lead and cadmium are dissolved, while the copper and bismuth remain behind, and may be dissolved in nitric acid, and separated by ammonium carbonate or potassium cyanide.

According to H. Rose (*Pogg. Ann.* cx. 411), bismuth may be very exactly estimated as *oxychloride*, BiClO , or $\text{Bi}^2\text{Cl}^2 \cdot \text{BiO}^2$, which is quite insoluble in dilute hydrochloric acid. The solution, not containing too much free acid, is mixed with hydrochloric acid, and diluted with water, till no further turbidity is produced; and the precipitated oxychloride is washed with water on a weighed filter, and weighed, after drying at 100° . As however the precipitate is apt to lose a little chlorine by prolonged washing, it is better to reduce it by fusion with potassium cyanide, and weigh the metallic bismuth. This reduction is especially necessary when the solution contains sulphuric acid, as in that case the precipitate will contain a small quantity of basic bismuth sulphate. This mode of precipitation answers well for the separation of bismuth from copper, cadmium, cobalt, or zinc, but not from iron or lead.

Bismuth may also be very exactly estimated as *arsenate*, $2\text{BiAsO}^4 \cdot \text{H}^2\text{O}$ (at 100° – 120°), by precipitating the nitric acid solution with arsenic acid, disodic arsenate, or trisodic arsenate, washing the yellow precipitate with water by decantation, collecting it on a weighed filter, and weighing the precipitate and filter together, after drying at 120° . This method serves also for the separation of bismuth from cadmium. It cannot however be used for the estimation of arsenic acid, inasmuch as the bismuth arsenate is soluble in excess of acid bismuth-solutions (Salkowski, *Zeitschr. f. Chem.* [2] iv. 551).

According to Nicklès (*Bull. Soc. Chim.* [2] v. 49), bismuth may be distinguished from lead by means of *ammonio-thallic chloride* (v. 748), which gives a white precipitate with bismuth salts, but none with any salt of lead, excepting the basic acetate. The same reaction is exhibited by ammonio-thallic bromide.

Compounds of Bismuth.

Bismuth belongs to the nitrogen group of elements, being trivalent in its best defined compounds, quintivalent only in the pentoxide Bi^5O^5 , and in the bismuthate $\text{Bi}^5\text{O}^4(\text{OM})$; the so-called di-compounds of bismuth contain two atoms of

trivalent bismuth in their molecule, the dichloride for example being $\begin{array}{c} \text{Bi}^3\text{Cl}^3 \\ | \\ \text{Bi}=\text{O} \\ | \\ \text{Bi}=\text{O} \end{array}$, the dioxide $\begin{array}{c} \text{Bi}^3\text{O}^3 \\ | \\ \text{Bi}=\text{O} \\ | \\ \text{Bi}=\text{O} \end{array}$.

Tribromide. BiBr^3 .—This compound may be prepared by adding pulverised bismuth to a mixture of equal parts of bromine and anhydrous ether. It is soluble in ether, and separates from the solution on evaporation in a vacuum, in deliquescent

prisms which are decomposed by water (Nicklès, *Rép. Chim. pure*, i. 366). Its syrupy solution mixed with ammonium bromide yields yellow tables or prisms of a double salt: $2\text{NH}_4\text{Br} \cdot \text{BiBr}_3 \cdot 5\text{H}_2\text{O}$. The same compound is obtained in groups of transparent dichroic rhombic pyramids by heating an alcoholic solution of the two component bromides in a sealed tube.

Bismuth bromide heated with anhydrous ether to 100° in a sealed tube dissolves, forming two layers, the lower of which contains a compound of bismuth bromide and ether, crystallising on evaporation in very deliquescent rhombic prisms containing $\text{BiBr}_3 \cdot \text{C}_2\text{H}_5\text{O}$. 2aq.: this compound destroys paper (Nicklès, *Rép. Chim. pure*, iii. 189).

Trichloride. BiCl_3 .—A solution of this compound in hydrochloric acid leaves on evaporation, slender white needles of *hydrogen-bismuth chloride*, $\text{BiCl}_3 \cdot 2\text{HCl}$ (Jacquelin, *Ann. Ch. Phys.* [2] lxii. 363).

Potassium-bismuth chloride, $\text{BiCl}_3 \cdot 2\text{KCl} \cdot \frac{1}{2}\text{H}_2\text{O}$, obtained by evaporating a solution of bismuth chloride in hydrochloric acid mixed with potassium chloride, crystallises, according to Rammelsberg (*Krystallogr. Chemie*, p. 213), in rhombic combinations, $\infty \text{P} : \text{P} : \infty \text{P} : \text{P} \infty \cdot \frac{1}{2} \text{P} \infty$. Ratio of axes $a : b : c = 0.6873 : 1 : 1.7979$. Angle $\infty \text{P} : \infty \text{P} = 111^\circ$; $\text{P} : \text{P}$ (brach.) = $114^\circ 36'$; $\text{P} : \text{P}$ (maer.) = $76^\circ 22'$; $\text{P} : \text{P}$ (basal) = 145° . The *sodium salt* $\text{BiCl}_3 \cdot 2\text{NaCl} \cdot 3\text{H}_2\text{O}$ is obtained in a similar manner. Both these salts are decomposed by water (Jacquelin).

When *ammonia gas* is passed over bismuth chloride contained in a retort, three different products are formed, one of which, being very volatile, passes into the receiver, while the other two remain in the retort. One of these, consisting of $2\text{BiCl}_3 \cdot \text{NH}_3$, is red, fusible, and crystallisable; the other, $\text{BiCl}_3 \cdot 2\text{NH}_3$, is dingy green, and difficult to purify: its composition was established by that of the double salt which it forms when treated with hydrochloric acid. The volatile compound is white, and consists of $\text{BiCl}_3 \cdot 3\text{NH}_3$ (Déhérain, *Compt. rend.* liv. 724).

These ammoniochlorides treated with hydrochloric acid yield double chlorides of bismuth and ammonium, viz. $2\text{BiCl}_3 \cdot \text{NH}_4\text{Cl}$, crystallising in deliquescent needles; $\text{BiCl}_3 \cdot 2\text{NH}_4\text{Cl}$ in hexagonal laminae, isomorphous with the corresponding antimony salt, and containing, according to Rammelsberg, $2\frac{1}{2}$ mol. water; and $\text{BiCl}_3 \cdot 3\text{NH}_4\text{Cl}$ in rhombic laminae (Déhérain). These double chlorides may also be obtained by evaporating acid solutions of bismuth chloride mixed in due proportion with sal-ammoniac. In preparing the last-mentioned compound by this method, the mother-liquors yield another salt, $2\text{BiCl}_3 \cdot 5\text{NH}_4\text{Cl}$, in rhombohedral crystals with angles of $113^\circ 32'$ and $102^\circ 22'$ (Rammelsberg). Déhérain has also obtained a double chloride containing both potassium and ammonium, viz. $\text{BiCl}_3 \cdot 2\text{NH}_4\text{Cl} \cdot \text{KCl}$, which crystallises in rhombic laminae.

A *seleniochloride*, containing BiSeCl or $\text{BiCl}_3 \cdot \text{Bi}^2\text{Se}^2$, is obtained by adding pulverised bismuth selenide to fused bismuth-ammonium chloride, heating the mass till it boils quietly, and no more unaltered bismuth selenide can be perceived in it, and treating the cooled mass with dilute hydrochloric acid. The seleniochloride then remains in small needle-shaped crystals having a dark steel-grey colour and metallic lustre. Heated in a stream of carbonic acid gas, it is resolved into chloride and selenide of bismuth, the former volatilising. It is also quickly and completely decomposed by strong nitric acid (R. Schreider, *Pogg. Ann.* xciv. 628).

Tri-iodide. BiI_3 (i. 594).—A solution of this compound in hydriodic acid yields by evaporation rhombic octahedrons of *hydrogen-bismuth iodide*, $\text{BiI}_3 \cdot \text{HI} \cdot 4\text{aq.}$ (Arppe).

Bismuth iodide forms a large number of double iodides, isomorphous with the corresponding compounds of antimony; they are obtained by direct union of the component iodides, or by the action of iodine on bismuth in presence of the iodide of another metal (Nicklès, *Compt. rend.* li. 1097; *Jahresb.* 1860, p. 176; *J. Pharm.* [3] xxxix. 116; *Jahresb.* 1861, p. 272. Linan, *Pogg. Ann.* cxi. 240; *Jahresb.* 1860, p. 177).

Black needles; obtained by action of iodine on bismuth, in presence of ammonium iodide.

Black crystals yielding a red powder.

Deposited from absolute alcohol in red crystals.

Dichroic deliquescent crystals; obtained by action of bromine on bismuth, in presence of ammonium iodide.

Dark red-brown rectangular prisms; powder cinnabar-red; obtained by direct combination.

- | | |
|---|--|
| (6) $KI \cdot BiI^3 \cdot H^2O$ | Black needles; prepared like (1). |
| (7) $NaI \cdot BiI^3 \cdot H^2O$ | Black-brown efflorescent crystals, yielding a red powder. |
| (8) $NaI \cdot (Bi; Sb)I^3 \cdot 2H^2O$ | Obtained by treating a mixture of bismuth and antimony with iodine in presence of ammonium iodide. |
| (9) $3NaI \cdot 2BiI^3 \cdot 12H^2O$ | Garnet-red rectangular prisms; obtained by direct combination. |
| (10) $BaI^2 \cdot BiI^3 \cdot 9H^2O$ | Small, red, shining, rhombic prisms, black when dried at 260° . |
| (11) $CaI^2 \cdot BiI^3 \cdot 9H^2O$ | Dark red, shining, rhombic prisms, with basal end-face. |
| (12) $MgI^2 \cdot BiI^3 \cdot 12H^2O$ | Garnet-red rectangular prisms; anhydrous at 175° . |
| (13) $ZnI^2 \cdot BiI^3 \cdot 12H^2O$ | Resembles (12); anhydrous at 100° . |

The last four double iodides are obtained by adding bismuth iodide to a concentrated solution of the other iodide and evaporating (Linna). Among the compounds examined by Nicklès, those containing $2H^2O$ crystallise in rhombic prisms of 97° ; those with $1H^2O$ in right rhombic prisms of $135^\circ 25'$, with a dome and numerous secondary faces. All these double salts are more or less deliquescent, decomposable by water, and in some cases by alcohol, and cannot be recrystallised. They are quickly altered by light, especially by the violet rays, their surface acquiring a red colour—an alteration which likewise takes place in bismuth iodide itself (Nicklès).

Bismuth Sulphide, BiS_2 , may be obtained, as a sublimate composed of long needles, by disposing iodine, sulphur, and bismuth sulphide in alternate layers in a capacious crucible, and subjecting the whole to a prolonged calcination (Linna).

Oxides. Bismuth forms four oxides, viz. Bi^2O^3 , Bi^2O^2 , Bi^2O^4 , and Bi^2O^5 .

The *dioxide* or *suboxide*, Bi^2O^2 or $\begin{array}{c} Bi=O \\ | \\ Bi=O \end{array}$, is formed by the action of the air on

bismuth heated a few degrees above its melting point; also by reduction of bismuth salts, with stannous chloride for example. To prepare it, bismuth trioxide and stannous chloride in equivalent proportions are dissolved in hydrochloric acid; the mixed solution is poured into moderately strong aqueous potash; and the resulting black-brown precipitate of stannic oxide and bismuth dioxide is treated with strong potash-ley, which dissolves the stannic oxide and leaves the bismuth dioxide. The latter dried at 100° is a greyish-black crystalline powder, very difficult to reduce, but easily oxidisable, burning in the air like tinder (Schneider, *Pogg. Ann.* lxxxviii. 46; Schiff, *Ann. Ch. Pharm.* cxix. 331).

Bismuth dioxide shows but little tendency to unite with acids, but it exists in the form of stannate in the precipitate obtained in preparing it. This stannate is also produced, as a compound of a deep yellow colour, when a solution of stannous chloride is poured upon pulverised bismuth nitrate; if the operation is performed at ordinary temperatures, the compound may be preserved unaltered for several days; but on applying heat, it changes to a brown or grey-black powder, which, however, when washed with water, is reconverted into the yellow compound. The latter dried at 100° is of a deep orange or ochre-yellow colour, insoluble in water and in dilute acetic acid, but soluble in mineral acids, the solutions giving a black precipitate with potash. The yellow compound consists of

By heating in the air it is oxidised to bismuthous stannate,

Potash removes the stannic oxide from the salt $SnBi^4O^6$, leaving the bismuth dioxide, which may thus be obtained in the pure state (Schiff).

Trioxide or *Bismuthous Oxide*, Bi^2O^3 .—By fusing the ordinary pulverulent oxide with potassium hydrate, it may be obtained in rhombic prisms, $\infty P \cdot \infty P \cdot \frac{2}{3} P \infty$. Axes $a : b : c = 0.8165 : 1 : 1.0640$ (Nordenskjöld, *Pogg. Ann.* cxiv. 512).

Pentoxide, *Bismuthic Oxide* or *Anhydride*, Bi^2O^5 .—Formed by heating the corresponding hydrate to 180° ; also, according to Schönbein (*Jahresb.* 1864, p. 174), by the action of ozone on metallic bismuth. It is easily reducible, giving off part of

its oxygen when heated a little above 130° ; being instantly decomposed by hydrochloric acid; with evolution of chlorine and formation of bismuth trichloride, and by strong sulphuric or nitric acid, with evolution of oxygen; dilute nitric acid does not act upon it; according to Arppe, boiling nitric acid converts it into an oxide containing $\text{Bi}^{\text{I}}\text{O}^{\text{I}}$. It is not attacked by aqueous alkalis. According to Schönbein, it decomposes hydrogen dioxide, and is itself reduced to $\text{Bi}^{\text{I}}\text{O}^{\text{I}}$.

Bismuthic Hydrate, Hydrogen Bismuthate, or Bismuthic Acid, HBiO^{I} or $\text{H}^{\text{I}}\text{O} \cdot \text{Bi}^{\text{I}}\text{O}^{\text{I}}$, analogous in composition to nitric acid, HNO^{I} , is produced by the action of chlorine on bismuthous hydrate suspended in concentrated potash-ley (i. 594). Another bismuthic hydrate, $2\text{Bi}^{\text{I}}\text{H}^{\text{I}}\text{O}^{\text{I}}$ or $\text{Bi}^{\text{I}}\text{O}^{\text{I}} \cdot 2\text{H}^{\text{I}}\text{O}$ (corresponding to pyrophosphoric acid), is obtained by treating a solution of bismuth nitrate with excess of potassium cyanide. It is a dark brown powder which gives off its water at 150° , and is reduced to trioxide by subsequent ignition in a glass tube (Bödeker, *Ann. Ch. Pharm.* cxxiii. 61).

The tetroxide, or *Bismuthous Bismuthate*, $\text{Bi}^{\text{I}}\text{O}^{\text{I}} = \text{Bi}^{\text{I}}\text{O}^{\text{I}} \left\{ \text{O}^{\text{I}} \right\} = (\text{Bi}^{\text{I}}\text{O}^{\text{I}})^{\text{I}} \left\{ \text{O}^{\text{I}} \right\} = \text{Bi}^{\text{I}}\text{O}^{\text{I}} \cdot \text{Bi}^{\text{I}}\text{O}^{\text{I}}$, is produced when the trioxide is treated with oxidising agents in presence of an alkali. When chlorine is passed into cold aqueous potash of sp. gr. 1.385 containing bismuth trioxide in suspension, a yellow, red, or brown oxide is formed, which when heated with strong nitric acid, is converted into an orange-yellow hydrate, $\text{Bi}^{\text{I}}\text{O}^{\text{I}} \cdot 2\text{H}^{\text{I}}\text{O}$, which gives off its water at 150° , leaving the light brown tetroxide (Schrader, *Ann. Ch. Pharm.* cxxi. 204; *Jahresh.* 1861, p. 269). With still more concentrated potash-ley, bismuthic acid is produced (*vid. sup.*). The tetroxide may also be prepared by adding basic bismuth nitrate, gradually and with constant stirring, to sodium hydrate fused at a low red heat in an iron dish, continuing the heating and stirring till the mass has become black-brown, or nearly black, boiling the decanted and pulverised mass with water, digesting the undissolved reddish-brown powder with cold dilute nitric acid, then washing and drying it (Böttger, *J. pr. Chem.* lxxiii. 494).

Selenide. $\text{Bi}^{\text{I}}\text{Se}^{\text{I}}$.—According to R. Schneider (*Pogg. Ann.* xciv. 628), the selenide prepared, according to the method of Berzelius, by fusing bismuth with selenium (i. 595), generally contains excess of bismuth. The pure selenide obtained by fusing 2 at. bismuth with 3 at. selenium, and frequently remelting the product with fresh addition of selenium out of contact with the air, exhibits on the newly fractured surface a light steel-grey colour, metallic lustre, and distinct crystallo-granular structure; it has a sp. gr. of 6.82, the hardness of galena, and is easily pulverised. It is scarcely attacked by strong hydrochloric acid, even at the boiling heat, but easily and completely decomposed by nitric or nitromuriatic acid. With bismuth chloride it forms the compound BiClSe or $\text{BiCl}^{\text{I}} \cdot \text{Bi}^{\text{I}}\text{Se}^{\text{I}}$ (p. 347).

Sulphide. $\text{Bi}^{\text{I}}\text{S}^{\text{I}}$.—A compound of this sulphide with potassium sulphide, $\text{K}^{\text{I}}\text{Bi}^{\text{I}}\text{S}^{\text{I}} = \text{K}^{\text{I}}\text{S} \cdot \text{Bi}^{\text{I}}\text{S}^{\text{I}}$, is obtained in light steel-grey shining needles, by fusing 1 pt. pulverised bismuth, 6 pts. dry potassium carbonate, and 6 pts. sulphur, and exhausting the fused mass with water, in which the double sulphide is soluble (R. Schneider, *Zeitschr. f. Chem.* [2] v. 630).

An *oxysulphide* of bismuth, $\text{Bi}^{\text{I}}\text{SO}^{\text{I}}$, occurs native as *Karelinite* in the Altai (iii. 445). An artificial oxysulphide may be prepared by heating the trioxide with sulphur to low redness in a retort. The mass blackens, gives off sulphuric oxide, and then the excess of sulphur, leaving a grey scorineous mass having a faint metallic lustre, becoming strong by burnishing, and a sp. gr. of 6.31. It contains no metallic bismuth, but if again strongly ignited, gives off sulphurous oxide and then exhibits small globules of bismuth. A product obtained in this manner by igniting 142 pts. bismuth trioxide with 40 parts of sulphur, yielded by analysis numbers which may be represented by the formula $\text{Bi}^{\text{I}}\text{S}^{\text{I}}\text{O}^{\text{I}}$, or perhaps $\text{Bi}^{\text{I}}\text{O}^{\text{I}} \cdot 2\text{Bi}^{\text{I}}\text{S}^{\text{I}}$ (H. Hermann, *J. pr. Chem.* lxxv. 452).

BITUMENE. This name is given by Berthelot to the least volatile of the hydrocarbons obtained by passing benzene vapour through a porcelain tube heated to bright redness. On distilling the liquid portion of the product the bitumene remains in the retort, even at a red heat, as a blackish liquid, which solidifies on cooling. It dissolves only in boiling ether, and in small quantity, forming a fluorescent liquid, which leaves a metallically lustrous film on evaporation (*Bull. Soc. Chim.* [2] vi. 272).

BIURET. $\text{C}^{\text{I}}\text{H}^{\text{I}}\text{N}^{\text{I}}\text{O}^{\text{I}} = \text{CO}^{\text{I}} \left\{ \begin{array}{l} \text{NH}^{\text{I}} \\ \text{NH}^{\text{I}} \\ \text{NH}^{\text{I}} \end{array} \right.$.—This compound is formed, together with monocyanurate of urea, on passing the vapour of cyanic acid into melted urea, till a

solid mass is produced. It is isomeric with cyanate of urea, and probably stands to the latter in the same relation as urea to cyanate of ammonium (Finck, *Ann. Ch. Pharm.* cxxiv. 331). It is also produced, together with phenate of ammonium, on dissolving urea in phenol at 150°-160°, and may be extracted from the solid mass which forms on cooling, by washing with ether, boiling the aqueous solution of the residue with hydrated lead oxide, and evaporating the solution after freeing it from lead. It appears from this reaction that urea when heated with phenol decomposes in the same manner as when heated alone, namely into biuret and ammonia (i. 600): $2\text{CH}^{\text{N}}\text{N}^{\text{O}} = \text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^2 + \text{NH}^3$ (Baeyer, *Ann. Ch. Pharm.* cxxxi. 261).

According to Huppert a. Dogiel (*Zeitschr. f. Chem.* [2] iii. 691), the easiest way of preparing biuret from urea is to treat the urea with chlorine at 150° till the mass becomes pasty. The product, consisting chiefly of biuret, is freed from cyanuric acid, formed at the same time, by precipitation with basic lead acetate.

Biuret is also produced by the action of ammonia on allophanic ether; in fact, it has the composition of allophanic amide, $\text{N} \begin{Bmatrix} \text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^2 \\ \text{H}^2 \end{Bmatrix}$ (Huppert a. Dogiel).

The aqueous solution of biuret mixed with silver sulphate yields, on addition of ammonia, a precipitate of silver cyanurate, and the filtrate freed from silver and evaporated yields crystals of urea and urea nitrate. Biuret dried at 120° slowly absorbs hydrochloric acid gas at 100°, forming the hydrochloride $2\text{C}^{\text{H}}\text{N}^{\text{O}}\text{O}^2 \cdot \text{HCl}$, which, when heated to 160°-170° in the stream of hydrochloric acid gas, gives off water and carbon dioxide, leaving a yellowish white tumid mass, partially soluble in cold, completely in hot water. The portion easily soluble in cold water contains sal-ammoniac, together with hydrochloride of guanidine, while the less soluble portion consists of cyanuric acid and monocyanurate of urea:

Biuret boiled with strong hydrochloric acid yields sal-ammoniac, together with small quantities of urea and guanidine hydrochloride. With nitric acid, it forms cyanuric acid, urea nitrate, and, as ultimate product, ammonium nitrate. By boiling with baryta-water, it is decomposed in the manner represented by the equation:

(Finck, *loc. cit.*)

The relation of biuret to urea may be represented by the following formulæ:

BIXIN, the red resinous colouring matter of annatto (the red paste obtained by crushing the seeds of *Bixa Orellana*), has been examined by Bolley a. Mylius (*Bull. Soc. Chim.* [2] iii. 330), who assign to it the empirical formula $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^2$, and by W. Stein (*J. pr. Chem.* cii. 175), according to whose analyses it has the composition $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^2$.

Bolley a. Mylius prepare it by digesting the dried alcoholic extract of annatto with ether; repeatedly treating the least soluble portion (which contains the greater part of the colouring matter) with hot ether; dissolving the remainder in alcohol; precipitating the alcoholic solution with lead acetate; decomposing the washed precipitate with hydrogen sulphide; extracting the colouring matter therefrom by hot alcohol; and precipitating the alcoholic solution with water. Stein examined bixin prepared by De Vrij from the fresh fruits of *Bixa Orellana* by treating them with alkaline water, precipitating the solution with sulphuric acid, and repeatedly boiling the precipitate with water and ether to remove a bitter principle and resin.

Pure bixin is an amorphous substance of the colour of vermilion, not melting at 145°, nearly insoluble in water, slightly soluble in cold alcohol and in ether, easily

soluble in hot alcohol and in alkalis. It is not altered by dilute sulphuric or hydrochloric acid; dilute nitric acid turns it yellow; strong nitric acid converts it into a yellow substance precipitable by water and smelling like musk (Bolley a. Mylius). According to Stein, it dissolves in 25.4 pts. boiling and 89 pts. cold alcohol, in 345 pts. ether, 3435 pts. carbon bisulphide, 93.3 pts. chloroform; also in alkalis and alkaline carbonates. The bitter, yellow, or brown-red alcoholic solution gives an orange precipitate with neutral lead acetate; brown-yellow with mercuric chloride and cupric acetate; brown-red with ferric chloride; reddish-yellow with aluminium acetate; and deep yellow with stannous or stannic chloride on addition of ammonia. When boiled with hydrochloric acid it deposits a brown substance. Aqueous sulphurous acid partially decolorises the solution at the boiling heat. Bixin fused with potassium hydrate forms a black-brown amorphous product. It is coloured deep blue by strong sulphuric acid, and forms nitro-compounds when treated with fuming nitric acid.

When a solution of bixin in very weak spirit is saturated with chlorine, chlorobixin, $C^{12}H^{10}Cl^2O^2$, separates as a white cloud, forming when dry a yellow-brown amorphous powder, insoluble in water, easily soluble in alcohol and ether. The action of chlorine also gives rise to other products richer in chlorine and less soluble in ether.

Nascent hydrogen converts bixin, in acid or alkaline solution, into a substance insoluble in water, and drying up to a brownish amorphous mass whose percentage composition is expressed by the formula $C^{10}H^{20}O^2$ (Stein).

BLOOD. The following are recent determinations of various constituents of the blood:

Iron.—According to Pelouze (*Compt. rend.* lx. 880), the blood of various warm-blooded animals contains in 10,000 pts. by weight, the following quantities of iron:

	Man	Ox	Pig	Goose	Turkey	Domestic Fowl	Duck	Frog
Max.	637	540	595	358	336	357	344	425
Min.	506	480	506	347	333	—	342	

Hæmoglobin.—See p. 352.

Cholesterin, Protagon, and Fats.—Hoppe-Seyler (*Medicin.-chem. Unters.* i. 140; *Jahresb.* 1866, p. 745) has determined the quantity of cholesterin in goose- and ox-blood: I. and II., from very fat young geese; III. and IV., from a fat old goose; V. from the ox:

In the Blood-corpuscles.

	I.	II.	III.	IV.	V.
Grm. cholesterin } in 100 c.c. blood. }	0.043	0.052	0.040	0.060	0.048.

In the Serum.

	I.	II.	III.	IV.
Grm. cholesterin } in 100 c.c. blood. }	0.234	0.314	0.019	0.036.

The amount of cholesterin in the corpuscles (0.04–0.06 grm. in 100 c.c. blood) is independent of the amount of cholesterin and of fat in the serum or plasma. The proportion of the same substance in the serum varies considerably, increasing and diminishing with the amount of fat. The corpuscles of the same kinds of blood were found to contain no saponifiable fats, even when the serum was very rich in fat. The serum may contain a large quantity of saponifiable fats, together with cholesterin and protagon.

Sugar and Alcohol.—Respecting the presence of sugar in blood, see GLYCOGEN (ii. 907). According to T. H. Ford (*Jahresb.* 1861, p. 792), blood in its normal state contains a minute quantity of alcohol produced by fermentation of the sugar.

Urea.—Poisseuille a. Gobley (*Compt. rend.* xlix. 164) found in 1,000 grammes of the blood of herbivorous and carnivorous animals, an average quantity of 0.220 grm. urea. Hence, supposing that the kidneys of an adult man are traversed by 1,000 kilogrammes of blood in 24 hours, and that out of the 220 grms. of urea therein contained, 20 grms. are separated in the urine, they conclude that 200 grms. are returned into the circulation.

Trimethylamine.—According to Dessaignes (*J. Pharm.* [3] xxxii. 43; *Jahresb.* 1857,

p. 382), calf's blood, twelve hours after removal from the vessels, contains a small quantity of trimethylamine, emitting the peculiar crab-like odour of that base when agitated with milk of lime. The fresh blood does not exhibit this odour.

Hæmoglobin, Hæmatoglobulin, or Hæmato-crystallin (Hoppe-Seyler, *Med.-chem. Unters.* i. 169; *Zeitschr. f. Chem.* [2] v. 243; *Jahresh.* 1867, p. 798).—This substance is the only colouring matter of the blood of vertebrate animals. The red corpuscles of the blood of man and many other mammalia consist almost exclusively of hæmoglobin, but in those of certain mammalia and birds the hæmoglobin is associated with considerable quantities of albuminous substances.

Preparation.—The separation of the corpuscles from the plasma or serum is best effected by mixing the blood—after separating the fibrin by beating it for ten minutes with a stick or a goose feather, and filtering through a linen cloth—with 1 vol. of a saturated solution of common salt and 9 vol. distilled water, and repeatedly washing the precipitated magma with the same liquid. To separate the hæmoglobin from the other constituents of the corpuscles (proteids, cholesterin, a substance rich in phosphorus, which swells up in water, potassium chloride, and sodium phosphate), the washed magma is agitated with a small quantity of water and from 4 to 10 times its volume of ether; the ether is drawn off after some hours; the removal of the cholesterin is completed by repeated agitation with ether; and the red watery liquid is filtered. The solid matter collected on the filter consists of coagulated proteids, mixed, in the case of dogs', guinea-pigs', or squirrels' blood, with crystals of hæmoglobin. The ethereal solution contains the whole of the cholesterin, together with part of the phosphorised substance; and the aqueous solution contains the remainder of the latter, together with hæmoglobin, alkali-salts, and a (still unknown) nitrogenous extractive matter.

Crystallised Hæmoglobin (Oxyhæmoglobin).—The aqueous solution obtained as above from the blood of the dog, guinea-pig, rat, or squirrel is for the most part immediately converted at low temperatures into a pulp of hæmoglobin crystals. The same crystals may be obtained from the blood of birds by cooling the clear deep red aqueous solution to 0°, mixing it, while stirring, with $\frac{1}{4}$ vol. of 80 p. c. alcohol also cooled to 0°, and leaving the mixture to itself for a few days at a temperature of -5° to -10°. To purify the crystals, they are washed on a filter with a cooled mixture of 1 vol. alcohol and 4 vols. water, pressed in the filter, stirred up with from 5 to 30 times their volume of water, according to their solubility; and the liquid, after being heated to 30° or 40°, is quickly filtered. It is then cooled to 0°, shaken up with air, mixed with $\frac{1}{4}$ vol. alcohol, and left to crystallise. After several repetitions of this treatment (which may likewise be applied to the crystals which separate from the blood of the dog and other animals on addition of ether), the hæmoglobin is obtained pure, in the form of a vermilion-coloured pasty mass, which when dried below 0° yields a light brick-red powder. From many kinds of blood, especially that of man, and of the ox, sheep, and pig, it cannot be obtained by this process in any considerable quantity (forming at most an amorphous precipitate), and the preparation succeeds for the most part only at low temperatures. Above 0° the solutions quickly assume a dark colour from decomposition, and are then difficult to crystallise. If the solution cooled below 0° be gradually mixed with alcohol cooled to a very low temperature, amorphous hæmoglobin separates, which is soluble in water, but is reprecipitated by alcohol in the amorphous state. All other modes of preparation were found by Hoppe-Seyler to yield less satisfactory results. The crystals are mostly prismatic, but those of the rat and mouse are tetrahedral, those of the squirrel six-sided tables. They are sparingly soluble in cold water, more soluble in warm water, and freely soluble in feebly alkaline solutions, such as serum.

Amorphous hæmoglobin may be obtained, not quite pure, from any of the kinds of blood above mentioned in the following manner. The defibrinated blood—or better the isolated blood-corpuscles—is agitated with water and ether; the aqueous solution, after separation from the ether, is precipitated with basic lead acetate; the liquid quickly filtered; and the lead separated from the filtrate by potassium carbonate. To the ice-cold solution, pulverised potassium carbonate is added till the colouring matter is completely precipitated; and the precipitate is washed at 0° with a nearly saturated solution of the same salt, and pressed between paper. It may be freed from the greater part of the potassium carbonate by diffusion in water, but is apt to undergo partial decomposition at the same time. Amorphous hæmoglobin may be separated in the same manner from the solution of the hæmoglobin crystals. If the solution is mixed with several volumes of alcohol (instead of potassium carbonate), part of the hæmoglobin becomes insoluble in water, and is subsequently decomposed.

Hæmoglobin from the blood of the dog and of the goose, repeatedly crystallised and dried at 110° – 120° , exhibited the following composition :

	C	H	N	S	Fe	O	P ₂ O ₅		
Dog	53.85	7.32	16.17	0.39	0.43	21.84	—	=	100
Goose	54.26	7.10	16.21	0.54	0.43	20.69	0.77	=	100.

The crystals, after drying in a vacuum at 0° , experience at 110° – 120° a loss of weight due chiefly to water, but partly also to loosely combined oxygen, and amounting in the crystals from dogs' blood to 3.4 p. c., in those from goose-blood to 7.2 p. c.

In contact with alkalis or acids, hæmoglobin is resolved into hæmatin and globulin. Treated with a great excess of glacial acetic acid, in presence of metallic chlorides, it yields globulin and hæmatin hydrochloride (hæmin) amounting to 3.86 p. c. of the hæmoglobin.

The optical properties (absorption-spectrum) of hæmoglobin, and its functions as a carrier of oxygen, are described under RESPIRATION (v. 39). The method of spectral analysis has been applied by W. Preyer (*Ann. Ch. Pharm.* cxl. 187) to the determination of the quantity of hæmoglobin in blood. The determination depends upon the fact that a concentrated solution of hæmoglobin in a layer of a certain thickness is opaque, even in strong illumination, to all rays excepting the red, whereas less concentrated solutions in a layer of the same thickness give passage to other rays besides the red and orange, and especially to a portion of the green. If, therefore, a measured quantity of blood placed before the slit of the spectral apparatus be diluted with water till green light appears in the spectrum, then, if the proportion of hæmoglobin in a solution which transmits the green under exactly similar circumstances has once for all been determined, it is easy to estimate the percentage of hæmoglobin in the blood under examination. Preyer's determinations made in this manner agree very nearly with the quantities of hæmoglobin calculated from the amount of iron in the same samples (0.42 p. c. of the hæmoglobin). The mean quantities of hæmoglobin in blood from various animals were as follows (A estimated by the amount of iron; B by the spectral method) :

	Dog	Sheep	Ox	Pig	Cock	Duck
A	13.8	11.2	11.4–13.0	12.0–14.1	8.51–2.7	8.1
B	13.3	11.2	13.6	14.3	9.0–9.8	9.3

These results further show that hæmoglobin is the only ferruginous constituent of the blood-corpuscles.

Solutions of hæmoglobin free from oxygen are not perceptibly altered by *hydrogen sulphide*, or at least only after several days, even in presence of ammonia. But on treating oxyhæmoglobin with the same reagent, several alterations take place simultaneously or successively. The first action (which shows itself also in the ammoniacal solution) is the separation of the loosely combined oxygen from the hæmoglobin, which is accelerated by heat, but always requires some time. In the ammoniacal solution of the colouring matter this abstraction of oxygen is the only reaction that takes place; but in the neutral solution another change soon shows itself by the appearance of an absorption-band at the red of the spectrum (from 67 to 72 of the scale on which C stands at 61 and D at 80). The colouring matter characterised by this band is distinguished from hæmatin and from meta-hæmoglobin (*q.v.*) by the fact that the solutions of these two substances, when treated with ammonia and ammonium sulphide exhibit the bands in the green from 86 to 94 and 102 to 110, whereas the band of the colouring matter produced from oxyhæmoglobin in the way just described remains unaltered when thus treated. From its mode of formation, Hoppe-Seyler regards it as a sulphur-compound of hæmatin or hæmoglobin. By the further action of hydrogen sulphide, this compound is decomposed (with separation of sulphur and an albuminous substance), whilst a body is formed which is olive-green in thin, brown-red in thicker layers, and dries up to a brittle hygroscopic mass having a pitchy lustre. This substance in aqueous solution is coagulated by heating, also by alcohol and acids. It contains all the iron (0.44 p. c.) of the hæmoglobin, and about four times as much sulphur (1.67 p. c. instead of 0.416). A solution of iron sulphide (as obtained with very dilute ferrous sulphate, tartaric acid, and ammonium sulphide) exhibits an absorption-band in the red, like that of the solution of hæmoglobin treated with oxygen and with hydrogen sulphide. But no formation of iron sulphide can take place in the above-described reaction, on account of the presence of oxygen; moreover, the product, as above stated, contains all the iron of the hæmoglobin.

According to Nawrocki (*Zeitschr. anal. Chem.* vi. 285; *Jahresb.* 1867, p. 805),
Sup.

A A

ammonium sulphide exerts on hæmoglobin at first merely a reducing, but afterwards a rapid decomposing action. A solution of hæmoglobin mixed with $\frac{1}{2}$ vol. of ordinary ammonium sulphide exhibits a dark band in the red at the line C; the broad reduction-band (between D and E) becomes narrower and more sharply defined; and afterwards a second broader band appears, covering E and extending beyond δ . After the appearance of these bands, which disappear in about 24 hours, those of oxyhæmoglobin are no longer reproduced by agitation with air. According to W. Freyer (*Jahresb.* 1867, p. 802), potassium persulphide also causes the two bands of oxyhæmoglobin solutions to disappear, and at first brings out the band of reduced hæmoglobin, but afterwards, especially on gentle heating, a sharply defined black band, beginning at $\frac{2}{3}$ of the distance from D to E and ending at $\frac{1}{3}$ of the same distance, and a further band beginning at $\frac{1}{3}$ of the distance from D to E and ending at $\frac{2}{3}$ of that from E to δ , make their appearance. At the boiling heat these bands disappear, the spectrum becoming shady, but reappear if the solution be quickly cooled. Solutions of the compound of hæmoglobin with carbon monoxide are altered by potassium sulphide only at the boiling heat, and again exhibit the two bands above mentioned on cooling. According to Hoppe-Seyler (*Medicin.-chem. Unters.* i. 299), the action of potassium sulphide and ammonium sulphide on oxyhæmoglobin takes place only in presence of free alkali, and depends on the formation and reduction of hæmatin.

Compound of Hæmoglobin with Carbon Monoxide.—By passing a stream of the gas, with frequent agitation, through an aqueous solution of blood-crystals, blood-corpuscles, or even defibrinated blood, cooling the liquid to 0°, mixing it with $\frac{1}{2}$ vol. cold alcohol, and leaving it to itself at or below 0°, bluish-red crystals are obtained less soluble and less easily decomposable than those of oxyhæmoglobin, with which they agree in external form. The solution, which is also bluish-red, gradually gives up its carbon monoxide when heated in a vacuum (100 grms. of the dry compound yielded 10·22 c.c. carbon monoxide) (Hoppe-Seyler).

Blood which has been treated with carbon monoxide exhibits, when properly diluted, almost exactly the same absorption-bands in the spectrum as oxygenated blood (v. 87); but these bands do not disappear on addition of ammonium sulphide even after several days, whereas when oxygenated blood free from carbon monoxide is mixed with ammonium sulphide, it exhibits after a few minutes only a single absorption-band midway between D and E. By this unalterability of blood containing carbon monoxide by ammonium sulphide, the presence of carbon monoxide may be detected in the blood of animals which have been poisoned even with small quantities of it (Hoppe-Seyler, *Zeitschr. anal. Chem.* iii. 439; *Jahresb.* 1866, p. 745). See also Pokrowsky and W. Kühne (*ibid.*). Potassium sulphide acts upon the compound of hæmoglobin with carbon monoxide only at the boiling heat, the liquid on cooling again exhibiting the two characteristic absorption-bands (Freyer, *Jahresb.* 1867, p. 802). Nawrocki (*ibid.* xvi. 640) finds that the quantity of oxygen displaced from arterial blood by passing a stream of carbon monoxide through it is equal to that which is evolved from the blood on placing it in a very perfect vacuum.

Compound of Hæmoglobin with Nitrogen Dioxide.—On passing nitrogen dioxide into a solution of the preceding compound, protected as far as possible from access of air, the carbon monoxide is displaced, and a compound of hæmoglobin with nitrogen dioxide is formed. The oxygen of oxyhæmoglobin is likewise displaced by nitrogen dioxide. The quantity of the gas absorbed by arterial blood is, however, but small. Blood from the crural artery of a dog took up, after addition of baryta-water, from 26·4 to 27·6 vol. p. c.; defibrinated dogs' blood 23 vol. p. c.; defibrinated ox-blood 31·8 vol. p. c. (reduced to 0° and 1 metre pressure). Blood saturated with nitrogen dioxide exhibits the same two absorption-bands as oxygenated blood; but the entire spectrum is darkened at the same time, and the progress of illumination on diluting the solution is different from that which takes place with oxyhæmoglobin.

Compounds of Hæmoglobin with Hydrogen Cyanide and Potassium Cyanide.—A concentrated solution of guinea-pigs' or dogs' blood mixed with prussic acid, deposits, on addition of $\frac{1}{2}$ vol. alcohol and cooling to 0°, crystals which are undistinguishable in appearance from those of oxyhæmoglobin, but still retain hydrogen cyanide even after repeated crystallisation and drying in a vacuum; the hydrogen cyanide may, however, be separated by distillation with water and a few drops of dilute sulphuric acid. This compound is more stable than pure oxyhæmoglobin, its solution not becoming perceptibly darker at temperatures above 0°.

The absorption-spectrum of blood is not altered by addition of prussic acid. A solution of blood or of oxyhæmoglobin enclosed in a tube, together with a few drops of prussic acid and a very small quantity of air, and left for several months, still

exhibits the two absorption-bands of oxyhæmoglobin, whereas if no prussic acid be added, nothing but the bands of reduced hæmoglobin can be seen, even after a few days. *Mercuric cyanide* exerts the same conservative action as hydrogen cyanide on hæmoglobin, whereas all other mercury salts and all acids decompose it. The blood-corpuscles themselves do not appear to take up hydrogen cyanide (Hoppe-Seyler).

Solutions of *potassium cyanide*, either concentrated or dilute, do not affect the optical characters of hæmoglobin at ordinary temperatures; but on raising the mixture to the temperature of the animal body, the two characteristic absorption-bands disappear, and a broad band comes to light somewhat nearer to the violet than that of reduced hæmoglobin. In this solution—which has a yellowish tint, is very permanent, and does not coagulate when heated—the two absorption-bands of oxyhæmoglobin are not reproduced by the action of a stream of oxygen. On adding ammonium sulphide, the broad band disappears, and a new spectrum is formed with two bands from $\frac{1}{10}$ to $\frac{1}{10}$ of the distance from D to E, and from $\frac{1}{10}$ between D and E as far as $\frac{1}{2}$ from E to δ . This spectrum is very much like that of the compound of hæmoglobin with carbon monoxide (the bands of the latter extend from $\frac{1}{10}$ to $\frac{1}{10}$ between D and E, and from $\frac{1}{10}$ between D and E as far as $\frac{1}{2}$ from E to δ). If the solution be subjected to the action of oxygen, the broad band reappears, and on repeated addition of ammonium sulphide the two other bands are reproduced; the solution is then also coagulated by heat. Hydrogen cyanide and ammonium sulphide, with aid of heat, produce the same phenomena, viz. disappearance of the bands of oxyhæmoglobin, appearance of the broad band, and then of the two bands; the reaction is moreover attended with separation of sulphur. On passing oxygen into the liquid, these appearances are reversed as far as the transient appearance of the oxyhæmoglobin bands. Hence it appears that the compounds of hydrogen cyanide and potassium cyanide with hæmoglobin also contain oxygen, which is removed by ammonium sulphide, but is more intimately combined than in oxyhæmoglobin, and that in presence of hydrogen cyanide or potassium cyanide, hæmoglobin cannot be converted into oxyhæmoglobin.

When potassium cyanide is added to the aqueous solution of the compound of hæmoglobin with carbon monoxide, the characteristic absorption-bands do not disappear till the mixture is heated to 40°, whereupon the above-mentioned broad band appears, and on addition of ammonium sulphide is further altered in the manner already described; by agitation with air, the broad band is reproduced, and afterwards the original spectrum of the carbonic oxide compound. Hydrogen cyanide and ammonium cyanide act in the same manner with aid of heat; but the filtered solution, after agitation with air, finally exhibits the bands of oxyhæmoglobin (Preyer, *Zeitschr. anal. Chem.* vi. 289; *Jahresb.* 1867, p. 803). According to Nawrocki (*Jahresb.* 1867, p. 204), the broad absorption-band produced in a solution of hæmoglobin on heating with potassium cyanide, belongs, not to hæmoglobin, but to hæmatin. It is obtained immediately and without heating if the solution of hæmoglobin, before the addition of potassium cyanide, be mixed with caustic potash.

Hæmatin. $C^{14}H^{102}N^{12}Fe^{10}O^{18}$.—This substance was formerly regarded as the red colouring matter of the blood. The investigations of Hoppe-Seyler have shown, however, that it does not exist ready-formed in blood, but is produced, together with globulin, from hæmoglobin when blood is treated with acids or alkalis (p. 353). It may be obtained pure by dissolving its hydrochloride (hæmin) in ammonia, evaporating to dryness, heating the residue to 130°, dissolving out the ammonium chloride by water, and heating the residue to 130° (Hoppe-Seyler); also by mixing defibrinated blood (or blood agitated with ether as long as it will take up that liquid, and filtered) with a strong solution of potassium carbonate, till the liquid adhering to the separated coagulum becomes colourless; drying the coagulum on a filter at a temperature not above 50°; and digesting it for some days with absolute alcohol in a close vessel at a moderate heat (below 50°). The red liquid filtered therefrom is an alcoholic solution of hæmatin (Wittich, *J. pr. Chem.* lxi. 11).

In acid liquids, as in the hot extract of blood with acidulated alcohol, the spectrum of hæmatin exhibits a very faint absorption of the light from the middle space between the lines A and α to the middle between b and C. On diluting with alcohol, a sharply defined absorption-band appears between C and D, near C; and on further dilution, two absorption-bands appear in the green, faintly defined and soon vanishing (Hoppe-Seyler, *Jahresb.* 1865, p. 867). According to Nawrocki (*Zeitschr. anal. Chem.* vi. 286; *Jahresb.* 1867, p. 804), the spectrum of hæmatin is best seen in the ethereal solution obtained by mixing diluted blood with a little acetic acid and an equal volume of ether. This solution exhibits a band coinciding with C, a second before E, and a third fainter one between b and F. The brown solution of hæmatin in potash or

potassium cyanide exhibits least absorption of light near the line C; on diluting this solution there remains a band between D and E, but nearer to D, which, however, likewise disappears while the solution still exhibits a strong colour: hydrochloric acid throws down from it unaltered hæmatin. Hence it appears that hæmatin forms with potassium cyanide a double cyanogen-compound, which, like the double metallic cyanides, differs in colour from the other compounds of hæmatin with acids or bases (Hoppe-Seyler, *loc. cit.*). According to Nawrocki, alkaline solutions of hæmatin (hæmin-crystals or Wittich's hæmatin) dissolved in ammonia give a spectrum with a band between C and D; but after treatment with a ferrous salt or with stannous chloride, they exhibit two other bands, which do not disappear on agitation with air, and are likewise visible for some time in the red ethereal solution obtained by mixing the ammoniacal liquid with ether and glacial acetic acid; but in this they gradually merge into the three bands of the normal hæmatin solution. If, on the other hand, the alkaline solution of hæmatin be mixed with ammonium sulphide, the liquid exhibits the same bands as hæmoglobin when similarly treated, and no longer yields up anything to ether on addition of acetic acid. Even very dilute solutions of putrefied blood exhibit this reaction with ammonium sulphide very distinctly (Nawrocki). Hæmatin (or hæmin) heated for some time with ammonia or a fixed alkali is converted into a body, the solution of which in acidulated alcohol or in an alkali has a dingy olive-green colour, dark red in thicker layers, and after treatment with reducing agents does not exhibit the spectrum of reduced hæmatin; neither can hæmin crystals be obtained from it (Hoppe-Seyler, *Jahresb.* 1867, p. 806).

By dissolving hæmin in strong sulphuric acid, and adding water to the solution, a substance is precipitated, resembling hæmatin but not containing iron; it is soluble in alkalis. The solution of this non-ferruginous hæmatin in strong sulphuric acid likewise absorbs blue and violet light strongly; on diluting it with sulphuric acid, a very dark well-defined band appears about midway between D and E; and a narrow band between C and D (near D), the spectrum appearing also very darkly shaded between D and the dark absorption-band. The solution of non-ferruginous hæmatin in dilute ammonia exhibits the smallest absorption for red light; on diluting with water, an absorption-band appears midway between C and D, and three others on further dilution. The absorption of this solution is altered by ammonium sulphide or potassium cyanide in the same manner as that of ferruginous hæmatin (Hoppe-Seyler, *Jahresb.* 1866, p. 667).

Hæmatin Hydrochloride. *Teichmann's Hæmin Crystals.* $C^{10}H^{12}N^{12}Fe^2O^{18} \cdot 2HCl$.—This compound is obtained in regular crystals by treating hæmoglobin or metahæmoglobin with common salt and glacial acetic acid. The crystals are rhombic or six-sided plates, dark blue by reflected, dirty brown by transmitted light. They are quite insoluble in water, alcohol, and ether, soluble in acids and alkalis, but decomposed at the same time by all acids excepting hydrochloric and acetic. They may be heated without decomposition to 130° , but burn at a red heat, leaving a residue of iron oxide.

The following mode of preparing these crystals is recommended by J. Gwosden (*Wien. Akad. Ber.* liii. [2] 683; *Jahresb.* 1866, p. 746): De fibrinated blood dried at ordinary temperatures, or the clot of blood cut up and dried, is triturated in the form of powder with $\frac{1}{2}$ pt. of pure potassium carbonate, and the dry mass is digested at 40° – 45° with alcohol of 94 p. c. till the resulting dark garnet-red solution no longer becomes deeper in colour. The liquid is then filtered; the residue again treated with alcohol; and the united extracts are mixed with rather more than an equal volume of water, and then with acetic acid sufficient to produce a slight acid reaction. The brown flocculent precipitate thereby produced is collected on a filter, slowly dried (finally at 100°), then triturated with $\frac{1}{2}$ pt. sodium chloride and 20 to 30 pts. glacial acetic acid, and the mixture is digested for some time at 80° till a crystalline mass separates. The whole is then heated to 100° and left to cool, and the crystals are washed on a filter with warm glacial acetic acid, then pressed, dried, and again boiled with water. According to Hoppe-Seyler (*Med.-chem. Unters.* i. 298; *Jahresb.* 1867, p. 805), the process may be advantageously modified as follows: The blood is coagulated by pouring it into alcohol or boiling water; the clot, separated by filtration and still moist, is warmed with alcohol to which a few drops of strong sulphuric acid have been added; the filtered brown solution is mixed with a warm saturated solution of sodium acetate, then immediately neutralised with sodium carbonate; and, in order to promote the separation of the hæmatin (if it has not taken place already), either mixed with water or freed from alcohol by distillation. The precipitate, after being washed on a filter and dried in the air, is ready for treatment with common salt and acetic acid as above.

Detection of Blood-stains.—The formation of hæmin crystals by the action of common salt and glacial acetic acid is quite characteristic of blood, and affords a very delicate indication of its presence. To ascertain whether a spot on linen, cotton, woollen cloth, wood, or metal consists of blood, the stained tissue or wood, or the substance scraped from the metal, may be simply boiled for a few minutes with glacial acetic acid, a few drops of the solution evaporated to dryness at 40°-60°, and the residue examined by the microscope. In operating on fresh still highly coloured spots, or on dried blood, the addition of sodium chloride may be dispensed with, as the blood itself contains sufficient of that substance to produce the reaction; but if the stain is old, or has been partly washed out with water, a small quantity of common salt must be added during the boiling or before the evaporation (Brücke, *Jahresb.* 1857, p. 609; Scriba, Simon, a. Büchner, *ibid.* 1859, p. 706). Or the substance may be triturated as above described with potassium carbonate, then digested with alcohol at 40°-50°, and the evaporated residue treated on the object-stage of the microscope with salt and glacial acetic acid, or with the latter alone (Gwooden, *loc. cit.*). According to Erdmann (*J. pr. Chem.* lxxxv. 1; *Jahresb.* 1862, p. 634), the colouring matter of blood cannot be extracted from dried clay or ferric oxide by glacial acetic acid; but by digesting a portion of dried soil containing blood with water, or in some cases with potash-ley, and treating the filtered solution with chlorine-water, a coagulum is obtained which yields hæmin crystals with salt and acetic acid. In applying the preceding method to the detection of blood in judicial investigations, it is important to remember that, according to the statements of most observers, the blood of the greater number of warm-blooded animals yields hæmin crystals exhibiting the same form and general appearance as those obtained from human blood. Krauss, however, states that the hæmin crystals from human blood are quite distinct in character from those produced from the blood of oxen, sheep, pigs, or poultry (*Jahresb.* 1861, p. 792).

Another very delicate test for blood is afforded by tincture of *guaiacum*, which, in conjunction with hydrogen dioxide, or ozonised oil of turpentine, or other substance capable of yielding ozone, changes the colour of the blood to blue. The same colour is however produced by guaiacum and ozonising substances, with fresh gluten, casein, legumin, gum arabic, and various iron compounds, especially ferric acetate and citrate: hence this reaction is useful only as a verification of other experiments, and cannot be regarded as affording positive demonstration of the presence of blood; its non-production may, however, be accepted as a proof that the spot under examination does not consist of blood (Van Deen, *Zeitschr. anal. Chem.* ii. 459. Liman, *ibid.*; *Jahresb.* 1863, p. 715. See also Taylor, *Guy's Hospital Reports*, 1868).

On the detection of blood by its absorption-spectrum, see H. C. Sorby (*Chem. News* [1865] xi. 186, 194, 232, 256).

BONE. A large number of carefully conducted analyses of the bones of man and other animals by Zaleski (*Med.-chem. Unters.* i. 19; *Jahresb.* 1866, p. 757) have led to the following results: 1. The proportion of organic to inorganic substance is nearly constant. The mean of several analyses gave:

	Man	Ox	<i>Testudo</i> <i>græca</i>	Guinea-pig
Inorganic substance	65.44	67.98	63.05	65.30
Organic ,,	34.56	32.02	36.95	34.70

2. The proportions of the several constituents of bone-ash (lime, magnesia, phosphoric oxide, carbon dioxide, calcium chloride, and calcium fluoride) exhibit only slight variations, scarcely beyond the limits of analytical error. 100 grms. of ash yielded:

	Man	Ox	<i>Testudo</i> <i>græca</i>	Guinea-pig
Carbon dioxide	5.784	6.197	6.276	—
Lime	52.965	53.887	52.396	54.025
Magnesia	0.521	0.468	0.565	0.483
Phosphoric oxide	39.019	40.034	38.672	40.381
Chlorine	0.183	0.200	—	0.133
Fluorine	0.229	0.300	0.204	—
or				
(PO ⁴)Mg ²	1.039	1.024	1.357	1.055
(PO ⁴)Ca ²	82.889	86.096	86.981	87.379
CaO*	7.648	7.357	6.319	7.027

3. With exception of the bones in the shield of *Testudo græca*, all bones contain

* As carbonate, fluoride, or chloride.

chlorine, in the form of a compound insoluble in cold water.—4. The quantities of chlorine and fluorine in all bones are nearly the same; the latter, however, is less according to these analyses than according to older determinations.—5. The quantity of calcium, not in the form of phosphate, is greater than that which corresponds with the formula of apatite, $(\text{PO}_4)_2\text{Ca}^2 \cdot \text{CaF}_2$.

Experiments with pigeons showed that an increase in the proportion of lime or phosphoric acid in the food does not produce any alteration in the proportion of organic to inorganic substance, or of lime to phosphoric acid.

Roussin (*J. Pharm.* [3] xliii. 102) found that the young of a rabbit which received in its food a small quantity of calcium arsenate contained in their bony skeleton (but not in the muscular tissue) notable quantities of arsenic.

Wicke (*Ann. Ch. Pharm.* cxiii. 251) has examined the ash of the bony plates in the scales of the armadillo (*Dasyus sexcinctus*), and that of the caudal vertebrae, with the following results:

	$(\text{PO}_4)_2\text{Ca}^2$	$(\text{PO}_4)_2\text{Mg}^2$	CO^2Ca	SO^2Ca	SiO^2	Fe^2O^2	KCl
Bony plates . . .	85.33	1.19	11.75	0.38	0.29	0.65	0.56
Caudal vertebrae . .	87.56	2.18	10.36	—	—	0.29	—

Respecting the composition of fossil bones, see Delesse, *Compt. rend.* lii. 728; *Jahresb.* 1861, p. 1087; Courbe, *Compt. rend.* liv. 49; Göbel, *J. pr. Chem.* lxxxvi. 318; Schwarzenbach, *Chem. Centr.* 1862, p. 706; *Jahresb.* 1862, p. 549;—of bones from Pompeii: De Luca, *Compt. rend.* lix. 567; *Jahresb.* 1864, p. 674.

BONSDORFFITE. The mineral thus named by Thomson, from Abo in Finland, appears from analyses made in Arppe's laboratory to be identical with Fahlunite (*Jahresb.* 1862, p. 748).

BORNEOL, $\text{C}^{10}\text{H}^{18}\text{O}$, is produced, together with sodium-camphor, by the action of sodium on common camphor:

(Baubigny, *Zeitschr. f. Chem.* [2] iii. 71).

Borneol heated with nitric acid yields camphretic acid, $\text{C}^{10}\text{H}^{18}\text{O}^2$, together with camphoric acid, $\text{C}^{10}\text{H}^{16}\text{O}^4$ (Schwanert, *Jahresb.* 1863, p. 400).

Borneol heated with organic acids to 200° forms compound ethers: with stearic acid, for example, it yields the ether $\text{C}^{20}\text{H}^{32}\text{O}^2 = \text{C}^{10}\text{H}^{18}\text{O}^2 + \text{C}^{10}\text{H}^{14}\text{O} - \text{H}^2\text{O}$. The stearate and benzoate are neutral, colourless, inodorous liquids, soluble in alcohol and in ether, and resolved by alkalis into borneol and the corresponding acids (Berthelot, *Compt. rend.* xlvii. 262).

A solid substance, $\text{C}^{11}\text{H}^{20}\text{O}$, homologous with borneol, is deposited from oil of patchouli (q.v.).

BORON. The so-called graphitoïdal boron (i. 628) appears from recent experiments by Wöhler a. Deville (*Ann. Ch. Pharm.* cxli. 268) to consist of aluminium boride, AlB^2 (anal. 54.91 aluminium, 45.09 boron; calc. 55.46 and 44.54). Its formation on fusing aluminium with amorphous boron or boric oxide appears to take place especially when the heat applied is neither very strong nor long-continued. It is also produced when aluminium is fused in vapour of boron chloride. Its crystals, as well as those of adamantine boron, appear from Miller's determinations (*Phil. Mag.* [4] xxxi. 397) to belong to the monoclinic system. When ignited in the air it acquires a steel-grey tarnish, but does not burn; but in chlorine gas it burns with vivid incandescence, yielding aluminium chloride and boron chloride. It is easily dissolved by moderately strong nitric acid; slowly, and with evolution of hydrogen, by hot strong hydrochloric acid and by solution of caustic soda.

Boron Chloride, BCl^3 , boils at 18.23° under a pressure of 760 mm. (Regnault, *Jahresb.* 1863, p. 70). It unites with ethyl cyanide, forming the compound $\text{C}^2\text{H}^3\text{N} \cdot \text{BCl}^3$, which crystallises in right rhombic prisms, may be fused, and for the most part volatilised, without alteration, and is decomposed by water into ethyl cyanide, boric acid, and hydrochloric acid. Boron bromide forms a similar compound (Gautier, *Ann. Ch. Pharm.* cxlii. 289).

According to Nicklès (*Bull. Soc. Chim.* [2] iv. 189), a solution of boric oxide in absolute alcohol absorbs hydrochloric acid gas, forming an oily liquid having the composition $3\text{B}^2\text{O}^3 \cdot 6\text{HCl} \cdot 10\text{C}^2\text{H}^4\text{O}$, and yielding by distillation at 85° a compound of boron chloride with ethyl oxide and water, $2\text{BCl}^3 \cdot 5\text{C}^2\text{H}^{10}\text{O} \cdot 9\text{H}^2\text{O}$. A bromine-compound containing $2\text{BBr}^3 \cdot 13\text{C}^2\text{H}^{10}\text{O} \cdot 16\text{H}^2\text{O}$ is obtained in a similar manner. According to Schiff, on the other hand (*Ann. Ch. Pharm. Suppl.* v. 164), an alcoholic solution of boric oxide saturated with hydrochloric acid gas yields, not a compound of boron chloride with ether, but a mixture of ethyl borate, alcohol, ethyl chloride, and

hydrochloric acid; in like manner, boron chloride in contact with alcohol forms ethyl borate and hydrochloric acid.

Boron nitride, BN, is easily produced by heating 1 pt. of fused and very finely pulverised boric oxide with $1\frac{1}{2}$ to 3 pts. urea; it always however retains a small quantity of boric oxide, which cannot be removed by washing. It is not altered by moderate ignition in chlorine gas, but acquires thereby the property of glowing very brightly at the edge of a flame. At a very strong red heat, boric chloride is formed. Vapour of iodine and dry hydrogen do not act upon it (Darmstadt, *Ann. Ch. Pharm.* cli. 255).

Boric Oxide, Acid, and Salts. According to Merz (*J. pr. Chem.* cxix. 179), crystallised boric acid heated to 270° retains from 2.8 to 3.1 p. c. water, the residue having the composition $8B_2O_3 \cdot H_2O$.

A compound of boric oxide with *sulphuric acid*, $5B_2O_3 \cdot 2H_2SO_4$, is produced by fusing boric oxide in strong sulphuric acid, and heating the clear liquid to 250° – 280° till the excess of sulphuric acid is driven off. The compound solidifies on cooling to a transparent glass, which for the most part may be further heated to 350° – 400° without decomposition, but sometimes gives off water and sulphuric acid, and is converted into a dry white mass (Merz). Boric oxide is dissolved by *acetic oxide* at the boiling heat, forming a syrupy liquid which solidifies on cooling to a vitreous mass consisting of acetic borate, $B(C^2H^3O)O^2$, which is resolved by water into boric and acetic acids (Schützenberger, *Rép. Chim. pure*, iv. 6).

In estimating boron or boric acid by evaporating the aqueous solution of the acid with a known weight of sodium carbonate, and determining the carbonic acid in the residue (i. 630), the process may be simplified—if the amount of the boric acid is known within certain limits—by so adjusting the quantity of alkaline carbonate added, that for each molecule of boric oxide, B_2O_3 , in the solution, there shall be present not less than 1 and not more than 2 molecules of sodium oxide, Na_2O (or between 1 and 2 at. sodium to 1 at. boron). Under these circumstances, the whole of the carbonate is decomposed, the weight of the residue is constant, and the carbonic acid estimation may be dispensed with. To avoid excessive tumescence and violent evolution of gas, it is best to evaporate the solution in a platinum dish, heat the residue therein till all decrepitation has ceased, and then introduce it by small portions into a red-hot crucible (Schaffgotsch, *Pogg. Ann.* cvii. 427).

Marignac (*Zeitschr. anal. Chem.* i. 405) gives the following method for estimating boric acid in solutions containing only alkali-metals. Insoluble borates must be previously decomposed by fusion with sodium carbonate, and any silica that may be present precipitated from the aqueous solution of the fused product with chloride or carbonate of ammonium. The solution is then to be neutralised with hydrochloric acid, mixed with a quantity of magnesium chloride (or, better, magnesium-ammonium chloride) such that 2 pts. of magnesia may be present for every 1 pt. of boric oxide, and after addition of ammonia (which should produce no turbidity, otherwise sal-ammoniac must be added) evaporated in a platinum dish. The boric acid appears to be present in this solution as magnesium-ammonium borate, and is held in firm combination; nevertheless it is advisable to maintain the alkaline reaction during the evaporation by occasional addition of ammonia. On heating the dried residue to redness, and lixiviating it with boiling water till the chlorine reaction is no longer apparent, the greater part of the boron remains as insoluble magnesium borate, a small portion however passing into the wash-water. The preceding series of operations must therefore be repeated on the entire filtrate; and even the wash-waters then obtained yield small quantities of magnesium borate by further evaporation, ignition, and washing. The whole of the residues thus obtained are ignited together in an open crucible to decompose any magnesium chloride that may be present, then weighed; and the quantity of magnesia in them is determined either by precipitation as ammonio-magnesian phosphate, or alkalimetrically by solution in a known volume of standard sulphuric acid and counter-titration. The quantity of boric oxide is determined by difference.

To decompose borofluorides, Marignac fuses them with alkaline carbonate; dissolves the fused mass in water; decomposes the greater part (not the whole) of the excess of alkaline carbonate by heating with sal-ammoniac; and precipitates the solution with a neutral or ammoniacal solution of calcium chloride. (If the liquid were acidulated, the borofluoride would be reproduced.) The precipitate of calcium carbonate and fluoride is easily washed, after which it is to be dried, gently ignited, mixed with acetic acid and evaporated, and further treated in the usual way. The liquid filtered from the precipitate formed by calcium chloride contains the whole of the boric acid, which, after the excess of lime has been removed by carbonate and oxalate of ammonium, may be estimated in the manner above described.

P. Le Roux (*Bull. Soc. Chim.* [2] vii. 485; *Jahresb.* 1867, p. 137) describes certain peculiar alterations exhibited by fused borates when rapidly cooled.

When boric acid and alumina are dissolved together in hydrochloric acid, and the solution is treated with ammonium carbonate, part of the boric acid goes down with the alumina, and can only be separated from it by heating with hydrofluoric acid (Wöhler, *Jahresb.* 1867, p. 836).

A compound of boric and phosphoric oxides, $B^2O^3 \cdot P^2O^5$, is formed by heating crystallised boric acid with concentrated aqueous phosphoric acid. It is a white earthy mass, which melts before the blowpipe, is not decomposed by boiling water or by strong acids, but is dissolved by boiling caustic alkalis. By fusion with sodium it yields sodium phosphide and a black scoriaceous mass, probably consisting of boron phosphide (Vogel, *Zeitschr. f. Chem.* vi. 125).

Metallic Borates. *Potassium triborate*, $K^2O \cdot 3B^2O^3 \cdot 6H^2O$ or $2(KBO^2 \cdot B^2O^3) \cdot 6H^2O$, crystallises from a hot solution containing 2 mol. boric oxide to 1 mol. potassium carbonate at 6° , in rhombic prisms having a vitreous lustre and permanent in the air. Combination $\infty P \cdot \infty P \cdot \infty P \cdot \infty P$, with the angles $\infty P : \infty P = 124^\circ 17'$; $P \infty : \infty P \infty = 132^\circ 38'$; $P \infty ; P \infty$ (at the principal axis) = $60^\circ 16'$. Ratio of axes $a : b : c = 0.6315 : 1 : 0.9206$. *Rubidium biborate*, $Rb^2O \cdot 2B^2O^3 \cdot 6H^2O$ or $2RbBO^2 \cdot B^2O^3 \cdot 6H^2O$, separates in like manner from a hot solution of 2 mol. B^2O^3 to 1 mol. Rb^2CO^3 at 6° , in small tabular rhombic crystals, exhibiting the combination $\infty P \cdot \infty P \cdot \infty P \infty$, with the angles $\infty P : \infty P = 82^\circ 23'$; $\infty P : \infty P \infty = 131^\circ 4'$. It is permanent in the air, has an alkaline taste, and is more soluble in hot than in cold water (Reissig, *Ann. Ch. Pharm.* cxxvii. 33).

Neutral sodium borate, $NaBO^2 \cdot 4H^2O$, crystallises, according to Hahn (*Arch. Pharm.* [2] xcix. 146), in monoclinic combinations, $-P \cdot \infty P \cdot \infty P \cdot \infty P \infty$ ($\infty P \infty$), with the angles $\infty P : \infty P$ (clinod.) = 87° ; $\infty P \infty : \infty P = 106^\circ 41'$; $\infty P : -P = 138^\circ 57'$. Twins often occur combined by the face $\infty P \infty$; cleavage imperfect parallel to $\infty P \infty$.

According to A. Vogel (*Jahresb.* 1867, p. 191), crystallised borax, $Na^2O \cdot 2B^2O^3 \cdot 10H^2O$, is soluble in 14.7 pts. of glycerin.

Copper Borates.—On adding borax to a solution of cupric sulphate, a basic sulphate $7CuO \cdot 2SO^2 + 8H^2O$ is precipitated in the first instance, and with excess of borax, a cupric borate $5CuO \cdot 2B^2O^3 + 12H^2O$. A solution of equivalent quantities of cupric acetate and borax in ammonia mixed with about half its volume of absolute alcohol, gradually deposits dark blue microscopic rhombic tables of the salt $CuO \cdot 2B^2O^3 \cdot 4NH^3 + 6H^2O$. The same salt is obtained by dissolving 1 mol. cupric acetate in ammonia, adding 2 mol. boric oxide, warming the liquid till the precipitate dissolves, and leaving it to cool. It smells strongly of ammonia, effloresces in contact with the air, dissolves in dilute acids, and is resolved by boiling with water into ammonia and cupric borate (E. Pasternack, *Ann. Ch. Pharm.* cli. 116).

Magnesium Borate.—A mixture of anhydrous magnesium chloride and a large quantity of sodium chloride, with addition of boric oxide and magnesia, subjected in a platinum crucible to the strongest heat of an air-furnace, and then left to cool as slowly as possible, yields a mass which, when exhausted with water, leaves a crystalline powder appearing under the microscope as a mixture of monometric and prismatic crystals. On leaving this mass for several days in contact with cold concentrated hydrochloric acid, the prismatic crystals (probably consisting of a mixture of $MgO \cdot B^2O^3$ and $2MgO \cdot B^2O^3$) dissolve, leaving regular crystals of the compound $Mg(Cl)^2 \cdot 2(3MgO \cdot 4B^2O^3)$, which exhibit the forms $\left(O \text{ and } \frac{O}{2} \right)$, and the pyroelectric properties of native boracite (Heintz a. Richter, *Pogg. Ann.* cx. 613).

Zinc Borates.—Borax reacts with zinc sulphate in the same manner as with copper sulphate, throwing down first a basic sulphate, afterwards a borate containing 38.58 p. c. ZnO and 36.55 water. On dissolving 4 pts. of this zinc borate and 5 pts. boric oxide in ammonia, and covering the solution with a layer of alcohol, the salt $ZnO \cdot 2B^2O^3 \cdot 4NH^3 + 6H^2O$ is deposited in efflorescent rhombic prisms, soluble in ammonia and in dilute acids. The same salt is produced by dissolving zinc acetate obtained from 20 grms. of basic zinc carbonate, and 38 grms. boric oxide in ammonia at a gentle heat, and mixing the cooled liquid with alcohol (E. Bäscher, *Ann. Ch. Pharm.* cli. 235).

Boric Esthers (Schiff a. Bochi, *Bull. Soc. Chim.* [2] v. 372; vi. 36. Schiff, *Giornale di Scienze naturali ed economiche di Palermo*, v. 9).—The tri-alcoholic borates were first prepared in 1846 by Ebelmen and Bouquet, who obtained them by the action of boron trichloride on the respective alcohols (i. 649). H. Rose, in 1856,

gave an easier mode of preparing them by the dry distillation of a mixture of potassium ethylsulphate and anhydrous borax; and this method was perfected by Frankland, in connection with his researches on the action of zinc-ethyl and zinc-methyl on triethyl borate (ii. 525). With regard to the preparation of the non-saturated boric ethers, Ebelmen, in 1855, published a research relating to the action of boric oxide or anhydride upon the alcohols, and he there describes a number of vitreous boric ethers, which he derives from a hydrate, $B^H^3O^3$, corresponding to borax. These however appear, from the experiments of Schiff, to have been nothing but mixtures, the supposed diethyl tetraborate, $B^4(C^2H^5)^2O^7$, for example, being a mixture of monethyl borate, $B(C^2H^5)O^2$, and monethyl triborate, $B^3(C^2H^5)O^4$.

When equal weights of pulverised boric oxide and absolute alcohol are mixed together, the temperature of the mixture rises considerably, and after eight or ten hours the alcohol is completely absorbed by the boric oxide, which partly becomes hydrated and converted into a white spongy mass. If the mixture, contained in a flask furnished with a long tube, be now raised to ebullition, a large part of the boric acid dissolves, and on then adding a little alcohol the whole may be easily made to enter into solution. As the liquid cools, a white mammellated crystalline mass separates, consisting of boric trihydrate, BH^3O^3 . The colourless or slightly yellow liquid, separated from the crystals and distilled, leaves a small vitreous residue, consisting of a boric ether (or rather a mixture of two such ethers), while the distillate contains a much larger quantity of a boric ether, which was supposed by Ebelmen to be the vitreous ether just mentioned mechanically carried forward by the alcohol. According to Schiff, however, it consists of triethyl borate or ethylic orthoborate, a considerable quantity of which passes over between 110° and 130° . From these results it appears that the reaction between absolute alcohol and boric oxide is that which is represented by the equation:

This, according to Schiff, is the easiest and most economical method of preparing triethyl borate.

The best way of separating the boric ether from the alcohol which distils over with it, is to mix the distillate with strong sulphuric acid, whereby two strata of liquid are formed, the upper consisting mainly of triethyl borate, which may be further purified by rectification.

Triethyl Borate is a limpid, very mobile liquid, which burns without a wick, with a green flame, exhaling vapours of boric acid. It boils at 120° under a pressure of 760 mm. (with the thermometer in the vapour, and pieces of platinum in the liquid). Sp. gr. 0.861 at 26.5° , and 0.887 at 0° : hence one volume of the liquid at 0° gives 1.033 vol. at 26.5° , an expansion nearly equal to that of ethylic acetate, propionate, and nitrate. It tastes like boric acid and alcohol together, and smells like the latter, the effect on the organs of taste and smell being evidently due to decomposition of the ether. The bitter taste and pungent aromatic smell attributed to this ether by Ebelmen and Bouquet and by Bowman were probably due to some chlorinated products of the ethylic group, arising from the chloride of boron used by them in the preparation. The ether is easily decomposed by atmospheric moisture, and a small quantity suffers decomposition at each distillation, probably in consequence of the presence of moisture in the vessel, the latter portions often exhibiting a higher boiling point, and ultimately leaving a resinous residue.

Triethyl borate heated to 160° – 180° in a sealed tube with boric hydrate, BH^3O^3 , is decomposed, partly according to the equation:

partly in the following manner:

These decompositions take place also in the above-described preparation of triethyl borate when the temperature is allowed to rise above 130° .

Strong sulphuric acid easily dissolves triethyl borate, and if the mixture be heated, water and ethylene gas are given off; and if water be then added before the temperature rises higher, sulphurous oxide is given off, monohydric borate separates, and ethyl-sulphuric acid is found in the liquid:

If water be added, drop by drop, to the solution of boric ether in sulphuric acid heated to 140°–150°, trihydric borate is likewise deposited, but at the same time vapour of ethylic oxide separates, and the liquid contains ethyl-sulphuric acid:

If an acid be added instead of water, the corresponding compound ether is formed, instead of ethylic oxide; thus, with benzoic acid at 120°:

A similar reaction takes place with other acids, as for example with acetic, butyric, and valerianic acids. In other cases triethylic borate etherifies directly; thus it dissolves, with rise of temperature, in nitric acid, and after a while ethylic nitrate is given off, while the liquid becomes filled with crystals of boric acid:

Acetic acid decomposes triethylic borate in a similar manner; so likewise do benzoic and succinic acids when heated with it in sealed tubes to 180°–200°. This mode of preparing compound ethers by means of triethylic borate may, in many cases, be preferable to the somewhat expensive process of decomposing the silver salts of the corresponding acids with ethylic iodide. Oxalic acid acts at 151°; hydrochloric and sulphurous acids may be heated with triethylic borate to 120°–140°, without producing any reaction.

Chlorine, bromine, and iodine act upon triethylic borate, taking the place of part of the hydrogen. The vapour of the ether, mixed with chlorine, takes fire and burns, leaving a carbonaceous residue. The liquid ether rapidly absorbs chlorine, forming a yellow jelly containing more than two atoms of chlorine, but not enough to form the compound $B(C^2H^5Cl)_3O^3$.

Phosphoric pentachloride at ordinary temperatures acts upon triethylic borate in such a manner as to form phosphoric oxychloride, ethyl chloride, and monethylic borate:

At higher temperatures, boric oxide and ethyl oxide are formed instead of monethylic borate:

Heated with antimonie chloride, triethylic borate yields antimonie oxychloride, ethyl chloride, ethyl oxide, and monethylic borate:

Monethylic Borate or Ethylic Metaborate. $B(C^2H^5)O^2$.—If the crude product of the action of alcohol on boric oxide be fractionally distilled till the vapours exhibit a temperature of 140°–150°, and a sufficient time be allowed to elapse between the collection of the separate fractions to let the boric acid crystallise out, a syrupy, more or less yellow liquid will be obtained on cooling, which after a time deposits a small quantity of boric acid. This liquid is monethylic borate, slightly contaminated with triethylic borate and boric acid. It appears to be formed by the action of boric acid (see above), or of boric oxide, on triethylic borate:

Monethylic borate is a dense inodorous liquid, having at 120° the consistence of fuming sulphuric acid. It attracts moisture from the air, and is decomposed into alcohol and boric acid. When directly decomposed by water, it evolves great heat; hence also it feels very hot when placed upon the tongue. It cannot be distilled without alteration. Introduced into a flame on the end of a wire, it burns with a green light, leaving boric acid mixed with charcoal. With alcohol, it forms triethylic borate and boric acid:

Heated with potassium ethylate, it yields potassium borate and triethylic borate:

It is decomposed by acids, but much less easily than triethylic borate, the reaction requiring a temperature of 180°–200°. With acetic acid the action is:

Monethylic triborate, $B^3(C^2H^5)O^3$, is produced, together with the triethylic ether, by the decomposition of monethylic monoborate at high temperatures:

When monomethyl borate is heated to 270°–280°, triethyl borate is given off, and the residue cools to a solid mass, which is to be broken up and digested with anhydrous ether; the solution filtered and evaporated leaves the ethylic triborate in the form of a mass resembling gum-arabic. When exposed to the air, it attracts moisture and becomes covered with a crust of boric acid. In water it decomposes rapidly, with evolution of heat. In a gas-flame it burns with a green light, leaving boric oxide mixed with carbon. It is not sensibly altered by heating to 300°. Absolute alcohol reacts with it in the same manner as with monomethyl borate, but less energetically, the action requiring a high temperature to complete it:

METHYLIC BORATES.—The *trimethyl ether*, $B(CH^3)O^3$, is prepared, like the corresponding ethyl-compound, by heating boric oxide with methyl alcohol to 100°, then distilling and treating the distillate with strong sulphuric acid, whereby two strata of liquid are formed, the upper containing the trimethyl borate. Schiff, however, did not obtain it pure. The specific gravity of his product was 0.915 at 20°, and 0.940 at 0°. Ebelen and Bouquet found the density to be 0.955 at 0° for an ether boiling at 72°. The reactions of this ether are analogous to those of triethyl borate. It burns with a flame green throughout, whereas that of triethyl borate is colourless in the middle, the difference arising mainly from the larger proportion of boron in the methyl ether. For this reason, as originally pointed out by Ebelen, it is better, in testing for boron by the colour of its flame, to use methyl ether instead of ethylic alcohol.

Monomethyl borate, $B(CH^3)O^2$, is prepared from the preceding compound in the same manner as the monomethyl from the triethyl ether. It is much less mobile than the monomethyl borate, but resembles the latter in all its chemical reactions. It begins to decompose at 160°, giving off trimethyl borate; and at 250° there remains a mass which, when purified, after cooling, with anhydrous ethyl oxide, exhibits the composition of *methyl triborate*, $B^3(CH^3)O^3$, or $B(CH^3)O^2 \cdot B^2O^3$. This ether colours flame green, forms trimethyl borate when heated with methyl alcohol, and is decomposed by water into monomethyl borate and boric acid.

The ether $B(CH^3)^2O^2$, described by Ebelen, appears to have been a mixture of monomethyl borate and triborate.

AMYLIC BORATES.—The *triarmylic ether* and *monarmylic ethers* were prepared similarly to the corresponding ethyl-compounds. The former may also be produced by decomposing triethyl borate with amylic alcohol at 160°–180°; but other ethers are formed at the same time, and the purification of the triarmylic ether is difficult. This ether boils, according to Schiff, at 254° with the barometer at 760 mm. Ebelen and Bouquet give 270°–275°, but they state that their determination was made with only a small quantity of impure substance. The reactions of this ether resemble those of the corresponding ethyl-compound, but it burns only with the aid of a wick, and the flame exhibits a green colour only at the base near the wick.

The *monarmylic ether* $B(C^2H^{11})O^2$, obtained by heating the crude product of the action of boric oxide on amylic alcohol to 290°, has a density of 0.949 at 20°, and 0.971 at 0°. It is much more fluid than the corresponding ethyl and methyl compounds, and burns like the triarmylic ether. It sustains a temperature of 300° without sensible alteration, but above that temperature it decomposes, a mixture of mono- and tri-armylic borate distilling over, and a vitreous mass being ultimately left, consisting of *amylic triborate*, $B^3(C^2H^{11})O^3$, mixed with boric oxide, charcoal, and other impurities. Monarmylic borate may also be prepared by the action of boric oxide on triarmylic borate; and, on the other hand, the action of amylic alcohol on monarmylic borate yields the triarmylic compound:

MIXED BORIC ETHERS.—These ethers may be prepared by treating a mono-alcoholic borate with an alcohol different from that whose radicle is contained in the ether. Thus with monomethyl borate and amylic alcohol are obtained the following:

At the same time, however, another reaction takes place, producing the simple trialcoholic borates, though in quantity smaller than that of the mixed ethers:

The several products are separated by fractional distillation.

Ethyl-diamylic borate, $B(C^2H^5)(C^2H^{11})O^3$, boils at 210°–215°, has a density of

0.852 at 28°, and 0.876 at 0°. It burns, like triamyllic borate, only with a wick, but with a more deeply coloured flame. *Amylo-diethyllic borate*, $B(C^2H^{11})(C^2H^9)O^2$, boils at about 172°–175°, and has a density of 0.858 at 26°; burns without a wick, but not so easily as triethyllic borate. These two mixed ethers act chemically like the other trialkoholic borates. An excess of amyl alcohol acts upon them at 160°–180°, with elimination of ethylic alcohol, and formation of triamyllic borate: this explains the presence of a rather large proportion of triamyllic borate in the product of the reaction of amyllic alcohol on monethyllic borate. The following equation embraces all the products which this reaction has yielded:

Altogether, the reaction of alcohols on the mono-alcoholic borates is very complicated; and for the further consideration of the products we must refer to the paper cited at the head of this article.

CETYLIC BORATE. $B(C^{16}H^{33})O^2$.—The action of boric oxide on cetylic alcohol differs from that which it exerts on the lower alcohols of the series, in this respect, that the water eliminated by the reaction, instead of uniting with the boric oxide to form boric acid, is set free in the liquid state, the difference apparently depending upon the higher temperature at which the action takes place. The boric oxide in excess is introduced in small lumps, together with the cetylic alcohol, into a short-necked retort, and heated as long as water separates. The fused mass is then decanted, digested when cold with anhydrous ether, and the decanted solution is evaporated. In this manner, *monocetylic borate*, $B(C^{16}H^{33})O^2$, is obtained, as a white or yellowish mass resembling cetylic alcohol, but somewhat less crystalline; it melts at 58°. The fused substance is permanent in dry air; slowly decomposed by moist air and by cold water, quickly by hot water. It is scarcely inflammable, even with the aid of a wick; dissolves but slightly in benzol. The mode of its formation may be thus expressed:

The other cetylic borates have not been obtained.

GLYCERIC BORATE. $B^2(C^3H^5)^2O^3$.—Coarsely pounded boric oxide dissolves, with elimination of aqueous vapour, in anhydrous glycerin heated to 200°; and if the mixture be kept hot as long as aqueous vapour continues to escape, two molecules of glycerin will dissolve one molecule of boric acid, forming glyceric borate, according to the equation:

The fused mass separated by decantation from the unaltered boric oxide forms, on cooling, a pale yellow, horny, transparent substance, very hygroscopic, insoluble in ether, benzol, and chloroform. It dissolves in absolute alcohol without alteration, a property which shows it to be a saturated compound, inasmuch as all the unsaturated boric ethers are decomposed by alcohol. The alcoholic solution, evaporated at 50°–60°, leaves the glyceric borate unaltered; but if the compound be heated to 120° in a sealed tube with absolute alcohol, it is decomposed in the manner shown by the equation:

Glyceric borate dissolves without alteration in a small quantity of cold water; but on heating it, the dense, somewhat acid solution suddenly conglutinates to a dense mass, and acquires a sweet taste, being in fact resolved into boric hydrate and glycerin. It has no fixed melting point, but behaves like a vitreous substance, gradually softening at about 170°. Ammonia gas does not act upon it, unless moisture is present, in which case a gelatinous mass is formed, containing ammonia borate. Strong sulphuric acid blackens glyceric borate even at 100°.

From the observations of Schützenberger (*Compt. rend.* liiii. 538), it appears that boric oxide and *acetic oxide* unite directly in the proportion of B^2O^3 to $C^2H^4O^2$, forming a vitreous substance, which is decomposed by water into boric and acetic acids, and therefore consists of *acetic borate*, $B(C^2H^3)O^2$.

PHENYLIC BORATES.—Boric oxide acts upon phenol at high temperatures in the same manner as on cetylic alcohol and glycerin, giving rise to direct elimination of water, producing however not merely one, but several boric ethers. When two parts of boric oxide are heated with three parts of phenol, and the mixture is cooled after reacting for half an hour, a syrupy liquid is obtained, from which ether extracts monophenyllic borate, $B(C^6H^5)O^2$:

As thus prepared, however, it is very impure. A purer product is obtained by heating phenylic triborate to 150° with ethylic alcohol, whereby monophenylic borate is produced, together with triethylic borate and boric acid :

The product is freed from triethylic borate by distillation, ultimately at 180° , and the monophenylic borate is extracted from the residue by solution in ether and evaporation. Thus obtained, it is a yellow substance having a faint odour and the consistence of turpentine.

Phenylic triborate, $B^3(C^6H^5)O^3$, is formed when phenol is boiled for several hours with boric oxide in a flask fitted with a condensing tube; an additional quantity of boric oxide then dissolves, and lastly also the boric hydrate formed at the commencement of the action, together with the monophenylic ether, in the manner shown by the last equation but one. The phenylic triborate is produced by the reaction of this boric hydrate and the oxide on the phenylic monoborate, thus :

Phenylic triborate, when freed from excess of boric acid by means of anhydrous ether, forms an orange-coloured vitreous mass, having a faint odour and internally the aspect of amber. It is slowly decomposed by moist air and cold water, quickly by hot water and dilute aqueous alkalis. Alcoholic potash scarcely attacks it, probably because potassium borate is insoluble in alcohol. It is almost insoluble in benzol, chloroform, and carbon bisulphide; begins to soften at about 80° , but does not exhibit any definite melting point. The alcoholic solution is not coloured violet by ferric chloride. The triborate dissolves in hot strong sulphuric acid; and on adding water, boric acid is deposited, and a solution of phenylsulphuric acid is obtained :

With hot nitric acid, it yields boric and picric acids :

Tetraphenylic diborate, $B^2(C^6H^5)^4O^5$, is produced, together with phenylic triborate, when monophenylic monoborate is heated to temperatures above 350° :

To complete the reaction, the temperature must be raised considerably above the boiling point of mercury. The yellow oil which passes over on distillation is rectified, and that which distils above 300° is collected apart. The tetraphenylic ether is also formed, together with ethylic phenate and common alcohol, by heating triethylic borate to 160° – 180° in a sealed tube with phenol :

Tetraphenylic diborate is a greenish-yellow oil, having a faint odour of phenol, a density of 1.100 at 20° , and 1.124 at 0° , at which latter temperature it has the consistence of castor oil. Its boiling point is above that of mercury. At each distillation it undergoes partial decomposition, leaving a residue of phenylic triborate. It is quickly decomposed by water. With strong sulphuric acid it forms a red-brown solution, which, when heated and poured into water, forms a deposit of boric acid and a solution of phenylsulphuric acid :

There are no mixed boric ethers containing phenyl.

BORIC ANILIDE. $B^2O^3 \cdot C^6H^5N$.—Aniline does not unite directly with boric oxide or boric hydrate, neither does it decompose the triethylic boric ethers when heated therewith; but when it is mixed with monethylic or monomethylic borate, the liquid becomes hot, and is transformed into a resinous mass which becomes pulverulent when treated with anhydrous ether. This mass contains the elements of boric oxide and aniline, and may be regarded as *hydrated diboric anilide*, or as *boranilic acid*, according to the formulæ :

Its formation is represented by the equation :

Boric anilide is a white, inodorous substance, as light as magnesia, and unalterable in dry air, if it has been thoroughly washed with ether. Water decomposes it immediately.

into aniline and boric acid. Alcohol dissolves it readily, and leaves it on evaporation in the form of a gummy mass; but when heated in a sealed tube with alcohol to 120° it is resolved into aniline, triethyllic borate, and boric acid:

It dissolves in strong sulphuric acid, forming a red-brown liquid, which blackens at a slightly elevated temperature without evolution of gas. The alcoholic solution of the anilide mixed with oxalic acid, also in alcoholic solution, yields a precipitate of aniline oxalate unmixed with boric acid; with platinic chloride also a precipitate of pure aniline platinochloride is obtained. With aldehydes it reacts like free aniline, forming diamides; thus with cænanthol:

Heated to 110°, it gives off water, and leaves a gummy amorphous body, which, when pure, probably consists of $\text{N}(\text{BO})^2(\text{C}^6\text{H}^5)$.

The action of monethyllic borate on ammonia dissolved in anhydrous ether is not analogous to its reaction with aniline, the product containing at least 2 mol. B^2O^3 to 1 mol. NH^3 . The white flocculent substance when heated gives off ammonia and water, and if the residue be exhausted with boiling water, a white powder is left, consisting of boron nitride:

Boric oxide heated in a current of dry ammonia gas is also partially converted into boron nitride; but the quantity of this substance formed in either case is but small.

BORONATROCALCITE. This name, as well as *Hydroborocalcite*, *Hayesin*, and *Tiza*, is applied to a mineral composed of the borates of calcium and sodium, found chiefly in the province of Tarapaca in Peru, and now extensively used for the manufacture of boric acid and the alkaline borates. It occurs in nodular masses of fibrous structure, often mixed with glauberite and common salt. The numerous analyses of the mineral—even when it is freed as far as possible from these admixtures—exhibit great diversities of composition, so that several formulæ have been assigned to it. Rammelsberg (*Mineralchemie*, p. 252) regards it as $(\text{Na}^2\text{O} \cdot 2\text{B}^2\text{O}^3) + 2(\text{CaO} \cdot \text{B}^2\text{O}^3) + 18\text{aq.}$, or $(\text{Na}^2\text{O} \cdot 2\text{B}^2\text{O}^3 \cdot 10\text{aq.}) + 2(\text{CaO} \cdot 2\text{B}^2\text{O}^3 \cdot 4\text{aq.})$; i.e. as 1 mol. of borax combined with 2 mol. of the borocalcite. Phipson (*Chem. News*, iv. 182) gives the formula $(\text{Na}^2\text{O} \cdot 2\text{B}^2\text{O}^3 \cdot 10\text{aq.}) + 2(\text{CaO} \cdot \text{B}^2\text{O}^3 \cdot 2\text{aq.}) + 2\text{aq.}$ Kraut (*Arch. Pharm.* [2] cxii. 25) gives $(\text{Na}^2\text{O} \cdot 2\text{B}^2\text{O}^3) + (2\text{CaO} \cdot 3\text{B}^2\text{O}^3) + 15\text{aq.}$; and Lunge (*Ann. Ch. Pharm.* cxxxviii. 56), from his analysis of a specimen from Chile, deduces the formula

For analyses, see *Jahresbericht f. Chem.* 1849, p. 799; 1853, p. 852; 1854, p. 867; 1856, p. 884; 1857, p. 697; 1858, p. 737; 1859, p. 816; 1861, p. 1028; 1862, p. 759; 1866, p. 953; also, Richardson and Watts's *Chemical Technology*, pt. iv. pp. 209–211.

NOTALLACKITE. See COPPER OXYCHLORIDES.

BOURBOULITE. This name is given by Lefort (*Compt. rend.* lv. 919) to a blue ferrous-ferric sulphate found, together with larger quantities of a greenish-yellow salt of similar composition, in the pyritiferous pumice-tufas of Bourboul (Puy-de-Dôme). The blue salt is regarded by Lefort as identical with the salt $3(\text{FeO} \cdot \text{SO}^3) + 2(\text{Fe}^2\text{O}^3 \cdot \text{SO}^3)$ artificially prepared by Barreswil.

BOURNONITE. $\text{Cu}^2\text{PbSbS}^3$ or $\text{Cu}^2\text{S} \cdot 2\text{PbS} \cdot \text{Sb}^3\text{S}^3$.—The primary form of this mineral is an orthorhombic prism of $93^\circ 40'$; $\alpha\text{P} : \text{P}\infty = 138^\circ 6'$. Axes $a : b : c = 0.662 : 1 : 0.95618$. For details of the crystalline form, see Zirkel, *Jahresb.* 1862, p. 711; Hessenberg, *ibid.* 1865, p. 798.

BRAGITE. The greyish-brown mineral from Arendal in Norway thus named by Forbes & Dahl (i. 657) appears, from an analysis by J. A. Michaelson (*J. pr. Chem.* xc. 108; *Jahresb.* 1863, p. 830), to be a niobate of yttrium, and identical with tyrite and fergusonite. (See Niobium, iv. 55.)

BRASSIDIC ACID. $\text{C}^{18}\text{H}^{32}\text{O}^2$.—An acid standing to erucic acid in the same relation as elaidic to oleic acid. It is obtained by heating erucic acid with dilute

nitric acid to 60°–70°, till gas begins to escape, and then cooling the mixture. The solidified product recrystallised from alcohol yields brassidic acid in white laminae, melting at 70°, and solidifying again in the crystalline form at 54°. Brassidic acid is a strong monobasic acid, less soluble in alcohol and ether than erucic acid; its alcoholic solution reddens litmus-paper. The sodium salt $C^{22}H^{41}NaO^2$ crystallises from alcohol in laminae, which easily become electric by friction, like those of the acid, and do not melt till heated above 200°. The potassium salt crystallises in scales; the magnesium salt may be crystallised from alcohol. The barium, calcium, lead, and silver salts are insoluble in water and in alcohol.

Brassidic acid, like erucic acid, unites with 1 mol. of bromine, forming brassidic acid bromide, $C^{22}H^{40}Br^2$, which separates from alcohol in small colourless crystals melting at 54° and solidifying at 38°–40°. It is attacked at 210° by alcoholic potash, which abstracts 2HBr, and converts it into benolic acid, $C^{22}H^{40}O^2$. When left in contact for eight or ten days with sodium-amalgam, it gives up all its bromine, reproducing brassidic acid (Haussknecht, *Ann. Ch. Pharm.* cxliii. 40).

BRASSYLIC ACID. $C^{11}H^{20}O^4$.—This acid, homologous with oxalic acid, is produced, together with the corresponding aldehyde and dioxybenolic acid, by the action of fuming nitric acid on benolic acid (p. 257). On subjecting the yellow oil which separates from the alcoholic mother-liquor of benolic acid to distillation with steam, brassylic aldehyde, $C^{11}H^{20}O^3$, passes over as a pungent oil, and the residue in the retort solidifies to a network of crystals consisting of benolic, dioxybenolic, and brassylic acids. The last-mentioned acid is obtained pure by leaving either the crude or the distilled oil under bromine and water for several days, and recrystallising the solid acid thereby produced from hot water. Brassylic acid melts at 108.5° and solidifies at 105°. It is nearly insoluble in cold water, slightly soluble in boiling water, easily in alcohol and ether. It is formed from the aldehyde by simple addition of oxygen; also, perhaps together with other acids of the same series, by the action of red fuming nitric acid on erucic acid. It is *bisacetic*. The brassylates of the alkali-metals are soluble in water; the sodium and ammonium salts crystallise in nodules; the calcium salt contains $C^{11}H^{18}CaO^4 \cdot 3H_2O$; the silver salt $C^{11}H^{18}AgO^4$ turns violet on exposure to light (Haussknecht, *loc. cit.*).

BRAYERA ANTHELMINTICA. The flowers of this plant, mixed with the peduncles and fragments of the leaves, constitute the drug called *Kusso* or *Koussou*, which is used as a remedy for tape-worm. Pavesi (*J. Pharm. d'Anvers*, Oct. 1858; *Jahresb.* 1859, p. 585) attributes the anthelmintic action of the drug to a substance, called kussin or taonin, which he prepares by repeatedly digesting the kusso, mixed with slaked lime, in alcohol of 60°–70° p. c., boiling the residue with water, uniting the filtered extracts, distilling off the alcohol, and mixing the aqueous residue with a slight excess of acetic acid. The kussin, purified by solution in alcohol and treatment with animal charcoal, and precipitated from the concentrated alcoholic solution by water, is a brittle resin having a dark yellow colour in powder, a slightly bitter taste, like that of koussou itself, soluble in alkalis, not in acids, melting at 100°, and decomposing at a higher temperature. It amounts to 4 p. c. of the kusso. According to C. Bedall (*Chem. Centr.* 1863, p. 124), kussin melts, with decomposition, at 193°–195°. It is not a glucoside. Its formula is $C^{28}H^{44}O^8$. Its alcoholic solution gives with lead acetate a precipitate containing $C^{28}H^{44}O^8 \cdot PbO$.

BRAZILIN, the colouring matter of Brazil wood, discovered by Chevreul, has been shown by Bolley to be identical with that of sapan wood (v. 191). The statements respecting this colouring matter given in vol. i. p. 555, on the authority of Frésser, are not to be trusted.

BROCHANTITE. Native tetracupric sulphate. $CuSO^4 \cdot 3CuH^4O^4$. See SULPHATES.

BROMINE. According to J. Slessor (*New Edinb. Phil. J.* vii. 287), aqueous solutions of bromine of different densities contain the following quantities by weight of bromine in 1,000 parts of water:

Density	Br. per 1,000	Density	Br. per 1,000
1.00901	10.72	1.01491	18.70 to 19.06
1.00931	10.78	1.01585	19.52 " 20.09
1.00995	12.05	1.01807	20.89 " 21.55
1.01223	12.3	1.02367	31.02 " 31.66

At the density of 1.02367 bromine-water is saturated.

Dancer (*Chem. Soc. J.* xv. 477) has determined the solubility of bromine in water at different temperatures:

Temp.	Br. per cent.	Temp.	Br. per cent.
5°	3.600	20°	3.208
10°	3.327	25°	3.167
15°	3.226	30°	3.126

When a current of electricity is passed through bromine-water or aqueous hydrobromic acid, bromic acid is formed at the positive pole.

Bromine-vapour bleaches moist litmus-paper, but not permanently, the paper on exposure to the air turning red in consequence of the formation of hydrobromic acid: the original colour is restored by ammonia (Reinsch, *N. Jahresh. Pharm.* xi. 269).

Bromine in presence of water, and under the influence of direct sunshine, oxidises many neutral organic compounds and converts them into acids: such is the case with benzene, toluene, mannite, sugar, glycerin, &c. (Blomstrand, *Ann. Ch. Pharm.* cxxiii. 248).

Detection and Estimation of Bromine.—Fresenius (*Zeitschr. anal. Chem.* i. 46) recommends the use of chloroform or carbon bisulphide instead of ether in testing for bromine by means of chlorine. In a liquid containing only $\frac{1}{25000}$ part of bromine, ether does not become coloured after addition of chlorine; but chloroform or carbon bisulphide under the same circumstances exhibits a pale yellow colour. A solution containing only $\frac{1}{35000}$ of bromine colours carbon bisulphide, but not chloroform. If an iodide is also present, the violet coloration due to the iodine is first observed, and when this has been made to disappear by further addition of chlorine, the yellow tint of the bromine becomes apparent. Phipson (*ibid.* vii. 97) acidulates the dilute solution with hydrochloric acid, mixes it in a tube two feet long with a small quantity of carbon bisulphide, and agitates it with a strong solution of chloride of lime.

Reimann (*Ann. Ch. Pharm.* cxv. 140) estimates bromine, in presence of iodine and chlorine, by means of a graduated solution of chlorine. Thus, to analyse a mixture of bromide and iodide of potassium, a quantity of chloroform is first added, such that, after agitation, a drop about the size of a nut may remain undissolved, and the graduated chlorine-water is added by small portions. The chloroform then acquires a blue or rose colour, which disappears completely as soon as 6 atoms of chlorine have been added to 1 mol. of the iodide, the ultimate products of the reaction being potassium iodate and hydrochloric acid:

On continuing the addition of the chlorine-water, the chloroform becomes first yellow, then orange-coloured, then again yellow, and finally, when 2 at. chlorine have been added to 1 at. bromine, yellowish-white:

If organic substances are present, the liquid must be previously mixed with caustic soda, evaporated to dryness, and the residue ignited in a silver dish.

The following method, founded, like that of Field (i. 678), on the differences between the atomic weights of chlorine, bromine, and iodine, is given by R. Tatlock (*Chem. News*, 1869, p. 290). The solution containing the iodine, bromine, and chlorine, preferably in combination with an alkali-metal, is divided into three equal portions, one of which is treated with excess of silver nitrate to precipitate the whole of the iodine, bromine, and chlorine. The second is treated with excess of bromine-water to decompose the iodide, and then precipitated with silver nitrate, which throws down bromide and chloride of silver. The third portion is treated with excess of chlorine to decompose the iodide and bromide, and yields a precipitate consisting wholly of silver chloride. These three precipitates having been weighed, the quantities of iodine, bromine, and chlorine may be calculated by the method given in vol. i. p. 679.

To apply this method to the analysis of kelp, the kelp is digested in hot water; the filtrate and washings are neutralised with hydrochloric acid; chlorine is passed into the solution; and the liquid is shaken up with about one-fourth its volume of carbon bisulphide to dissolve the liberated iodine and bromine. The heavy, coloured solution of these elements is then drawn off by a fine syphon, and shaken up with water and zinc-filings, whereby a solution of zinc bromide and iodide is obtained, in which the iodine and bromine may be estimated as above.

For the estimation of bromine in organic compounds, see ANALYSIS, ORGANIC (p. 148).

Bromides. *Hydrogen Bromide* or *Hydrobromic Acid* is produced directly by subjecting a mixture of dry bromine-vapour and hydrogen gas to the prolonged action of the induction-spark (A. Riche, *Compt. rend.* xlv. 348).

Kekulé (*Ann. Ch. Pharm.* cxxx. 14) prepares pure aqueous hydrobromic acid by passing the gas evolved by allowing a slow stream of water to flow upon phosphorous tribromide, into water or dilute hydrobromic acid, till a saturated solution is formed; heating this solution (which still contains a considerable quantity of phosphorous bromide); and passing the gas thereby evolved either into pure water or into pure dilute hydrobromic acid.

Metallic Bromides.—According to Henner a. Hohenhauser (*Jahresb.* 1864, p. 148), the process recommended by Klein for the preparation of metallic bromides (see POTASSIUM BROMIDE, iv. 696) is not adapted for production on the large scale. These chemists dissolve bromine in a slight excess of barium or calcium hydrate; evaporate the clear liquid to the crystallising point; precipitate the bromates (to be reduced to bromides by ignition with charcoal) with alcohol of 90 p. c., then distil off the alcohol, and evaporate the remaining liquid to the crystallising point.

Potassium bromide is most easily prepared from the barium salt by precipitation with potassium sulphate.

Chloride of Bromine. When a light yellow mixture of equal volumes of saturated chlorine-water and of bromine-water containing 1 p. c. bromine, is treated with oxidisable substances, it first assumes a brown-red colour, and then, on further addition of the oxidisable substance, becomes perfectly colourless. This reaction is produced by finely divided sulphur or phosphorus, zinc or iron filings, ferrous or stannous salts, nitrogen dioxide and tetroxide, sulphurous, hypophosphorous, phosphorous, arsenious, oxalic, and formic acids, hydrogen dioxide, and ammonia. The chlorine, under these circumstances, is converted into hydrochloric acid, and if the quantity of the reducing agent is sufficient, the bromine is likewise converted into hydrobromic acid. Oxalic acid alone exhibits an exception to this general rule, being oxidised by chlorine, but not by bromine, and therefore colouring the liquid brown, even when in considerable excess. Hydrogen dioxide is resolved into oxygen and hydrogen, which latter unites with the chlorine and bromine. Ether shaken up with the yellow solution takes up the bromine chloride, forming a solution which exhibits the reactions above described. These reactions show that bromine may be detected in presence of free chlorine by the cautious addition of reducing agents (Schönbein, *Ann. Ch. Pharm. Suppl.* ii. 211).

Oxygen-acids of Bromine.

Bromic Acid. HBrO^3 .—According to Kämmerer (*J. pr. Chem.* lxxxv. 452), this acid, prepared by the usual method of decomposing a metallic bromate with an acid, is not pure, because the decomposition of bromates by the stronger acids is never complete. It may, however, be obtained absolutely pure by the direct action of chlorine on aqueous bromine, or by decomposing silver bromate with bromine:

Kämmerer obtained a hydrated bromic acid containing $\text{HBrO}^3 \cdot 7\text{H}^2\text{O}$, and is of opinion that another hydrate, $2\text{HBrO}^3 \cdot 9\text{H}^2\text{O}$, exists at very low temperatures.

The bromates of the *alkali-metals* are advantageously prepared by passing bromine into solutions of alkaline carbonates, previously saturated with chlorine till they begin to effervesce; the ultimate products of the reaction are chlorine gas, which escapes, and nearly pure bromate of the alkali-metal. From either of these salts the bromate of silver may be obtained by double decomposition.

Didymium bromate, $\text{Di}(\text{BrO}^3)^2 \cdot 6\text{H}^2\text{O}$, crystallises in rose-red hexagonal prisms $\infty \text{P} : \text{P}$; P, permanent in the air, seldom distinctly developed at the ends. Angle $\text{P} : \text{P}$ in the terminal edges = $147^\circ 58'$, in the lateral edges = 67° . Cleavage distinct parallel to ∞P . *Lanthanum bromate* forms crystals of similar character (Marignac, *Ann. Min.* [5] xv. 272).

Perbromic acid, HBrO^4 , is produced by the action of bromine on perchloric acid (iv. 374).

Hypobromous acid, HBrO , is formed by the action of bromine and water on silver nitrate and on mercuric oxide (iii. 237); also, according to Schönbein (*Jahresb.* 1862, p. 66), on mercuric chloride, nitrate, or acetate.

BROMOFORM. CHBr^3 .—Produced from dibromosuccinic acid by the action of bromine in excess in presence of water (Kekulé, *Ann. Ch. Pharm. Suppl.* i. 354):

Sup.

B B

Decomposed by ammonia, with formation of bromide and cyanide of ammonium (Cloeze, *Compt. rend.* xlv. 344):

It acts strongly on zinc-ethyl, producing ethyl bromide, zinc bromide, and propylene (Alexeyeff n. Beilstein, *Bull. Soc. Chim.* [2] ii. 51):

BROMOXAFORM, $\text{C}^3\text{HBr}^3\text{O}^2$, originally obtained by Cahours by the action of bromine on solution of potassium citrate (i. 996), is likewise formed, under certain circumstances, by the action of an excess of bromine on dibromocitraconic acid:

It is separated from the distillate by water as a heavy oil which soon solidifies. It melts at 77° , dissolves easily in alcohol and ether, and crystallises from the former in long hard needles, from the latter in thick transparent prisms. By distillation with potash, it yields bromoform; with alcoholic ammonia, dibromacetamide (Cahours, *Ann. Ch. Phys.* [3] lxvii. 129; *Jahresb.* 1862, p. 318).

BRUCINE. $\text{C}^{22}\text{H}^{28}\text{N}^2\text{O}^4$.—According to Wittstein (*Arch. Pharm.* [2] c. 129; cix. 28), this alkalioid exists, together with strychnine, in the urari or curara poison (ii. 185); but according to Buchner (*ibid.* ex. 19), this poison contains curarine, but neither strychnine nor brucine.

Brucine heated in a small cup of platinum-foil covered with a watchglass (p. 87) yields a granular sublimate which becomes crystalline by contact with sulphuric or nitric acid, and is converted by ammonia into a deep yellow amorphous mass, and by chromic acid into dark yellow stars or rosettes formed of short prisms (Helwig, *Zeitschr. anal. Chem.* iii. 43). With *phosphomolybdic acid*, brucine forms an orange precipitate, which dissolves in ammonia with yellow-green colour, turning brown on boiling (Trapp, *Jahresb.* 1863, p. 702). According to F. F. Mayer (*Rép. Chim. app.* v. 102), a solution of brucine containing 1 pt. in 50,000 produces a perceptible precipitate with a solution of *potassio-mercuric iodide* formed by dissolving 13.546 grms. mercuric chloride ($\frac{1}{10}$ eq.) and 49.8 grms. potassium iodide in a litre of water. This reaction may be used for the quantitative estimation of brucine (iii. 1053).

When a strong solution of *sodium sulphhydrate* is added to a solution of brucine in nitric acid heated to 40° – 50° , the liquid assumes at first a violet colour, and after the sodium salt has been added in excess, a fine green colour, which is not altered by alkalis, but is changed by dilute acids into rose-red, with evolution of hydrogen sulphide. After a day or two the green colour disappears, and a greenish precipitate appears. This mode of testing, if well performed, will reveal the presence of 0.002 grm. brucine in half a litre of water (S. Cotton, *Zeitschr. f. Chem.* [2] v. 728).

Brucine treated with a chlorate or with chlorine tetroxide in presence of strong sulphuric acid, assumes an orange-red colour, which does not turn violet on addition of stannous chloride. Free chloric and perchloric acids do not exhibit this reaction (Luck, *ibid.* vi. 276).

Methyl-brucine. $\text{C}^{22}\text{H}^{24}(\text{CH}^3)\text{N}^2\text{O}^4$.—Brucine is converted by methyl iodide, with evolution of heat, into *methyl-brucine hydriodide*, $\text{C}^{22}\text{H}^{24}(\text{CH}^3)\text{N}^2\text{O}^4$.III, or *methyl-brucium iodide*, $\text{C}^{22}\text{H}^{24}(\text{CH}^3)\text{N}^2\text{O}^4$.I, which crystallises from boiling water in shining laminae containing 8 mol. water of crystallisation. It is not further altered by repeated treatment with methyl iodide. By decomposing this salt with recently precipitated silver iodide (or the sulphate with baryta-water) a solution of the free base is obtained, which is colourless at first, but soon turns violet, and when evaporated gives off carbon dioxide and leaves a dark-coloured uncrystallisable syrup, apparently containing a base different from methyl-brucine. The *hydrobromide* of *methyl-brucine*, $\text{C}^{22}\text{H}^{24}\text{N}^2\text{O}^4$.HBr + $\frac{1}{2}$ aq., is formed on mixing the hydrochloride with potassium bromide, as a crystalline precipitate which dissolves easily in alcohol and water, and crystallises from the latter in small shining crystals, easily soluble in water at 130° . The *hydrochloride*, $\text{C}^{22}\text{H}^{24}\text{N}^2\text{O}^4$.HCl + $\frac{1}{2}$ aq., obtained by neutralising the free base with hydrochloric acid, forms small shining crystals, easily soluble in water and in alcohol. The *platinochloride*, $2(\text{C}^{22}\text{H}^{24}\text{N}^2\text{O}^4$.HCl).PtCl $_4$, is a yellow precipitate, insoluble in ether, easily soluble in alcohol and in water, and crystallises from the latter in needles. The *aurochloride*, $\text{C}^{22}\text{H}^{24}\text{N}^2\text{O}^4$.HCl.AuCl $_3$, is an orange-yellow precipitate slightly soluble in cold water. Mercuric chloride added to the solution of the hydrochloride forms a white precipitate. The *neutral sulphate*, $(\text{C}^{22}\text{H}^{24}\text{N}^2\text{O}^4)^2$.H $_2$ SO $_4$ + 8 aq., obtained by decomposing the hydriodide with silver sulphate, forms a radiate crystalline mass easily soluble in water and in alcohol. An

acid sulphate, $C^{23}H^{22}N^2O^4 \cdot H^2SO^4 + 2aq.$, obtained from the preceding by addition of dilute sulphuric acid, forms indistinct crystals, somewhat easily soluble in water and in alcohol. Methyl-brucine given in the form of sulphate to rabbits in doses of ten grains exerts no poisonous action (Stahlschmidt, *Pogg. Ann.* cviii. 513; *Jahresb.* 1859, p. 398).

The experiments of Crum-Brown & Fraser (*Edin. Phil. Trans.* vol. xxv.) have also shown that the salts of methyl-brucine are much less poisonous than those of brucine; moreover, their physiological action is different from that of brucine: the latter is a violent convulsive poison, whereas its methyl-derivatives, though fatal in large doses, never produce convulsions.

Ethyl-brucine, $C^{23}H^{24}(C^2H^5)N^2O^4$, is described in vol. i. p. 684.

Brucine-bromethylammonium, $C^{23}H^{22}N^2Br^2O^4$.—Brucine unites directly with ethylene bromide when the two are heated together to 100° , forming a clear liquid, which on cooling solidifies to a crystalline mass, and when recrystallised from boiling water forms furcate groups of nacreous laminae, easily soluble in water, sparingly soluble in alcohol, insoluble in ether. This compound, which contains the elements of brucine and ethylene bromide, may be regarded as *Brucine-bromethylammonium bromide*, $C^{23}H^{22}N^2O^4 \cdot (C^2H^5Br)$, the brucine exhibiting the functions of a tertiary amine.

The crystals when air-dried contain 3 molecules of water. The solution of this bromide is not precipitated by ammonia or the fixed alkalis. Silver nitrate throws down half, and recently precipitated silver oxide at the boiling heat the whole of the bromine as silver bromide. The corresponding *platinochloride*, $2(C^{23}H^{22}N^2O^4 \cdot C^2H^5BrCl) \cdot PtCl^4$, is an orange-yellow crystalline precipitate.

Brucine-vinylammonium hydrate, $C^{23}H^{22}N^2O^4 \cdot C^2H^5(OH)$, is the base formed by treating the aqueous solution of the above-described bromide with moist silver oxide. The resulting solution has a strong alkaline reaction, absorbs carbonic acid from the air, and dries up to a brown varnish exhibiting traces of crystallisation. Its *platinum salt* has the composition $2(C^{23}H^{22}N^2O^4 \cdot C^2H^5Cl) \cdot PtCl^4$. An *acid sulphate*, forming hydrated crystals, is obtained by treating the base with excess of dilute sulphuric acid (L. Schud, *Ann. Ch. Pharm.* cxviii. 207).

Periodides of Brucine (S. M. Jørgensen, *Ann. Ch. Phys.* [4] xi. 114).—*Brucine Hydro-triiodide*, $C^{23}H^{22}N^2O^4 \cdot HI^3$, or *Brucium Tri-iodide*, $C^{23}H^{22}N^2O^4 \cdot I^3$, is obtained, by mixing brucine sulphate with a solution of iodine in potassium iodide, as a brown-red precipitate crystallising from alcohol in long brown-violet needles, which in polarised light appear light yellow when their longitudinal axis is parallel to the plane of polarisation, and purple-brown with blue shade when the same axis is at right angles to the plane of polarisation.

Brucine Methyl-triiodide, $C^{23}H^{22}N^2O^4 \cdot CHI^3$, or *Methyl-brucium Tri-iodide*, $C^{23}H^{22}(CHI^3)N^2O^4 \cdot I^3$, crystallises from a mixture of 1 mol. methyl-brucium iodide and 2 at. iodine, in *rosettes* of brown-red laminae, which are yellowish-red by transmitted, dark blue by reflected light, and have no action on polarised light. *Methyl-brucium Penta-iodide*, $C^{23}H^{22}(CHI^3)N^2O^4 \cdot I^5$, separates from the solution of the last-described compound in tincture of iodine, in nearly black prisms, which are blue by reflected light, and in polarised light appear opaque and black, or more or less dark red, accordingly as their longitudinal axis is parallel or perpendicular to the plane of polarisation.

Ethyl-brucium Tri-iodide, $C^{23}H^{24}(C^2H^5)N^2O^4 \cdot I^3$, obtained like the methyl-compound, separates from alcohol in hemispherical groups of reddish-yellow crystals having a golden lustre, and exhibiting in mass the aspect of reduced copper. The *penta-iodide*, $C^{23}H^{24}(C^2H^5)N^2O^4 \cdot I^5$, crystallises in four-sided needles, which in ordinary light have a deep metallic green colour, and in polarised light appear opaque or a purple-red, accordingly as their longitudinal axis is parallel or perpendicular to the plane of polarisation.

Amyl-brucium Tri-iodide, $C^{23}H^{26}(C^4H^{11})N^2O^4 \cdot I^3$, crystallises in very thin yellowish-red needles which have a silky lustre; and in polarised light appear brown or yellow accordingly as their axis is parallel or perpendicular to the plane of polarisation. The *penta-iodide*, $C^{23}H^{26}(C^4H^{11})N^2O^4 \cdot I^5$, crystallises in long bluish-green, metallically lustrous rhombic needles, which, on account of their perfect opacity, cannot be examined in polarised light.

Allyl-brucium Tri-iodide, $C^{23}H^{24}(C^3H^5)N^2O^4 \cdot I^3$, obtained like the methyl-compound, forms stellate groups of brown crystals, which in polarised light are yellow or red according to their position. The *penta-iodide*, $C^{23}H^{24}(C^3H^5)N^2O^4 \cdot I^5$, crystallises in

splendid long four-sided needles having the colour and lustre of the wing-cases of cantharides. The crystals are mostly opaque; the thinner ones appear in polarised light, deep violet-red or opaque, accordingly as their axis is parallel or perpendicular to the plane of polarisation.

BRUCITE. MgH^2O^2 .—On the crystalline form of this mineral, see G. Rose (*Jahresb.* 1860, p. 753), Hessenberg (*ibid.* 1861, p. 989), and Brush (*ibid.* 1861, p. 990).

BRUSHITE. A dicalcic orthophosphate, $\text{Ca}^2\text{H}^2(\text{PO}^4)^2 \cdot 4\text{H}^2\text{O}$, occurring in small crystals in guano from the island of Avis in the Caribbean sea; also together with other calcic phosphates in the guano of Sombbrero. (See PHOSPHATES in this volume.)

BUCKWHEAT. *Polygonum fagopyrum*.—According to Nobbe a. Siegert (*Chem. Centr.* 1863, p. 296), whose results are corroborated by Leydhecker (*Jahresb.* 1867, p. 760), this plant forms ripe and germinating seeds only in soils containing potassium chloride or calcium chloride. In soils free from chlorine (containing only nitrates, sulphates, and phosphates) it grows, flowers, and begins to form fruit, but does not ripen its seeds. Even sodium or magnesium chloride cannot replace the chlorides of potassium and calcium.

J. W. Gunning (*Zeitschr. f. Chem.* [2] iv. 371) has analysed buckwheat flour with the following results:

	Friesland	French	Holstein
Water	15.39	15.29	15.17
Ash	1.08	0.94	0.82
Fat	1.98	1.96	1.63
Albuminous principles .	9.96	9.16	8.63
Starch	59.84	61.35	62.62
Cellulose	11.75	11.20	8.63

The yellow colouring matter of buckwheat (i. 686) has been further examined by Schunck (*Manchester Lit. and Phil. Soc. Memoirs*, 1858; *Jahresb.* 1859, p. 527), who assigns to it the formula $\text{C}^{12}\text{H}^{20}\text{O}^{10}$, and to its lead-salt the formula $\text{C}^{12}\text{H}^{12}\text{PbO}^{10}$. Schunck regards this colouring matter as identical with rutin and ilixanthin, though the preceding formula does not quite agree with the formulæ attributed to these compounds (iii. 244; v. 139).

BUCKLANDITE. (See ERIBOTE).—The mineral of this name from Lauch in the Eifel has been shown by v. Roth to be identical with orthite (iv. 238).

BUTALANINE. Syn. with AMIDOVALERIC ACID. (See VALERIC ACID, v. 978).

BUTAMYLENE. See AMYLENE.

BUTYL ALCOHOLS. These compounds have been described in vol. v. 732, under the title TETRYL ALCOHOLS. Recent researches, however, have somewhat modified the account to be given of them.

The butyl alcohol of fermentation is a *primary* alcohol, not the *normal primary*, as was believed until quite recently, but the abnormal or iso-primary. There are two varieties of primary butylic alcohol, viz. *Propyl-carbinol*, and *Isopropyl-carbinol*.

Propyl-carbinol or *Normal Primary Butylic alcohol*, $\text{C} \begin{cases} \text{CH}^3\text{CH}^2\text{CH}^3 \\ \text{H} \\ \text{H} \\ \text{OH} \end{cases}$

is comparatively little known, and has not hitherto been found as a natural product. It was obtained synthetically by Schöyen (*Ann. Ch. Pharm.* cxxx. 235) from ethyl gas, by submitting it to the action of chlorine and subsequent conversion of the resulting butyl chloride into butyl acetate, which latter product was transformed into the alcohol. A much more complete investigation of this compound has been just published by Lieben and Rossi (*Compt. rend.* lxxviii. [1869] 1561 *et seq.*). These chemists first prepared butyric aldehyde by distilling a mixture of butyrate and formate of calcium. From the aldehyde the alcohol was obtained by hydrogenation with sodium-amalgam. The alcohol, when perfectly dried, boils at 115°. It is considerably lighter than water. In smell it resembles isobutylic alcohol. It is very sparingly soluble in water. Treated with sodium, it gives sodium butylate, with disengagement of hydrogen gas. Iodine and phosphorus transform it into the iodide, boiling at 127°. Oxidation by means of dilute chromic acid gives normal butyric acid, unaccompanied by any other acid.

Isopropyl-carbinol or *Isoprimary-butyllic Alcohol*. $C \begin{cases} CH(CH^3) \\ H \\ H \\ OH \end{cases}$ — This

alcohol constitutes the butylic alcohol of Wurtz, which was extracted from fusel-oil. For a long time it was the only butyl alcohol known to chemists. Erlenmeyer and also Chapman have recently shown that this common butylic alcohol gives isobutyric acid, by oxidation with dilute chromic acid, and that therefore it is an iso-alcohol. On its occurrence in crude spirit, see Krämer a. Pinner (*Zeitschr. f. Chem.* [2] v. 690). It has recently been examined very completely by Chapman a. Smith (*Chem. Soc. J.* 1869 [2] vii. 153). Its boiling point is 109° , being sensibly lower than that of the normal alcohol. Sp. gr. = 0.8055 at 16.8° . It dissolves 1 at. sodium but slowly, and only on brisk agitation and warming; but calcium chloride, potassium acetate, and potassium hydrate are dissolved by it with facility. It mixes easily with glacial acetic acid, with the same acid diluted with twice its bulk of water, and with hydrochloric acid. It dissolves in about eleven times its own bulk of water. By strong sulphuric acid at -15° to -16° it appears to be completely converted into butyl-sulphuric acid; at ordinary temperatures chiefly into polymerides of butylene; with sulphuric acid diluted with three times its weight of water, it yields chiefly butyl-sulphuric acid. The dilute and gently warmed solution of this acid deposits, on addition of an excess of crystallised Glauber's salt, a colourless peculiar-smelling liquid which appears to be a hydrate of isobutyl alcohol, inasmuch as it is resolved by distillation into water and that alcohol.

Respecting the conversion of isobutyl alcohol into tertiary butyl alcohol, see p. 374.

The various compounds described in vol. v. as derivatives of normal butyl alcohol are in reality derivatives of isopropyl-carbinol. According to Chapman a. Smith, the iodide and bromide cannot be advantageously prepared by the action of iodine or bromine and phosphorus on isobutyl alcohol, since in both cases a large quantity of the alcohol is converted into butylene.

The bromide, C^4H^9Br , is best prepared by saturating the alcohol with gaseous hydrobromic acid, and then heating it to 100° in sealed tubes with an equal volume of aqueous hydrobromic acid of sp. gr. 1.6, till the separated oily layer no longer increases. On fractional distillation the greater part goes over at 92° , but a small portion having the same composition distils 16° or 17° lower. The colourless bromide boiling at 92° has a sp. gr. of 1.2702 at 16° , and behaves with reagents just like the iodide.

Isobutyl iodide, C^4H^9I , is most easily prepared by boiling the alcohol for thirty or forty minutes with four times its volume of hydriodic acid of sp. gr. 1.8. The greater part of the product distils constantly at 121° . Sp. gr. = 1.6301 at 0° ; 1.6032 at 16° ; 1.64816 at 50° . By alcoholic potash or sodium ethylate it is for the most part converted into butylene, only a small portion yielding butyl-ethyl oxide. Alcoholic ammonia converts it into butylamine, with little or no butylene. Heated with potassium acetate and glacial acetic acid, it is chiefly converted into isobutyl acetate, a small quantity of butylene being however formed at the same time. Heated with mercuric chloride it yields butyl chloride and a small quantity of butylene. Heated with zinc and ether, it gives off a large quantity of gas, and yields but little zinc-butyl. With sodium-amalgam and ethyl acetate it yields mercury-butyl, together with a large quantity of gas. Potassium cyanide converts it into butyl-cyanide without much formation of butylene. With sodium it gives off butylene and butyl-hydride, with but little butyl.

Morkownikoff has lately shown that this iodide may be converted into tertiary butyl iodide, $(CH^3)_3CI$, by heating it with alcoholic potash, which abstracts HI and leaves isobutylene, and then combining the latter directly with HI (p. 374).

Secondary Butylic Alcohol. The possible forms of the secondary alcohol are *ethyl-methyl carbinol*, $C \begin{cases} CH^2CH^3 \\ CH^3 \\ H \\ OH \end{cases}$, and *methyl-ethyl carbinol*, $C \begin{cases} CH^3 \\ CH^2CH^3 \\ H \\ OH \end{cases}$,

but according to our present theory these two formulæ do not represent any real difference of composition, and there is consequently only one secondary butylic alcohol, which may bear either of the above names.

De Laynes obtained the secondary alcohol from erythrite by reduction with hydriodic acid. Lieben has also obtained it by another process, viz. by the successive action of zinc-ethyl and hydriodic acid on chlorinated ether (*Ann. Ch. Pharm.* xlii. 236).

The changes which take place in the latter process are expressed by the following equations:

The resulting organic iodide, $\text{C}^2\text{H}^3\text{C}^2\text{H}^3\text{HI}$, may then be either at once treated with moist silver oxide, or else converted into acetate, which latter is transformable, in the usual manner, into the alcohol. This alcohol boils at 99° , according to Lieben and Bauer. According to De Luynes, the boiling point is 95° to 98° . Its sp. gr. at 0° is 0.827 (Lieben & Bauer); 0.850 (De Luynes). By oxidation it yields neither normal nor isobutyric acid, but acetic acid. See further v. 734, where this alcohol is described as isotetrylic alcohol.

Secondary butyl iodide, $\text{C} \left\{ \begin{array}{c} \text{C}^2\text{H}^4 \\ \text{CH}^3 \\ \text{H} \\ \text{I} \end{array} \right.$, is described at p. 736, vol. v., as isotetrylic iodide.

Tertiary Butyl Alcohol. Trimethyl-carbinol. $\text{C} \left\{ \begin{array}{c} \text{CH}^3 \\ \text{CH}^3 \\ \text{CH}^3 \\ \text{OH} \end{array} \right.$ —Discovered

by Butlerow (*Ann. Ch. Pharm.* cxliv. 1). At the ordinary temperature of the air it is a solid substance. Butlerow prepared it by the slow action of excess of zinc-methyl on acetyl chloride. 100 grms. of acetyl chloride were slowly dropped into 250 grms. of zinc-methyl, the latter being kept cool by immersion of the containing vessel in cold water. After the lapse of several days, water was added to the product, until it ceased to give a precipitate. A certain quantity of oily product separated on this treatment, and this was carefully removed from the aqueous liquid, which contained the trimethyl-carbinol in solution. Carbonate of potassium was next added to the aqueous solution, whereupon the new alcohol formed an oily layer which was subsequently dried (when it solidified). From the above quantity of materials 75 grms. of trimethyl-carbinol were obtained. The boiling point is 82° . It forms large colourless crystals.

The reaction by which the tertiary alcohol is produced is the following:

On adding the water there is disengagement of gaseous methyl hydride and formation of zinc hydrate and the tertiary alcohol.

This alcohol may also be formed from the primary alcohol of fermentation (*vide infra*). J. A. W.

Tertiary Butyl Iodide or Trimethyl Carbonyl Iodide, $\text{C}(\text{CH}^3)_3\text{I}$, is easily formed by passing gaseous hydriodic acid into well-cooled trimethyl-carbinol, or, though less completely, by agitating the alcohol with fuming hydriodic acid. The iodide decolorised by caustic potash or alkaline bisulphite, and dried over calcium chloride, is a heavy liquid, insoluble in water, smelling like petroleum, and boiling, with partial decomposition, at 98° – 99° . With a solution of potash in strong alcohol, it is easily resolved into butylene and hydriodic acid; if, however, water is present, a large quantity of trimethyl-carbinol is formed, with but little butylene. By dry silver-oxide it is decomposed explosively; with moist silver oxide it yields trimethyl-carbinol and a small quantity of butylene.

This iodide has lately been obtained in a remarkable manner by Morkownikoff (*Zeitschr. f. Chem.* [2] vi. 29), from isobutyl-iodide or isopropyl-carbinyl iodide, by heating the latter with alcoholic potash, whereby it is converted into isobutylene, and combining the latter directly with hydriodic acid. The conversion is represented by the following equations:

The tertiary butyl iodide thus obtained is converted by moist silver oxide into tertiary butyl alcohol, identical with that obtained by Buttlerow (see also Buttlerow, *ibid.* vi. 237).

Tertiary Butyl Chloride, $\text{C}(\text{CH}_3)_3\text{Cl}$, is formed, together with the corresponding acetate, by the action of acetyl chloride on trimethyl-carbinol; also by the action of phosphorus pentachloride on that alcohol. By prolonged heating to 100° with water it is resolved into hydrochloric acid and trimethyl-carbinol. Buttlerow has observed the formation of trimethyl-carbinol by the action of water on a butyl chloride prepared from commercial alcohol: hence it appears probable that this tertiary alcohol likewise occurs amongst the products of alcoholic fermentation.

Tertiary Butyl Acetate, $\text{C}_4\text{H}_{10}\text{O}_2 = \text{C}(\text{CH}_3)_3 \cdot \text{C}_2\text{H}_3\text{O}_2$, is easily obtained by mixing the iodide with silver acetate previously moistened with strong acetic acid. After rectification over silver acetate, washing with water, and drying over calcium chloride, it forms an aromatic oil, smelling like mint and acetic acid, soluble in a large quantity of water, boiling at 96° , and resolved by heating with baryta-water into barium acetate and trimethyl-carbinol.

BUTYLENE. C_4H_8 .—This hydrocarbon might exhibit the following modifications:

The modifications I. to V. might be formed by dehydration of normal butyl alcohol or propyl-carbinol; II. to V., also from secondary butyl-alcohol or methyl-ethyl carbinol; VI., only from the latter; VII., VIII., and IX., from isopropyl carbinol; VII. and IX., also from the tertiary alcohol (trimethyl-carbinol).

Our actual knowledge of these modifications is, however, very incomplete. a. The hydrocarbons C_4H_8 described under **TETRYLENE** (v. 737)—as produced by the condensation of oil-gas, by the electrolysis of valeric acid, by the dehydration of isobutyl carbinol with sulphuric acid, and by the action of alcoholic potash on secondary butyl iodide—are probably not all identical. That obtained by the first process boils below 0° (Faraday); that obtained from secondary butyl iodide at $+3^\circ$ (De Laynes). The latter may have the constitution represented by either of the formulæ III., IV., V., or VII., according to the particular hydrogen-atom which is removed from the molecule

combining this butylene (boiling at $+1^\circ$) with hypochlorous acid, and treating the resulting chlorhydrin, $\text{C}_4\text{H}_9\text{Cl}_2$, with sodium-amalgam, has obtained secondary butyl alcohol, whence he infers that the butylene in question has the constitution IV. or V.

B. Dimethyl-ethylene, $C^3H^2(CH^3)^2$, Buttlorow's *pseudobutylene*, as obtained by heating tertiary butyl-iodide with alcoholic potash, has the composition represented by formula IX.:

It is given off as a gas, which may be freed from condensable products by passing through a bottle and bulb-apparatus cooled by water. It smells like coal-gas, burns with a very bright but sooty flame, is quickly absorbed by strong sulphuric or hydriodic acid, and condenses at 15° – 18° under a pressure of 2 to 2½ atmospheres to a liquid which boils at -7° to -8° under a pressure of 762 millim. By its combination with hydriodic acid, tertiary butyl iodide is reproduced, whereas butylene from erythrite yields secondary butyl iodide (v. 736). Strong sulphuric acid absorbs dimethyl-ethylene, with separation of a liquid capable of combining with bromine, and apparently consisting of polymerides of butylene. A mixture of 2 vol. strong sulphuric acid and 1 vol. water absorbs the gas, with formation of trimethyl-carbinol, which may be separated by distillation from the solution after dilution with water.

Dimethyl-ethylene is likewise evolved on heating a solution of trimethyl-carbinol in sulphuric acid diluted with 2 vols. water; by heating isobutyl iodide with alcoholic potash; and by the electrolysis of ordinary valerianic acid.

Dimethyl-ethylene is absorbed by a cold solution of hypochlorous acid (obtained by passing chlorine into recently precipitated mercuric oxide mixed with ice); and the solution freed from excess of hypochlorous acid by means of sodium bisulphite yields by distillation, agitation of the distillate with ether, and evaporation of the latter, a

liquid consisting of isobutylic chlorhydrin, $C \begin{Bmatrix} CCl(CH^3)^2 \\ H^2 \\ OH \end{Bmatrix}$, which has a burning taste, boils at 137° , and is converted by sodium-amalgam into isobutyl alcohol, $C \begin{Bmatrix} CH(CH^3)^2 \\ H^2 \\ OH \end{Bmatrix}$ (Buttlorow, *Ann. Ch. Pharm.* cxliv. 1; *Jahresb.* 1867, p. 578; further, *Zeitschr. f. Chem.* [2] vi. 236, 238).

γ. Methyl-allyl. $CH^3.C^3H^5$.—This modification of the hydrocarbon C^4H^8 may be structurally represented by the formula IV. or VII. It is produced by the action of zinc-methyl on allyl iodide:

or more easily by heating a mixture of methyl-iodide and allyl-iodide (diluted with 2 vol. ether) with sodium to 100° :

After several hours' action, the tubes are cooled, quickly connected with a receiver cooled to -12° , and then gently warmed. The ethereal liquid which passes over is saturated at a low temperature with bromine, and the brominated product, freed from excess of bromine by agitation with potash, and from ether by evaporation, is distilled under reduced pressure. If the distillation be interrupted when the thermometer shows a temperature of 100° under a pressure of 10 centim. of mercury, the residue, which solidifies on cooling, consists of diallyl-tetrabromide, and the portion which passes over yields by fractional distillation, a colourless mobile liquid, boiling between 155° and 166° , and having the composition of butylene bromide, $C^4H^6Br^2$. This liquid attacks the eyes, boils at 156° – 159° under a pressure of 755 millim. (normal butylene bromide boils at 158°), and has a sp. gr. of 1.8299 to 1.8119 at 0° . Sodium decomposes it somewhat rapidly, forming a dry white mass; and on opening the tubes, previously cooled to -12° , a gas escapes, which may be condensed by cold to a liquid boiling between -4° and $+8^\circ$. This liquid (methyl-allyl) forms with hydriodic acid the compound $C^4H^8.HI$, which in sp. gr. 1.643, and boiling point, 116° – 118° , agrees sensibly with butylene hydriodide or secondary butyl iodide (v. 736) (Wurtz, *Bull. Soc. Chim.* [2] viii. 285).

δ. Ethyl-vinyl, $C^2H^5.C^2H^3$, may have the structure represented by II., III., or V. It is formed by the action of zinc-ethyl on bromethylene:

This reaction was first observed by Chapman (*Chem. Soc. J.* [2] v. 28), and has been further studied by Wurtz (*Zeitschr. f. Chem.* [2] v. 407). The two bodies do not act on one another at ordinary temperatures, and the reaction takes place but slowly at 100°, or even at 140°; but when the heated tubes are left for several weeks, a white (or sometimes grey) crystalline precipitate of zinc bromide is formed. On opening the cooled tubes and passing the evolved gas into bromine, a bromide is formed which, after purification, is colourless, does not attack the eyes, has a sp. gr. of 1.876 at 0°, and boils at 165°–166° (bar. 755.5 mm.). On condensing the gas itself by a freezing mixture, liquid ethyl-vinyl was obtained, boiling between –8° and 0°. The purer product obtained by decomposing the bromide in strong tubes with excess of sodium, and condensing the evolved gas in a freezing mixture, boiled constantly at –5°, gave with bromine a bromide $C^4H^8Br^2$, which boiled at 166°, was identical with that obtained directly as above, and when heated with concentrated hydriodic acid in a sealed tube to 100°, yielded an iodide, which, after purification, boiled at 120°–121°, and had a sp. gr. of 1.034 at 0°. This iodide is very much like ordinary butyl iodide, but is distinguished from that compound by the facility with which it acts on silver acetate at ordinary temperatures, yielding a butyl acetate which boils at about 110°, and gives with potassium hydrate a butyl alcohol boiling at about 95° (? secondary butyl alcohol).

The preceding characters are sufficient to show that ethyl-vinyl is different from ordinary butylene, pseudobutylene, and methyl-allyl.

BUTYRIC ACIDS. In the article ACIDS, ORGANIC (p. 40), it has been explained that butyric acid is the first of the series of fatty acids, $C^4H^8O_2$, which admits of isomeric modifications, and that it exhibits the two modifications

NORMAL BUTYRIC, PROPYL-FORMIC, OR ETHYL-ACETIC ACID is produced by oxidising propyl-carbinol, by decomposing normal propyl cyanide with acids or alkalis, and by the fermentation of sugar in contact with putrid curd. The same modification appears also to be formed in the putrefaction of diabetic urine (Klinger; Fönberg, *Jahresb.* 1858, p. 571), of wheat-flour (Sullivan, *ibid.* p. 231), and of rye-flour (Ritthausen, *Zeitschr. f. Chem.* [2] iv. 314); in the distillation of peat (*Jahresb.* 1858, p. 280; 1859, p. 742); in the oxidation of valeric acid by permanganic acid (Neubauer, *Ann. Ch. Pharm.* cvi. 59), and of Chinese wax by nitric acid (Buckton, *Chem. Soc. J.* x. 166); further by the following definite reactions:

a. By the action of hydriodic acid on succinic acid:

(Berthelot, *Bull. Soc. Chim.* ix. 455).—*β.* By fusing ethyl-crotonic acid with potash (Frankland & Duppa, *Chem. Soc. J.* [2] iii. 133).

γ. From fillic acid (dibutyl-phenylglucine) by evaporation with potash-ley (Grabowsky, *Ann. Ch. Pharm.* cxliii. 279):

δ. In like manner from calnoctin and aphrodæcin (Rocheder, *Bull. Soc. Chim.* [2] ix. 382, 385):

Butyric acid (probably normal) has been found ready-formed in flesh-juice, guano, excrements, putrid yeast, bad cider, and the water of peat-bogs, dung-heaps, and other accumulations of decomposing organic matter; also in the fruit of *Ginkgo biloba*, in enanthic ether (wine fassel-oil) and in wood-tar (*Jahresb. f. Chem.* 1857, pp. 353, 402, 403, 559; 1859, pp. 363, 384; 1861, p. 454; 1866, p. 311).

It is only, however, within the last few years that normal butyric acid has been distinguished from its isomeride, and the accounts which have been given of the

properties of butyric acid and butyric compounds generally must be taken to refer confusedly sometimes to one and sometimes to the other variety of the acid. In general, normal butyric derivatives have a slightly higher specific gravity and boiling point than the corresponding derivatives of isobutyric acid. Thus:

	Normal compounds.			Iso-compounds.	
Butyric Acids,	164°	0.9817 sp. gr.	.	154°	0.9598 sp. gr.
„ Anhydrides,	190°	—	.	180.5°	—
„ Chlorides,	—	—	.	92°	—
„ Ethyl-ethers,	119°	0.9019 sp. gr.	.	110°	0.8893 „

The specific gravities in the above tabular statement are given at 0° C. Normal butyric acid has a much more offensive smell than the iso-acid. There are also striking differences between the calcium salts of the two acids. Butyrate of calcium is more soluble in cold than in hot water, whereas the isobutyrate is more soluble in hot than in cold water.

Butyric acid heated with *bromine* in sealed tubes, is converted into mono- and di-bromobutyric acids. With *chlorine* in sunshine, it yields di- and tetra-chlorobutyric acids (i. 694); in the shade it is very slowly attacked, apparently yielding mono-chlorobutyric acid; in presence of iodine this product is more quickly formed (Morkownikoff). With *sulphuric chlorhydrate*, it forms disulphopropionic acid, $C^4H^4S^2O^6$, together with other products (Baumstark, *Ann. Ch. Pharm.* cxli. 25). By *permanganic acid* in alkaline solution, it is converted into succinic, propionic, acetic, and carbonic acids; and by hydriodic acid into butane or butyl hydride:

(Berthelot, *Jahresb.* 1867, pp. 335, 345).

ISOPROPYL-FORMIC ACID, DIMETHYL-ACETIC, OR ISOBUTYRIC ACID, $C \begin{Bmatrix} CH(CH^1)^2 \\ O \\ OH \end{Bmatrix}$, is obtained by oxidising isopropyl-carbinol (*i.e.* Wurtz's alcohol from fusel-oil); by the action of acids and alkalis on isopropyl cyanide; also by the oxidation of hexyl alcohol (Wanklyn & Erlenmeyer), &c.

The existence of this acid, as distinguished from common butyric acid, was established in 1865 by Morkownikoff, who showed that the acid given by isopropyl cyanide (from glycerin) is distinct from the acid given by normal propyl cyanide. According to Morkownikoff, isobutyric acid (from isopropyl cyanide) boils at 153.5° to 154.5°. Sp. gr. 0.9598 at 0°; 0.9208 at 50°; 0.8965 at 100°. According to Chapman, isobutyric acid has not so high a degree of stability in presence of oxidising agents as the normal acid.

J. A. W.

Isobutyrates.—The *potassium salt* remains on evaporation as a cauliflower-like deliquescent mass, easily soluble in alcohol. The *sodium salt* is crystalline. The *silver salt* $C^4H^3O^2Ag$ is a white precipitate, slightly soluble in cold water, and crystallising from a hot saturated solution in microscopic very flat rectangular plates; in a cold solution small prisms are also formed. The *barium salt* $(C^4H^3O^2)_2Ba$ is easily soluble in water and in alcohol, and difficult to crystallise; over sulphuric acid it crystallises in small prismatic forms; from a hot saturated solution, in efflorescent triclinic prisms. The *calcium salt* $(C^4H^3O^2)Ca \cdot 5H^2O$ dissolves easily in hot water, and separates on cooling from a hot saturated solution, in a pulp of microscopic needles. From a not completely saturated solution it separates by slow cooling in long efflorescent prisms, and from a cold solution by slow crystallisation in four-sided monoclinic prisms + P. — P. — ($\infty P \infty$). $\infty P \infty$, which are permanent in the air.

The *magnesium salt* $(C^4H^3O^2)_2Mg$ crystallises in white shining laminæ, easily soluble in water and in alcohol, and giving off part of their acid in drying. The *lead salt* crystallises from a solution of lead hydrate in the hot aqueous acid, in beautiful rhombic tables, which dissolve in 11 pts. water at 16°, and melt to a clear liquid in boiling water (normal lead butyrate prepared in the same manner separated from the cooling solution in oily drops, which unite into a viscid mass). The *copper salt* is a blue-green precipitate slightly soluble in water, more soluble in alcohol, and crystallising in dark green prisms. *Mercury salts.*—A solution of recently precipitated mercuric oxide in the hot dilute acid deposits on evaporation a reddish-yellow crystalline mixture of mercuric and mercurous isobutyrate, and if afterwards left over sulphuric acid, yields spherical groups of needles, together with a pulverulent basic salt. In a solution of neutral mercurous nitrate, isobutyrate form a white crystalline

precipitate, which blackens and partly dissolves at the boiling heat, and the solution deposits white interlaced needles, which in contact with water are converted, without change of form, into a yellow basic salt. *Ethyl isobutyrate*, $C^4H^7O^2 \cdot C^2H^5$, is a transparent colourless liquid, of purer and more agreeable odour than the butyrate, of sp. gr. 0.8893 at 0° , boiling at 110° , slightly soluble in water (Morkownikoff, *Ann. Ch. Pharm.* cxxxviii. 361).

Bromobutyric Acids (Friedel a. Machuca, *Ann. Ch. Pharm.* cxx. 279; *Suppl.* ii. 70. Gorup-Besanez a. Klinksieck, *ibid.* cxviii. 248. A. Naumann, *ibid.* cxix. 116. R. Schneider, *ibid.* 279).

Monobromobutyric acid, $C^4H^7BrO^2 = C^4H^6BrO\left\{ \begin{smallmatrix} H \\ H \end{smallmatrix} \right\} O$, may be prepared by heating 1 mol. butyric acid with 2 at. bromine to 130° – 150° in sealed tubes for three or four hours. The tubes should be well cooled before they are opened; and the yellow liquid, consisting chiefly of bromobutyric acid, heated for a short time to 100° , and then treated with a small quantity of water, to remove the last traces of hydrobromic acid. The bromobutyric acid thus obtained contains about 20 p. c. water, which may be gradually removed by calcium chloride, the hydrate $C^4H^7BrO^2 \cdot H^2O$ being first produced, and afterwards the pure hydrogen bromobutyrate, $C^4H^7BrO^2$ (Schneider). According to Gorup-Besanez a. Klinksieck, the best way of obtaining the pure acid is to dissolve the contents of the tubes in four times their volume of alcohol; saturate the solution with hydrochloric acid gas; precipitate the resulting ethyl bromobutyrate with water; and, after purifying it in the usual way by washing, drying, and distillation, decompose it with recently precipitated lead hydrate, and separate the acid from the resulting lead salt by hydrogen sulphide.

Bromobutyric acid is an oily liquid, smelling of butyric acid and bromine, remaining liquid at -15° , having a sp. gr. of 1.64 at 15° , boiling at 180° (Schneider), at about 200° (Naumann), and then decomposing with rise of temperature. According to Friedel a. Machuca, it boils under ordinary pressure at 217° with partial decomposition, but under a reduced pressure of 3 mm. it boils without decomposition at 110° , and may thus be obtained colourless. Dissolves in 14 to 15 pts. water (Schneider); sparingly soluble in cold, moderately soluble in hot water (Naumann); miscible in all proportions with alcohol and ether. From solution in nitric acid of sp. gr. 1.2, or in strong sulphuric acid, it is precipitated by water without alteration; decomposed by heating with sulphuric acid. With zinc, it yields zinc-bromide and butyric acid. Boiled with ammonia, it forms ammonium bromide and amidobutyric acid (Schneider). By supersaturating the acid with soda-ley, evaporating, heating the residue for some time on the water-bath, then supersaturating with sulphuric acid, agitating with ether, and evaporating the latter, a syrupy acid is obtained, which, when saturated with zinc carbonate, yields needles of a salt isomeric or identical with zinc butylactate or oxybutyrate, $(C^4H^7O^2)^2Zn \cdot 2H^2O$ (i. 688; iv. 296) (Naumann).

The *metallic bromobutyrate*s are mostly soluble in water and in alcohol, and difficult to crystallise. The *lead salt* $(C^4H^7BrO^2)^2Pb$, obtained from the potassium salt by precipitation with neutral lead acetate, is a white pearly precipitate moderately soluble in alcohol. A second lead salt, $(C^4H^7BrO^2)^2Pb \cdot 2PbO$, is obtained by evaporating the liquid filtered from the neutral salt, or by precipitating the potassium salt with basic lead acetate. The *silver salt* $C^4H^7BrO^2Ag$ is a white crystalline precipitate, which becomes darker on exposure to light, and is resolved by boiling water into silver bromide and (probably) butylactic acid (Schneider).

Ethyl bromobutyrate, $C^4H^7BrO^2 \cdot C^2H^5$, is a colourless, fragrant, heavy, oily liquid of sp. gr. 1.33 at 15° , boiling at about 185° , but with partial decomposition even in a current of carbonic acid gas (Schneider); of sp. gr. 1.345 at 12° , boiling at 175° – 178° (Cahours). It is but imperfectly decomposed by boiling with caustic alkalis, but when heated with lead hydrate it yields the lead salt of bromobutyric acid.

Bromisobutyric acid is formed by heating isobutyric acid with bromine to 130° , and forms on cooling a crystalline mass, which may be purified by heating in a stream of carbonic acid gas, pressing, and drying in a vacuum. It melts at 42° , decomposes on distillation, dissolves easily in alcohol and ether, and forms with water a heavy oil, which dissolves when warmed, but separates again on cooling. Heated with caustic baryta it yields barium bromide and the barium salt of iso-oxybutyric acid (perhaps identical with dimethoxallic acid, iv. 274), which when separated from its barium salt by sulphuric acid, is crystallisable, melts at 80° , solidifies at 76° , and sublimates below 100° in long needles (Morkownikoff).

Dibromobutyric acid, $C^4H^6Br^2O^2$, is formed by heating a mixture of 1 mol. (2½ vol.) butyric acid and 4 at. (3 vol.) bromine (or 1 mol. monobromobutyric acid and

2 at. bromine) to 140°–160° for six or eight hours in strong sealed tubes. After purification it is a light yellow oil having a peculiar aromatic odour, a sp. gr. of 1.97, soluble in 30 pts. water, becoming buttery at –15°, decomposing before it boils (Schneider); boils at 150° under a pressure of 3 mm. of mercury (Friedel a. Machuca). According to Cahours (*Rép. Chim. pure*, iv. 145), dibromobutyric acid obtained as above, crystallises in thin colourless prisms melting at 45°–48°, boils under ordinary pressure at 232°, with partial decomposition, and is converted by treating its alcoholic solution with hydrochloric acid gas, into ethyl dibromobutyrate boiling at 191°–193°. By zinc and dilute sulphuric acid, dibromobutyric acid is converted into butyric acid. Its salts resemble those of monobromobutyric acid. The bromotriconic acid of Cahours, obtained by the action of bromine on potassium citraconate (i. 693), is isomeric, not identical, with dibromobutyric acid (Schneider).

By heating 1 mol. dibromobutyric acid with 4 at. bromine to 150°–180°, there is formed a light brown viscid liquid, which gradually deposits needle-shaped crystals, easily soluble in ether, and probably consisting of tetrabromobutyric acid (Schneider).

Chlorobutyric Acid. *Monochlorobutyric acid*, $C^4H^7ClO^2$, is formed, together with more highly chlorinated products, by passing chlorine into butyric acid containing a little iodine. On distilling the thick liquid thereby produced, till decomposition sets in, a distillate is obtained containing butyric and chlorobutyric acids, and by fractional distillation a portion may be separated which boils at 200°–210°, and on cooling yields monochlorobutyric acid in white prismatic needles. The product is however very small. Chlorobutyric acid dissolves easily in hot water, and crystallises therefrom in slender flexible needles. It melts at 98°–99°, solidifies again at 93°, sublimates at 80° in white iridescent laminae, and volatilises partially under the air-pump at ordinary temperatures (Morkownikoff, *Zeitschr. f. Chem.* [2] iv. 621).

Dichlorobutyric acid, $C^4H^5Cl^2O^2$, is formed by the action of chlorine on butyric acid in sunshine (i. 694). If the action of the chlorine be assisted by heating the butyric acid, first in the water-bath, afterwards to the boiling point of the acid, a white sublimate is formed in the neck of the retort, consisting of carbon trichloride C^2Cl^6 (Naumann, *Ann. Ch. Pharm.* cxix. 120).

BUTYRIC ALDEHYDE. $C^4H^7O = C \begin{matrix} C^6H^7 \\ O^7 \\ H \end{matrix}$.—This compound is obtained,

together with propionic aldehyde, by heating a mixture of calcium formate and butyrate in equivalent proportions. The product, after treatment with lead oxide and calcium chloride, is resolved by fractional distillation into propionic aldehyde boiling between 54° and 63°, and butyric aldehyde boiling between 73° and 77°, identical therefore with the butyric aldehyde which Guckelberger obtained by oxidation of fibrin, albumin, and casein (i. 689). It has a sp. gr. of 0.8341 at 0°, is less soluble in water than propionic aldehyde, and on exposure to the air is quickly converted into butyric acid. Isobutyl alcohol (from fusel-oil), oxidised with chromic acid, also yields a butyric aldehyde boiling at 70°–78°, together with propionic aldehyde, propionic acid, and butyric acid (Michaelson, *Ann. Ch. Pharm.* cxxxiii. 182). According to Pierre a. Puchot (*Compt. rend.* lxx. 434), butyric aldehyde obtained by oxidation of isobutyl alcohol boils at 74°, and has a sp. gr. of 0.8226 at 0°, 0.7919 at 27.75°, and 0.7638 at 50.4°.

BUTYRYL or DIBUTYRYL. $(C^4H^7O)^2 = C^8H^{14}O^4$ (Freund, *Ann. Ch. Pharm.* cxviii. 33).—Produced by the action of sodium-amalgam on butyryl chloride, or of zinc on the same compound mixed with ether. To prepare it, butyryl chloride is gently heated with an amalgam of 1 pt. sodium and 2 pts. mercury, and the viscous mass which separates is freed by distillation from excess of butyryl chloride. On treating the residue with water, an oily layer rises to the surface, consisting of impure butyryl, which may be purified by agitation with solution of potassium carbonate, drying over calcium chloride, and distillation, the portion which goes over between 245° and 260° being collected apart. Butyryl thus obtained is an aromatic oil, slightly soluble or insoluble in water. Heated with potash, it yields potassium butyrate, and an aromatic liquid which passes over on fractional distillation between 175° and 185°, and exhibits the composition of butyrene, $C^8H^{14}O$, but boils at a higher temperature, and does not unite with alkaline bisulphites or with ammonia.

BUTYRYL CHLORIDE or BUTYRIC CHLORIDE. C^4H^7OCl , is decomposed at a gentle heat by sodium-amalgam, yielding butyryl (or dibutyryl), $C^8H^{14}O^2$; also in ethereal solution by granulated zinc, according to the equation:

(Fround, *Ann. Ch. Pharm.* cxviii. 33.)

With *zinc-ethyl*, it yields ethyl-butyryl or ethyl-propyl ketone (Popoff, *Zeitschr. f. Chem.* [2] iv. 619).

Isobutyric chloride, formed, together with isobutyric oxide, by the action of phosphoric oxychloride on sodium isobutyrate, is a colourless liquid, boiling at 92° (butyric chloride boils at 95°), and decomposed by water (Morkownikoff).

BUTYRIC OXIDE or **ANHYDRIDE**. $(\text{C}^4\text{H}^7\text{O})_2\text{O}$. *Preparation and properties* (i. 694).—Isobutyric oxide, formed as above mentioned, is a colourless liquid, lighter than water, boiling at 180° – 181° (butyric oxide boils at 190°), and converted into isobutyric acid by warming with water (Morkownikoff).

Butyro-hypochlorous Oxide or *Butyrate of Chlorine*, $\left. \begin{array}{l} \text{C}^4\text{H}^7\text{O} \\ \text{Cl} \end{array} \right\} \text{O}$, isomeric with chlorobutyric acid, is produced by exposing butyric oxide in a well-cooled vessel to the action of gaseous hypochlorous oxide:

It is a yellowish liquid, which detonates when heated, is slowly decomposed by light, and is analogous in its chemical relations to acetate of chlorine (p. 25) (Schützenberger, *Rép. Chim. pure*, iv. 268). The corresponding *bromine-compound*, $(\text{C}^4\text{H}^7\text{O})\text{BrO}$, a colourless explosive liquid, is produced by the action of bromine on the chlorine-compound (Schützenberger), or on silver-butyrate (Borodine, *Ann. Ch. Pharm.* cxix. 121; *Zeitschr. f. Chem.* [2] v. 342).

Tributyro-hypoiodous Oxide or *Iodine Tributyrate*, $(\text{C}^4\text{H}^7\text{O})_3\text{O}^2$, is formed by mixing iodine chloride with an equivalent proportion of sodium, potassium, or zinc butyrate, or by gradually adding iodine to butyro-hypochlorous oxide, or better by passing hypochlorous oxide into butyric oxide mixed with iodine till the latter disappears. The resulting flocculent precipitate dissolved in acetic oxide at 60° , crystallises therefrom in slender white needles. It is not altered by light, but when heated is quickly decomposed into iodine, carbon dioxide, and propyl butyrate (Schützenberger).

BUXINE. See BEBIRINE (p. 255).

C

CADMIUM. On the extraction of cadmium from zinc-blende at Engis in Belgium, see Städelor (*J. pr. Chem.* xci. 359; *Jahresb.* 1864, 759).

The solution of cadmium in acids is greatly facilitated by addition of a small quantity of platonic chloride. The combination of cadmium with bromine and iodine is likewise facilitated by the presence of platinum (Alberta, *Jahresb.* 1865, p. 242).

The following table exhibits the solubility of cadmium chloride and iodide at different temperatures, as determined by Kremers (*Pogg.* ciii. 67; *Jahresb.* 1858, p. 40):

	At 20°	40°	60°	80°	100°
1 pt. CdCl_2 dissolves in	0.71	0.72	0.72	0.70	0.67 pt. water
" CdI_2 "	1.08	1.00	0.93	0.86	0.75 "

Respecting the specific gravities of solutions of cadmium chloride, bromide, and iodide of various strengths and at different temperatures, see Kremers (*Jahresb.* 1858, p. 41; 1859, p. 49; 1860, p. 46).

Cadmium oxide may be obtained in red crystals, apparently cubic, by heating the amorphous oxide to whiteness for two or three hours in a porcelain tube through which a stream of oxygen is passed. The oxide melts, volatilises, and condenses at the cold end of the tube; the best crystals are obtained by placing a plug of asbestos at that end (Schütz, *Zeitschr. f. Chem.* [2] v. 606).

A compound of cadmium oxide with *potassium oxide* is obtained by saturating fused potassium hydrate with cadmium oxide, and adding cold potash-ley to the fused mass till the resulting precipitate becomes permanent. The solution on cooling yields crystals of potassium hydrate enclosing the potassio-cadmie oxide, and on dissolving them in water, the latter compound remains in hydrated crystalline scales having a pearly lustre and the colour of lead iodide. It is insoluble in water, but is decomposed by prolonged contact with water, with separation of cadmium hydrate (St. Meunier, *Compt. rend.* lxxiii. 330).

CAESIUM. Occurrence, and separation from rubidium (i. 1113; iv. 126).

Stannic chloride added to a solution of the chlorides of sodium, potassium, lithium, rubidium, and cesium containing free hydrochloric acid, forms a heavy white precipitate consisting of nearly pure *casio-stannic chloride*, $\text{Sn}^{\text{IV}}\text{Cs}^2\text{Cl}^6$; and by dissolving this precipitate in hot water acidulated with hydrochloric acid, evaporating till crystals form on the surface, and leaving the solution to cool, the salt is obtained perfectly pure. This reaction affords an easy method of detecting cesium in a mixture of alkaline chlorides, and of preparing pure cesium-compounds; but it is not adapted for quantitative analysis, as the precipitate is not formed in a neutral solution, and is soluble to a slight extent in concentrated hydrochloric acid (J. P. Sharples, *Sill. Am. J.* [2] xlvii. 178).

According to Debray (*Bull. Soc. Chim.* [2] v. 404), cesium—as well as potassium, rubidium, and thallium—is precipitated by phosphomolybdic acid.

CAFFEIDINE. See the next article.

CAFFEINE or **THEINE**. $\text{C}^8\text{H}^{10}\text{N}^4\text{O}^2$.—This base has the composition of methyl-theobromine, $\text{C}^8\text{H}^7(\text{CH}^3)\text{N}^4\text{O}^2$, and may be formed synthetically by treating the silver-compound of theobromine (v. 761) with methyl-iodide:

(Strecker, *Ann. Ch. Pharm.* cxviii. 151). For the relations between xanthine, theobromine, and caffeine, see **XANTHINE** (v. 1051).

Caffeine has been found in the seeds of the Kola-tree of West Central Africa (*Cola acuminata*) to the amount of 2.13 p. c. of the dried seed (Attfeld, *Pharm. J. Trans.* [2] vi. 257).

C. Grosschoff (*Jahresb.* 1866, 471) describes a method of preparing caffeine on the large scale from tea, by heating the concentrated aqueous decoction with litharge, evaporating the decanted liquid to a syrup, and treating it with pearlsh and alcohol.

To estimate the amount of caffeine in tea-leaves, Claus (*Jahresb.* 1863, p. 708) exhausts them with ether; distills off two-thirds of the ether; agitates the residue repeatedly with dilute sulphuric acid; supersaturates the colourless caffeine-solution with magnesia; evaporates to dryness; and extracts the caffeine from the residue by ether, which on evaporation leaves it in white crystals. Tea-leaves, after exhaustion with ether, still yield a small quantity of caffeine to alcohol. Claus finds that the inferior commercial sorts of tea are richer in caffeine than the finer and more fragrant sorts.

Caffeine evaporated to dryness with a little *chlorine-water* yields a purple-red residue which becomes golden-yellow when more strongly heated; but red again on addition of ammonia. By this reaction, caffeine may be detected even in a single coffee-bean (Schwarzenbach, *Jahresb.* 1861, p. 871; 1865, p. 730). Caffeine forms with *phosphomolybdic acid* a yellow precipitate which dissolves without colour in ammonia (J. Trapp, *ibid.* 1863, p. 702).

Iodine-compounds of Caffeine (Tilden, *Chem. Soc. J.* [2] iii. 99; iv. 145).—A solution of caffeine in dilute alcohol strongly acidulated with *hydriodic acid* deposits after a few days, especially in sunshine, long prisms of caffeine hydrotri-iodide, $2(\text{C}^8\text{H}^{10}\text{N}^4\text{O}^2 \cdot \text{HI}^3) \cdot 3\text{H}^2\text{O}$, having a green metallic lustre and exhibiting the same polarising properties as Herapath's sulphate of iodoquinine. Caffeine ethyl tri-iodide, $\text{C}^8\text{H}^{10}\text{N}^4\text{O}^2 \cdot \text{C}^2\text{H}_5\text{I}^3$, is formed on heating caffeine with *ethyl iodide* to 130° for about four hours, evaporating at a gentle heat, mixing the residue with a solution of iodine in hydriodic acid, and recrystallising the resulting precipitate from alcohol. It forms brown shining scales permanent at 100° . When caffeine is heated for a shorter time with ethyl iodide, part of it remains unaltered, and after the ethyl-caffeine has been precipitated with iodine, the solution deposits monohydrated caffeine hydrotri-iodide, $\text{C}^8\text{H}^{10}\text{N}^4\text{O}^2 \cdot \text{HI}^3 + \text{H}^2\text{O}$, in shining crystals. *Methyl-iodide* forms with caffeine the compound $\text{C}^8\text{H}^{10}\text{N}^4\text{O}^2 \cdot \text{CH}_3\text{I}^3$, which dissolves easily in water, and when mixed in aqueous solution with tincture of iodine, is converted into the tri-iodated compound

$C^8H^{10}N^2O^2 \cdot OH^2P$. An acidulated solution of caffeine hydrochloride mixed with aqueous iodine monochloride, yields the compound $C^8H^{10}N^2O^2 \cdot HCl$, in crystals which appear to be obliquely rhombic.

Bromocaffeine.—Caffeine forms with bromine a brick-red pulp, which on further addition of bromine dissolves in the hydrobromic acid produced; and on expelling the excess of this acid and adding ammonia, bromocaffeine, $C^8H^8BrN^2O^2$, is obtained as a flocculent precipitate, whilst a crystallisable substance not yet examined remains in solution.

Nitrocaffeine. $C^8H^8(NO^2)N^2O^2$, is formed, together with a resinous substance, on evaporating caffeine with excess of strong nitric acid, and crystallises from hot water in yellow laminae. By prolonged treatment with nitric acid, another crystallisable body not yet examined is produced (Schultzen, *Zeitschr. f. Chem.* [2] iii. 614).

Bases produced by the action of Alkalis on Caffeine: 1. **Caffeidine**, $C^8H^{12}N^2O$ (Strecker, *Compt. rend.* lii. 1269. Schultzen, *loc. cit.*).—When caffeine is boiled with baryta-water, barium carbonate is precipitated, while methylamine and ammonia, resulting from another reaction which goes on simultaneously (*vid. inf.*), are disengaged; and on removing the still dissolved baryta with excess of sulphuric acid, and evaporating, caffeidine sulphate, $C^8H^{12}N^2O \cdot H^2SO^4$, is obtained in colourless prismatic crystals (Strecker). The same salt may be prepared by boiling caffeine for five or six hours with excess of alcoholic potash, removing the potash with alcohol containing sulphuric acid, evaporating the alcohol, saturating with dilute sulphuric acid, and concentrating the solution (Schultzen). By decomposing it with barium carbonate, caffeidine is obtained as an amorphous deliquescent mass, easily soluble in alcohol, sparingly in ether (Strecker). It is oxidised by moist silver oxide at ordinary temperatures, whereas caffeine is not altered by the same reagent even at the boiling heat. A solution of caffeidine strongly acidulated with sulphuric acid, forms with phosphotungstic acid, a white flocculent precipitate which dissolves on boiling, and crystallises out on cooling in garnet-red cubes (Schultzen).

The formation of caffeidine from caffeine is represented by the equation:

2. **Base** $C^8H^8NO^2$, **isomeric with Alanine**. When caffeine is boiled with baryta-water for some hours, the solution is found to contain—besides caffeidine—formic acid and another easily decomposable body, together with unaltered caffeine. If the boiling be continued for 60 hours, with excess of concentrated baryta-water, till ammonia is no longer evolved, the solution then freed from excess of baryta by carbonic acid, evaporated to a syrup, mixed with absolute alcohol (which throws down barium formate), then with a little sulphuric acid to remove baryta, and evaporated to a syrup, the base, $C^8H^8NO^2$, separates out, and may be obtained by recrystallisation from alcohol in large neutral deliquescent crystals. Its formation is represented by the equation:

Its *hydrochloride*, $C^8H^8NO^2 \cdot HCl$, has an acid reaction, dissolves easily in water and in alcohol, and crystallises in long colourless needles; the *sulphate*, $(C^8H^8NO^2)^2 \cdot H^2SO^4$, is nearly insoluble in alcohol, and crystallises with difficulty in rhombohedrons permanent in the air.

By treating the hot aqueous solution of this base with nitrous acid, a syrupy *nitroso-compound*, $C^8H^8(NO^2)O^2$, is obtained, the calcium salt of which, $[C^8H^8(NO^2)O^2]^2Ca \cdot H^2O$, dissolves easily in water, sparingly in alcohol, and crystallises in long thick needles (Schultzen).

Iso-alanine is distinguished from alanine by its crystalline form, and by the characters of its hydrochloride and sulphate. From caffeidine it is distinguished by yielding with phosphotungstic acid a compound which forms large colourless crystals, whereas the corresponding compound of caffeidine forms red crystals.

CAILCEDRA. *Kaya senegalensis* or *Swietenia senegalensis*. A tree of the cedrelaceous order, growing on the banks of the Gambia, and on the lowlands of the peninsula of Cape de Verde. Its bark is very bitter and is much prized by the natives for its febrifuge properties, on which account it has been called the *cinchona of Senegal*. Its wood resembles mahogany (*Swietenia mahogani*) and is used in making the finer kinds of furniture.

The bark contains, amongst other substances, an extremely bitter, neutral resinous substance called cail-cedrin, to which its active properties appear to be due.

Caill-cedrin is insoluble in water, but soluble in alcohol, ether, and chloroform. It is obtained by repeatedly exhausting the coarsely pulverised bark with boiling water; evaporating the filtered liquids over the water-bath to the consistence of a soft extract; exhausting this extract with alcohol of 90 p. c.; precipitating the alcoholic filtrate with basic lead acetate; filtering; distilling off the alcohol; and agitating the residue with chloroform, which dissolves nothing but the bitter principle: 1 kilogram of the bark yields about 8 milligr. of caill-cedrin (Caventou, *J. Pharm.* [3] xvi. 355; xxxiii. 123).

CAINCETIN. See the next article.

CAINCIC ACID or CAINCIN. $C^{10}H^{14}O^{18}$.—This substance, obtained from caïnca-root (i. 718), is resolved, by boiling its alcoholic solution with addition of water, into caincetin, $C^{12}H^{14}O^2$, and a sugar isomeric with glucose:

Caincetin separates from alcoholic solution in indistinct crystals. When fused with potassium hydrate, it is resolved into butyric acid and caincigenin, $C^{14}H^{24}O^2$, a substance which is homologous with æscigenin, $C^{12}H^{20}O^2$, and with the body $C^{11}H^{16}O^2$, sometimes found in horse-chestnut seeds, and resembles those substances in its properties:

Caïnctic acid in contact with *sodium-amalgam* and aqueous alcohol, dissolves to a brownish liquid, from which dilute sulphuric acid throws down a crystalline substance having the composition $C^{10}H^{14}O^{18}$:

When the alcoholic solution of this last-mentioned substance is heated with fuming hydrochloric acid, a gelatinous body, $C^{10}H^{12}O^2$, is formed, more soluble in ether than in alcohol (Rochleder, *J. pr. Chem.* lxxv. 275; cii. 16; *Jahresb.* 1862, p. 588; 1867, p. 749).

CALCIUM. The solubilities of the chloride, bromide, and iodide of calcium have been determined by Kremers (*Pogg. Ann.* ciii. 57; civ. 133; *Jahresb.* 1858, p. 40). The following table exhibits the quantities of water required to dissolve 1 pt. by weight of the anhydrous salts, at different temperatures:

	Chloride	Bromide	Iodide
0°	—	0·80	0·52
10·2	1·58	—	—
20	1·35	0·70	0·49
40	0·83	0·47	0·44
43	—	—	0·35
60	0·72	0·36	—
92	—	—	0·23
105	—	0·32	—

According to G. J. Mulder (*Jahresb.* 1866, p. 67), 100 pts. water dissolve 53 pts. calcium chloride at 4° and 56 pts. at 7°.

In the following table, column A denotes the quantities of the same three salts in 100 pts. water; column B, the specific gravities of the solutions at 19·5°, the sp. gr. of water at that temperature being taken for unity (Kremers, *Pogg. Ann.* xcix. 435; civ. 133; *Jahresb.* 1867, p. 67; 1868, p. 40).

Chloride		Bromide		Iodide	
A	B	A	B	A	B

The rate of expansion by heat of solutions of calcium chloride of various strengths has been determined by Gerlach (*Jahresb.* 1859, p. 47). The following table shows the volumes at different temperatures of solutions of this salt containing in 100 pts. the quantities of salt standing at the heads of the several columns, the volume of each solution at 0° being taken as unity. The last number (bracketed) in each column denotes the boiling point of the solution:

CALCIUM CHLORIDE.

	10	20	30	40
0°	1·0000	1·0000	1·0000	1·0000
10	1·0017	1·0027	1·0033	1·0043
20	1·0043	1·0060	1·0072	1·0089
30	1·0075	1·0096	1·0114	1·0136
40	1·0112	1·0139	1·0159	1·0183
50	1·0155	1·0183	1·0205	1·0231
60	1·0205	1·0231	1·0252	1·0280
70	1·0259	1·0280	1·0300	1·0329
80	1·0314	1·0330	1·0348	1·0377
90	1·0373	1·0382	1·0397	1·0424
100	1·0429	1·0432	1·0447	1·0472
	1·0442	1·0456	1·0466	1·0557
	(101·4°)	(104·2°)	(109·7°)	(118°)

On the rate of expansion of solutions of calcium chloride, bromide, and iodide, see also Kremers (*Jahresb.* 1858, p. 40; 1859, p. 49).

The following methods of preparing calcium iodide are recommended by R. Wagner (*Chem. Centr.* 1863, p. 143; *Jahresb.* 1862, p. 132): 1. Addition of iodine to an aqueous pulp of calcium sulphite and hydrate.—2. Addition of iodine, to saturation, to calcium hyposulphite stirred up with water, whereby a mixture of calcium iodide and tetrathionate is formed, which may be used for technical purposes (chlorimetry for example) instead of potassium iodide.—3. Mixing of iodine, finely divided or dissolved in hydriodic acid or potassium iodide, with calcium nitrite and hydrate, whereby calcium iodide and nitrate are produced:

The last portions of nitrite are not however converted into nitrate.—4. Addition of finely divided iodine to a concentrated mixture of arsenious oxide and milk of lime. The iodine then dissolves, with formation of insoluble arsenate, and soluble iodide of calcium. When the reaction is complete, the filtered solution of calcium iodide is quite free from arsenic. The arsenious oxide may be replaced by antimonious oxide (precipitated from the chloride by sodium carbonate).

For Liebig's method of preparing calcium iodide, and applying it to the preparation of potassium iodide, see POTASSIUM IODIDE (iv. 704).

Calcium Oxy sulphide.—According to P. W. Hoffmann (*Compt. rend.* lxii. 291), a non-ignited mixture of 2 mol. calcium sulphide and 1 mol. lime does not form oxy sulphide when boiled with water; but at a red heat the same mixture is converted into an oxy sulphide having the composition $2\text{CaS} \cdot \text{CaO}$, any larger addition of lime remaining uncombined. This oxy sulphide is contained in recently lixiviated soda residues.

Alloy of Calcium and Zinc.—Calcium fused with a large excess of zinc forms an alloy, CaZn^{13} , which crystallises in quadratic octohedrons of sp. gr. 6·37. It is decomposed by water (G. vom Rath, *Zeitschr. f. Chem.* [2] v. 665).

CALCULUS OF CHEMICAL OPERATIONS. See List of Memoirs at the end of the article CHEMICAL ACTION.

CAMPHOCARBONIC ACID. $\text{C}^{11}\text{H}^{14}\text{O}^3 = \text{C}^{10}\text{H}^{14}\text{O} \cdot \text{CO}_2$.—When a solution of camphor in a hydrocarbon (toluene or benzene) is treated with sodium, the metal dissolves without evolution of hydrogen, and a solution is formed containing sodium camphor and sodium borneol:

- C C

Sup.

On passing a stream of carbon dioxide into this solution, both of these compounds take up CO_2 , forming sodium camphocarbonate, $\text{C}^{10}\text{H}^{16}\text{NaO}_2$, and sodium borneol-carbonate, $\text{C}^{11}\text{H}^{18}\text{NaO}_2$; and if the resulting magma be treated with water, both salts dissolve, but the latter immediately begins to decompose, with separation of borneol; so that the aqueous solution decanted from the hydrocarbon becomes turbid and gradually deposits borneol. The camphocarbonate, on the other hand, remains undecomposed, and its clear aqueous solution separated from the borneol yields with hydrochloric or sulphuric acid a white precipitate of camphocarbonic acid.

This acid is sparingly soluble in water, easily in alcohol and ether, permanent at ordinary temperatures, melts at 118° – 119° , but begins to decompose even at this temperature; but on attempting to distil it at a stronger heat, it is completely resolved into camphor and carbon dioxide. After being once fused, it melts at a much lower temperature; in fact a mixture of the pure acid with camphor melts below 100° . Camphocarbonic acid is monobasic; its lead salt is insoluble in water and in acetic acid (Baubigny, *Zeitschr. f. Chem.* [2] iv. 481, 647).

CAMPOLIC ACID. $\text{C}^{10}\text{H}^{16}\text{O}_2$.—According to Malin (*Ann. Ch. Pharm.* cxlv. 200), the potassium salt of this acid is produced by adding potassium in small pieces to a boiling solution of camphor in 3 pts. of petroleum. This salt crystallises by evaporation in a vacuum in laminar crystals containing $\text{C}^{10}\text{H}^{16}\text{KO}_2 \cdot 2\text{H}_2\text{O}$. The acid separated from it by hydrochloric acid forms white lumpy flocks, which may be purified by recrystallisation from alcohol or by distillation.

CAMPHOR. $\text{C}^{10}\text{H}^{16}\text{O}$.—Ordinary camphor—the camphor of the Lauraceæ—might be regarded, so far as its composition is concerned, as the aldehyde of borneol, $\text{C}^{10}\text{H}^{18}\text{O}$, and it is produced by oxidising borneol with nitric acid. Nevertheless, it does not exhibit the characters of an aldehyde; for, as shown by Fittig & Tollens (*Ann. Ch. Pharm.* cxxix. 371), it does not unite with alkaline bisulphites; it is not converted into borneol by nascent hydrogen, nor into camphic acid, $\text{C}^{10}\text{H}^{16}\text{O}_2$, by direct oxidation with nitric acid (the products of that reaction being camphoric acid, $\text{C}^{10}\text{H}^{14}\text{O}_4$, and camphretic acid, $\text{C}^{10}\text{H}^{14}\text{O}_4$); and it is not oxidised by a mixture of potassium dichromate and sulphuric acid, even when heated therewith for a long time in sealed tubes.

Camphor, or a substance isomeric with it, is formed, together with other products, by oxidising rectified turpentine-oil with aqueous potassium permanganate, or by atmospheric oxidation of camphene, $\text{C}^{10}\text{H}^{16}$ (prepared from the monohydrochloride, $\text{C}^{10}\text{H}^{15} \cdot \text{HCl}$), in contact with platinum-black, also by chromic acid (Berthelot, *Compt. rend.* xlvii. 266; lxiv. 35; *Jahresb.* 1858, p. 441; 1867, p. 337; *Ann. Ch. Pharm.* cl. 374).

The crystals of camphor belong to the hexagonal system. Well-defined crystals obtained by very slow sublimation at ordinary temperatures exhibited the combination $\text{oP} : \infty \text{P} : \text{P}$; angle $\text{oP} : \text{P} = 118.9^\circ$ (Descloizeaux, *Ann. Ch. Phys.* [3] lvi. 219).

Reactions.—1. The oil obtained by the dry distillation of camphor in contact with clay (i. 728) is a mixture of cymene with unaltered camphor (Kraut, *J. Pharm.* [3] xlv. 105).—2. Camphor distilled with zinc chloride yields, not merely cymene, as supposed by Gerhardt, but a mixture of several hydrocarbons of the aromatic series. The distillate, freed as completely as possible from undecomposed camphor by repeated distillation with zinc chloride, is resolved by fractional distillation (the portions boiling above 150° being distilled over sodium) into the following products: α . Below 100° a small quantity of liquid containing oxygenated products (apparently including acetone), and perhaps a little benzene.— β . From 108° to 112° , chiefly toluene.— γ . From 138° to 143° , xylene.— δ . From 164° to 167° , pseudocumene or trimethylbenzene (p. 296).— ϵ . From 173° to 176° , cymene with a small quantity of pseudocumene.— ζ . From 185° to 188° , laurene, $\text{C}^{11}\text{H}^{18}$ (Fittig, Köbrich, & Jilke, *Ann. Ch. Pharm.* cxlv. 129). According to Lippman & Louguine (*Zeitschr. f. Chem.* [2] v. 413), the portion of the distillate boiling between 140° and 240° contains also cresol, $\text{C}^7\text{H}^8\text{O}$, which may be dissolved out from it by potash; also phenol (Rommier, *Compt. rend.* lxxviii. 930).—3. Camphor heated with phosphorus pentasulphide is almost wholly resolved into water and cymene (R. Pott, p. 302):

4. Camphor triturated with an equivalent quantity of phosphorus pentachloride is converted into a semifluid mass, which is resolved by very slow distillation into hydrochloric acid and cymene:

and

(Louguine & Lippmann, *Bull. Soc. Chim.* [2] vii. 374).

5. For the reaction of camphor with *nitric acid* and with *chromic acid*, see the commencement of this article.

6. Camphor heated to 200° with concentrated *hydriodic acid* gives off a mixture of three hydrocarbons, viz. $C^{10}H^{18}$, boiling at 135°–140°; $C^{10}H^{18}$, boiling at 163°; and $C^{10}H^{20}$, at 170°–175°. The two former take up bromine without giving off hydrobromic acid, and are easily oxidised, $C^{10}H^{18}$ yielding thereby acetic acid, together with three other acids (Weyl, *Zeitschr. f. Chem.* [2] iv. 496).

Brominated Derivatives of Camphor.—Camphor unites directly with bromine, forming a compound $C^{10}H^{16}O.Br^2$, easily decomposed by heat, by ammonia, and even by contact with the air (Laurent). Th. Swarts (*Instit.* 1862, p. 63) prepares this compound by mixing a saturated solution of camphor in chloroform with an equivalent quantity of bromine; the compound then partly separates after a few hours as a red powder, and the remainder is deposited from the mother-liquor in beautiful orange-coloured prisms.

The bromide $C^{10}H^{16}O.Br^2$ is resolved by heating to 100° in sealed tubes (Swarts), or by distillation (Perkin, *Chem. Soc. J.* [2] iii. 22), into hydrobromic acid and monobromocamphor, $C^{10}H^{16}O.BrO$. This compound may also be produced directly by heating bromine and camphor in sealed tubes for three hours in the water-bath (Swarts). It crystallises in transparent prisms very much like those of ordinary sodium sulphate, having a faint odour of camphor, and a turpentine-like taste; dissolves easily in alcohol and ether; melts at about 76° and solidifies at 74°, or when left at rest, sometimes not till cooled to 54° (Perkin), to 36° (Swarts); boils at 274° (Perkin; Swarts). It is not decomposed by alcoholic potash (Swarts). Heated with alcoholic ammonia to 180°, it decomposes to a slight extent, with formation of ammonium bromide and a peculiar base (Perkin). It unites with hydrobromic acid, forming an oily compound, $6C^{10}H^{16}O.BrO.11Br$. Heated with bromine to 120° in a sealed tube, it forms, together with hydrobromic acid, an oil the alcoholic solution of which, when decolorised by animal charcoal, deposits shining prisms of dibromocamphor, $C^{10}H^{14}O.Br^2O$. This latter compound smells like turpentine, has a bitter taste, is insoluble in water, and less soluble in alcohol than camphor or the monobrominated compound. It melts at 114.5°, becomes liquid even under boiling water, and distils with partial decomposition at 285° (Swarts, *Zeitschr. f. Chem.* [2] ii. 628).

Chlorocamphor, $C^{10}H^{14}ClO$, is produced by gradually adding camphor to a moderately concentrated solution of hypochlorous acid, and falls to the bottom as a liquid which ultimately solidifies:

After several recrystallisations from dilute alcohol, it forms white indistinct crystals having the smell and taste of camphor, and nearly insoluble in water. It melts at 95°, decomposes at about 200°, with evolution of hydrochloric acid; is but slowly attacked by nitric acid, even at the boiling heat; and dissolves without alteration in strong sulphuric acid at ordinary temperatures. Its alcoholic solution mixed at the boiling heat with silver nitrate yields a precipitate of silver chloride (Wheeler, *Sill. Am. J.* [2] xlv. 48).

Oxycamphor, $C^{10}H^{16}O^2$, isomeric or perhaps identical with camphic acid, is produced (together with two other non-chlorinated compounds not yet isolated) by heating chlorocamphor for several hours with alcoholic potash. It crystallises from alcohol in white needles melting at 137°, distils with vapour of water, may be sublimed without decomposition, and has the smell and taste of camphor (Wheeler).

Sodium-camphor, $C^{10}H^{15}NaO$.—When a solution of camphor in an inert hydrocarbon (toluene, for example) is carefully heated with sodium to 90°, the sodium dissolves, forming a mixture of sodium-camphor and sodium-borneol:

The solution on cooling deposits very unstable crystals of sodium-camphor (Baubigny, *Zeitschr. f. Chem.* [2] ii. 408; iv. 298). According to Malin (*Jahresb.* 1867, p. 724), a boiling solution of camphor in petroleum treated with potassium yields, on evaporation in a vacuum, crystals of potassium campholate, $C^{10}H^{17}KO^2$. If this statement be correct, cymene should also be formed, according to the equation $2C^{10}H^{16}O = C^{10}H^{16}O^2 + C^{10}H^{14}$; but the formation of this hydrocarbon was not actually observed; on the other hand, borneol was found to be produced.

The mixture of sodium-camphor and sodium-borneol obtained as above yields, when treated with alcoholic iodides, the corresponding alcoholic derivatives of camphor and borneol. *Ethyl-camphor*, $C^{10}H^{18}(C^2H^5)O$, is obtained by treating this mixture, or the crystals of sodium-camphor dissolved in a hydrocarbon, with

ethyl iodide, washing the product with water, distilling off the hydrocarbon, cooling the residue to -20° to separate the greater part of the unaltered camphor, and subjecting the remaining liquid to fractional distillation. It is a colourless liquid insoluble in water, soluble in alcohol and ether, boiling between 226° and 229° , having a sp. gr. of 0.916 at 22° , and a dextrogyrate power of about 161.4° for the transition tint (Baubigny).

The portion of the crude liquid obtained in the preparation of ethyl-camphor which distils between 195° and 210° , yields by repeated treatment with sodium, followed each time by distillation, the ethyl-derivative of borneol, $C^{10}H^{17}(C^2H^5)O$. These ethylated derivatives of camphor and borneol are not attacked by phosphorus pentachloride at ordinary temperatures; ethyl-camphor is slowly acted upon at 100° , yielding a small quantity of ethyl chloride. Ethyl-camphor is insoluble in cold nitric acid, but dissolves at 100° , and separates out unaltered on cooling. Ethyl-borneol, on the other hand, is decomposed by nitric acid at ordinary temperatures with evolution of nitrous acid vapours, the acid solution depositing camphor when mixed with water (Baubigny, *Zeitschr.* [2] iv. 481).

Amyl-camphor, $C^{10}H^{18}(C^4H^9)O$, obtained by treating the mixture of sodium-camphor and sodium-borneol with amyl iodide, boils at 277.5° (corr.) and has a dextro-rotatory power of 59.4° . Amyl-borneol could not be isolated from the product of the reaction.

The same mixture of sodium-compounds treated with methyl-iodide yields, on the other hand, methyl-borneol, $C^{10}H^{17}(CH^3)O$, but no methyl-camphor.

The same mixture treated with acetic anhydride, glacial acetic acid, or acetic chloride, yields acetyl-borneol, $C^{10}H^{17}(C^2H^3O)O$, which is optically inactive, and is resolved by potash-ley into borneol and acetic acid. No acetyl-camphor appears to be formed in either case (Baubigny, *Zeitschr.* [2] iv. 299, 481).

When the product of the action of sodium on camphor is treated with *ethylene bromide*, no ethylene derivatives are formed, but the ethylene bromide is decomposed in the same manner as when it is treated with alcoholic potash, yielding bromethylene, which by further reaction on the sodium-compounds is converted into acetylene, while camphor and borneol are set free:

When a stream of carbonic acid gas is passed to saturation into the mixture of sodium-compounds obtained as above, the sodium salts of camphocarbonic acid, $C^{10}H^{18}O^3$, and borneol-carbonic acid, $C^{10}H^{18}O^3$, are produced by direct addition of CO^2 . On adding water to the product, the sodium salts dissolve, and the aqueous solution, if immediately separated by decantation from the hydrocarbon, soon becomes turbid, and gradually yields an abundant precipitate of borneol, resulting from the decomposition of the very unstable borneol-carbonic acid; this reaction affords indeed an easy way of preparing borneol. The aqueous solution separated from the borneol contains the sodium camphocarbonate, and when mixed with sulphuric or hydrochloric acid, yields a precipitate of camphocarbonic acid (Baubigny, *Zeitschr.* [2] iv. 482, 647).

CAMPHOR RESIN. Camphor heated for three or four hours with alcoholic potash is partly converted into a soft tough golden-yellow resin, $C^{20}H^{30}O^2$, which becomes perfectly inodorous after prolonged heating to 100° (L. Barth, *Zeitschr. f. Chem.* [2] iii. 508).

CAMPHORIC ACID. $C^{10}H^{16}O^4$.—Blumenau (*Ann. Ch. Pharm.* lxxvii, 119) observed that when the crude acid produced by oxidising camphor with nitric acid was heated very strongly to expel the latter, a viscous mass was produced, which he regarded as an isomeric modification of camphoric acid. Monoyer has, however, shown (*J. Pharm.* [3] xlv. 177) that this substance consists of camphoric oxide or anhydride, $C^{10}H^{16}O^3$. To prepare camphoric acid, Monoyer boils camphor with 10 pts. of strong nitric acid and a few platinum-cuttings, renewing the acid from time to time till the supernatant oily layer disappears; then distils off the excess of nitric acid; and heats the camphoric acid, which crystallises out in cooling, till white fumes begin to appear. The residual mixture of camphoric acid with a small quantity of the oxide may be wholly converted, either into the acid by boiling with water, or into the anhydride by distillation. If the same mixture be dissolved in hot alcohol, the solution yields on cooling, especially if a little water be added, nothing but camphoric oxide.

Camphoric oxide treated with barium dioxide and water, is converted into the barium-compound of camphoric peroxide, $C^{10}H^{14}BaO^2$ (Brodie; see iv. 311).

Camphoric acid heated to 200° with concentrated hydriodic acid, yields, together with carbon dioxide and free iodine, a hydrocarbon, C^8H^{12} , which does not unite with bromine, and is oxidised by prolonged heating with chromic acid mixture, to an insoluble acid which crystallises in colourless needles (Weyl, *Zeitschr. f. Chem.* [2] iv. 496).

The camphorates of the alkali-metals yield by dry distillation, phorono or camphorone, $C^8H^{10}O$ (i. 733); but when fused with excess of caustic alkali, they yield chiefly three products, all of which are acids, one volatile consisting of butyric acid (perhaps mixed with valeric), and two fixed—viz. a crystalline acid melting at 114° , and exhibiting the composition of pimelic acid, $C^6H^{10}O^4$, and a liquid acid resembling Schwanert's camphretic acid (Hlasiwetz u. Grabowski, *Zeitschr. f. Chem.* [2] iv. 508).

Potassium camphorate, $C^{10}H^{10}O^4K^2$, obtained by saturating a boiling solution of potassium carbonate with camphoric acid, crystallises with difficulty in tufts of deliquescent crystals soluble in alcohol. The *sodium salt* $C^{10}H^{10}O^4Na^2$ prepared in like manner forms indistinct crystals which deliquesce in moist air. The *lithium salt* $C^{10}H^{10}O^4Li^2$ is a white powder soluble in an equal weight of water, soluble also in alcohol. Acid camphorates of the alkali-metals have not been obtained.

Barium salts.—By boiling camphoric acid with excess of barium carbonate, an acid and a neutral salt are formed together, the acid salt crystallising out first. The *neutral salt* $2C^{10}H^{10}O^4Ba \cdot 9H^2O$ crystallises in wavellic needles, soluble in an equal weight of water, sparingly soluble in alcohol, becoming anhydrous at 120° . The *acid salt* $(C^{10}H^{10}O^4)^2Ba \cdot 2H^2O$, or $C^{10}H^{10}O^4Ba \cdot C^{10}H^{10}O^4 \cdot 2H^2O$, obtained as above, or by dissolving camphoric acid in an equivalent quantity of the neutral salt, crystallises in tufts of prisms soluble in 50 pts. of boiling and 120 pts. of cold water. When heated it gives off part of the camphoric acid, which sublimes. *Calcium salts*.—The *neutral salt* $2C^{10}H^{10}O^4Ca \cdot 9H^2O$ is obtained by treating camphoric acid with milk of lime, in crystalline crusts soluble in 12 to 15 pts. water. The *acid salt* $(C^{10}H^{10}O^4)^2Ca$ is obtained in large anhydrous prismatic crystals by boiling the neutral salt with camphoric acid, evaporating to dryness, and crystallising the residue from aqueous solution. A *hydrated acid salt*, $(C^{10}H^{10}O^4)^2Ca \cdot 7H^2O$, was once obtained in crystalline crusts by boiling calcium carbonate with aqueous camphoric acid, evaporating to dryness, and crystallising the redissolved residue. By again boiling this last salt with calcium carbonate, crystalline crusts or prismatic crystals were formed, soluble in 15 pts. water, and agreeing approximately with the formula $2C^{10}H^{10}O^4Ca \cdot (C^{10}H^{10}O^4)^2Ca \cdot 8aq$. The *magnesium salt* $C^{10}H^{10}O^4Mg$, produced by heating aqueous camphoric acid with magnesia alba, crystallises, apparently under similar circumstances, with $7\frac{1}{2}$, 12, and $13\frac{1}{2}$ mol. water. The $7\frac{1}{2}$ -hydrate forms thin efflorescent tables soluble in 2.5 pts. water at 20° , and becoming anhydrous at 120° . A dilute solution of the neutral salt mixed with camphoric acid deposits the latter without forming an acid magnesium salt. The *zinc salt* $C^{10}H^{10}O^4Zn$, obtained by precipitation, is a white sparingly soluble powder (R. Kemper, *Arch. Pharm.* [2] ex. 106; exvii. 23; *Jahresb.* 1862, p. 270; 1864, p. 403). *Cupric camphorate* heated to 200° gives off, together with camphoric anhydride and water, a hydrocarbon which, after rectification over sodium, has the composition $C^{11}H^{14}$, boils at 105° , has a density of 0.793, vapour-density 3.984; smells like camphor and turpentine-oil; is converted by hydrochloric acid gas into a green oil of small volatility; and is resinised by nitric acid (Moitessier, *Jahresb.* 1866, p. 410).

Inactive Camphoric Acid—Paracamphoric Acid—is produced by oxidation of optically inactive camphor (i. 729), or by mixing equal weights of dextro-camphoric and lævo-camphoric acids in concentrated alcoholic solution; in the latter case a change of temperature takes place, amounting sometimes to 30° , and the inactive acid separates as a white precipitate.

Paracamphoric acid crystallises with difficulty in forms belonging to the monoclinic system, but not exhibiting hemihedral faces. It is less soluble than either of the optically active camphoric acids; 100 pts. alcohol dissolve 33 pts. of it; 100 pts. ether 28 pts.; 100 pts. water only 1 pt.; and in chloroform it is still less soluble. The paracamphorates of the alkali-metals are easily soluble and uncrystallisable. The barium salt forms needle-shaped crystals, soluble in about 10 pts. of water.

When 10 pts. of paracamphoric acid are boiled with 20 pts. absolute alcohol and 6 pts. sulphuric acid, and the liquid then mixed with water, a viscid oil separates, which is resolved by heat into ethyl paracamphorate and paracamphoric anhydride. On dissolving the mixture in boiling alcohol, the anhydride crystallises

out, while the ether remains in solution, and may be precipitated by water. *Para-camphoric anhydride* crystallises from chloroform in small needles; 100 pts. chloroform dissolve 25 pts. of it; 100 pts. ether, 4 pts.; 100 pts. alcohol, only $1\frac{1}{2}$ pt. *Ethyl paracamphorate* is a colourless strong-smelling oil, having a sp. gr. of 1.03 at 15° , and boiling at 270° – 275° . Boiling potash-ley decomposes it, with formation of an inactive camphoric acid, different from that which was employed in its preparation, being pulverulent, uncrystallisable, nearly insoluble, fusible, and subliming partially with loss of water (Chautard, *Compt. rend.* lvi. 698; *Jahresb.* 1863, p. 394).

CAMPHERENE. $C^{10}H^{14}O$.—A product isomeric with phorone, formed by the action of sulphuric acid upon camphor. It was first obtained by Chautard (who assigned to it the formula $C^{10}H^{12}O$, i. 727), and has been further examined by Schwanert (*Ann. Ch. Pharm.* cxxiii. 298). To prepare it, 1 pt. of camphor is heated to 100° for five or six hours with 4 pts. sulphuric acid; the resulting solution is mixed with water; the oil which rises to the surface is distilled; and the portion which goes over between 220° and 240° (the distillate of lower boiling point containing a larger proportion of unaltered camphor) is heated nearly to its boiling point in a stream of hydrogen for four or five days, or till no more camphor is deposited on the neck of the retort, then rectified, the portion boiling between 230° and 235° being collected apart.

Camphrene is a nearly colourless liquid having a pleasant aromatic odour and a sharp taste, a sp. gr. of 0.9614 at 20° ; optically inactive; insoluble in water, easily soluble in alcohol and ether. From phorone, which resembles it in its chemical reactions, it is distinguished chiefly by its boiling point, which is from 27° to 30° higher than that of phorone (208°); a similar difference of boiling point is exhibited also by the corresponding derivatives of the two. Both phorone and camphrene are converted by phosphoric anhydride into hydrocarbons having the composition of cumene, C^8H^{12} , that from phorone boiling at 150° – 160° , that from camphrene at 170° – 175° . Both camphrene and phorone are oxidised by nitric acid to camphenic acid.

Methyl-camphrene, $C^9H^{13}(CH^3)O$, is formed by adding sodium to a mixture of equal parts of camphrene and benzene in an atmosphere of hydrogen, till the sodium remains unaltered even when heated, and cohobating the solution with excess of methyl iodide. Water added to the resulting liquid separates a brown oil, from which, by repeated rectification, methyl-camphrene is obtained as a colourless aromatic liquid boiling at 225° – 230° .

Acetyl-camphrene is obtained in like manner, using acetyl chloride instead of methyl iodide. It is a yellowish viscid liquid, having an unpleasant odour, a sp. gr. of 0.954 at 18° , and boiling at 230° – 240° . Its analysis leads to the formula $C^{10}H^{27}(C^2H^3O)^2$, from which it may be inferred that the true formula of camphrene is $C^{10}H^{24}O^2$, and that of methyl-camphrene $C^{10}H^{26}(CH^3)O^2$. This double formula of camphrene is quite consistent with the difference of boiling point between camphrene and phorone, which seems to indicate that these compounds are polymeric with one another, rather than merely isomeric.

CAMPHERNIC ACID. $C^9H^8O^4$? (Schwanert, *loc. cit.*).—Produced, by treating camphrene or phorone for a considerable time with 3 or 4 pts. of strong nitric acid, as a resinous mass which may be purified by solution in sodium carbonate, precipitation with an acid, and evaporation of the alcoholic solution, after decolorisation with animal charcoal. It is white or pale yellow, tasteless and inodorous, nearly insoluble in water, easily soluble in alcohol and ether, and crystallises in microscopic nodules. Heated to 250° it suffers partial carbonisation, and gives off the anhydride $C^9H^8O^3$, in white feathery crystalline groups. The *barium salt* $C^9H^8O^4Ba$ is a brownish-yellow amorphous mass easily soluble in water. The *lead salt* $C^9H^8O^4Pb$, and the *silver salt* $C^9H^8O^4Ag$, are white precipitates.

CAMPHERETIC ACID. $C^{10}H^{14}O^2$?—An acid occurring, according to Schwanert (*Ann. Ch. Pharm.* cxxviii. 77), amongst the products obtained by heating camphor with dilute nitric acid, and yielding by dry distillation pyrocampheretic acid, $C^{10}H^{14}O^4$, in the form of an oil; metacampheretic acid, $C^{10}H^{14}O^3$, in tabular crystals; and a sublimate of camphoric anhydride (iv. 756). The existence of this acid is, however, by no means well established. The acid itself and all its salts and ethers are uncrystallisable, and therefore their analyses are not much to be depended upon.

CAMPHYRYL CHLORIDE, $C^{10}H^{13}Cl$, is produced by the action of phosphorus pentachloride on camphrene. The distillate, washed with water and sodium carbonate and repeatedly rectified, yields camphryl chloride as a colourless neutral liquid of sp. gr. 1.038 at 14° and boiling at 205° . The isomeric compound, phoryl or camphoryl

chloride, boils at 175° . Camphryl chloride is not decomposed by sodium ethylate (Schwanert, *Ann. Ch. Pharm.* cxxiii, 298).

CANADOL. A term applied by H. Vohl to that portion of the volatile hydrocarbons of Canadian and Pennsylvanian petroleum which boils at 60° and has a sp. gr. of 0.650 to 0.700. This liquid is recommended by Vohl, instead of carbon bisulphide, for extracting the fixed oils of seeds (*Dingl. pol. J.* clxxii, 319; *Jahresb.* 1866, p. 893).

CANARIUM. The fixed oil of the East Indian plant, *Canarium commune*, contains about 51 p. c. olein and 49 p. c. stearin and myristin. The oleic acid obtained from it by saponification is identical with that from olive oil (Oudomans, *J. pr. Chem.* cxix, 407).

CANAÜBA WAX. This wax, which forms a coating on the leaves of the Canaüba tree of Brazil (*Copernicia cerifera*), has been investigated by Maskelyne (*Chem. Soc. J.* [2] vii, 87). It is light yellow with a tinge of green; considerably harder than beeswax at ordinary temperatures; melts at about 84° ; has a sp. gr. of 0.99907; and leaves about 0.14 p. c. ash when burnt. By saponification with alcoholic potash it yields a considerable quantity of myricyl alcohol, $(C^{30}H^{40}O)$ or $(C^{31}H^{40}O)$, melting at about 88° , which exists in the wax in the free state, and may also be dissolved out from it by alcohol. By treating this alcohol in the fused state (at 120° – 135°) with phosphorus and iodine, it was converted into an iodide, $C^{30}H^{41}I$ or $C^{31}H^{41}I$, insoluble in ether and melting at 67° ; and another substance melting at 70° – 75° , which was dissolved by the ether. With phosphorus pentachloride it yielded a chlorinated substance probably consisting of a mixture of the compounds $C^{30}H^{41}Cl$ and $C^{30}H^{40}Cl_2$ or $C^{31}H^{41}Cl$ and $C^{31}H^{40}Cl_2$. Hoated with sulphuric acid and then saturated with alcoholic potash, it yielded a potassium salt agreeing with the formula $C^{31}H^{42}KSO_4$ more nearly than with $C^{30}H^{41}KSO_4$.

The wax also contains small quantities of other alcohols, very difficult to separate. By repeated crystallisation from benzol and ether, it appears to yield an alcohol $C^{32}H^{46}O$, melting at 78° , and a substance $C^{32}H^{46}O_2$, melting at 105° .

Lastly, the wax contains a mixture of several acids differing in their melting points, but very difficult to separate from a resinous body which adheres to them.

Carnaüba or *Carnahuba wax*, which coats the leaves of *Corypha cerifera* (i. 805), also a Brazilian tree, is probably the same as Canaüba wax, inasmuch as it melts at about 84° and yields by saponification an alcohol melting at 88° . According to Bérard (*Zeitschr. f. Chem.* [2] iv, 415 $^{\circ}$), it also contains cerotic acid, which may be dissolved out by alcohol.

CANNABENE. See the next article.

CANNABIS. When Indian hemp (*Cannabis indica*) is distilled in considerable quantity with an equal weight of water, an oil lighter than water is obtained, which at 12° deposits small crystals, and is therefore a mixture of two substances, one liquid, the other solid. The liquid portion, cannabene, is colourless; has a powerful odour; boils between 235° and 240° ; distils in a vacuum between 90 and 96° ; gives by analysis numbers agreeing with the formula C^9H^{10} , and has a vapour-density of 4.38 (calc. 3.99). When heated it appears to be partly converted into isomeric modifications which interfere with the exact determination of its boiling point and vapour-density. It dissolves with red colour in strong sulphuric acid, and is oxidised by chromic acid, yielding acetic and valerianic acids, together with other products. Cannabene exerts a powerful intoxicating action, though in this respect it is less energetic than *cannabin*, the resin of Indian hemp (i. 734). The solid substance which separates from the crude oil, as above mentioned, crystallises from alcohol in small scales having a fatty lustre and a faint odour of hemp; it contains 84.02 p. c. carbon and 16.98 hydrogen (Personne, *J. Pharm.* [3] xxxi, 46).

Oxycannabin, $C^9H^8O_2$, is obtained by repeatedly treating the resinous extract of Indian hemp with nitric acid of sp. gr. 1.32 to 1.42 till the whole is dissolved, then evaporating the acid liquors, washing the deposited substance with cold water, and crystallising it from hot methylated spirit. It forms long, flat, white or slightly yellow prisms, tasteless, insoluble in water, slightly soluble in alcohol, soluble also in benzol and in chloroform, insoluble in carbon bisulphide and in ether. It dissolves in hot nitric acid and separates unchanged on evaporation; also in oil of vitriol, the solution blackening when heated. It is not altered by boiling with moderately strong potash, soda, or ammonia; its alcoholic solution is neutral to test-paper. Heated on platinum-foil it melts and burns; heated in a tube it melts at 175° – 176° , and at a higher temperature sublimes without residue in long asbestos-like needles.

The acid mother-liquors of oxycannabin left, on further evaporation, an acid substance crystallising in plates (Bolas & Francis, *Chem. Soc. J.* [2] vii, 417).

CANTHARIDIN. According to Ferrer (*Jahresb.* 1863, p. 597), this substance exists in all parts of cantharides, but most abundantly in the soft parts. From 20 grms. of *Mylabris pustulata* he obtained 0.066 grm. cantharidin; from other species of *Mylabris*, smaller quantities.

Mortreux (*J. Pharm.* [3] xlv. 33) prepares cantharidin by exhausting pulverised cantharides with chloroform (or ether) and treating the evaporated extract with carbon bisulphide, which dissolves the admixed fat, and leaves nearly pure cantharidin, to be finally purified by recrystallisation from alcohol. By the use of a suitable displacement apparatus, the same process may be applied to the quantitative estimation of cantharidin. According to Mortreux's experiments, cantharides contain on the average 0.5 p. c. of cantharidin. A similar method of preparation and estimation is recommended by Fumouze (*ibid.* [4] vi. 161). According to Werner (*Jahresb.* 1867, p. 736), a quantity of cantharidin, larger by $\frac{1}{5}$ to $\frac{1}{2}$, is obtained by treating the insects with $\frac{1}{10}$ pt. finely pulverised heavy spar and $\frac{1}{950}$ dilute sulphuric acid, then quickly drying them over calcium chloride, with addition of $\frac{1}{32}$ pt. of burnt alum, and exhausting with ether.

According to Bluhm (*Zeitschr. f. Chem.* [2] i. 675; *Jahresb.* 1865, p. 571), cantharidin exists in cantharides in two modifications, one soluble, the other insoluble, in alcohol, ether, and chloroform; but the insoluble modification may be rendered soluble by treating the pulverised cantharides with an acid, or drying them mixed with water and calcined magnesia, and treating the dried mass with dilute sulphuric acid. When cantharides are desiccated with magnesia, a crystalline compound is formed, insoluble in alcohol, ether, or chloroform, and only partially soluble in water, but still possessed of vesicating properties. With baryta also cantharidin forms a compound sparingly soluble in water; with the alkalis, easily soluble compounds. Cantharidin does not volatilise with vapour of water or alcohol. 100 pts. of the following liquids dissolve at 18° the quantities of cantharidin stated below:

Alcohol	Carbon bisulphide	Ether	Benzol	Chloroform
0.03	0.06	0.11	0.20	1.20

For the estimation of cantharidin, 30 grms. of pulverised cantharides are mixed with water and 8 to 10 grms. of calcined magnesia, and dried over the water-bath; the residuo is supersaturated with dilute sulphuric acid and shaken up with ether frequently renewed; or the mass is dried a second time and treated with ether or chloroform. The residuo of the ether or chloroform extract, consisting of cantharidin, fat, and a yellow substance, is treated with carbon bisulphide to remove the fat, and with alcohol to remove the yellow substance, and the residuo is weighed, the quantities of cantharidin dissolved by the carbon bisulphide and the alcohol being estimated by calculation and added to the weight. By this method Bluhm found in cantharides 0.264 p. c. cantharidin, and in *Mylabris quatuordecimpustulata* 0.486 p. c.; in *M. melanura* only a very small quantity.

Dragendorff a. Mosing (*Zeitschr. f. Chem.* [2] iii. 464; iv. 308) have obtained a number of metallic derivatives of cantharidin, mostly crystallisable and represented in composition by the formulæ $C^2H^2O^2M$ and $(C^2H^2O^2)^2M$. The compounds with the alkali-metals separate in the crystalline form on heating cantharidin with the solution of an alkaline hydrate; those of the alkaline earth-metals and heavy metals are obtained by double decomposition with the potassium compound, as sparingly soluble mostly crystalline precipitates. These precipitates, however, are generally mixed with free cantharidin, so that their composition as determined by analysis is uncertain.

According to Dragendorff (*Zeitschr. f. Chem.* [2] iii. 187), cantharidin is not poisonous to all animals, and acts upon different animals with various degrees of intensity.

Dragendorff finds also that cantharides contain a small quantity of a volatile body which passes over in distillation with water, and exerts the same physiological action as cantharidin.

CAOUTCHOUC. W. A. Miller (*Chem. Soc. J.* [2] iii. 273) has made important observations on the alteration of caoutchouc (and of gutta-percha) by the action of air and water. Caoutchouc may be left for years in the dark, exposed to the air or under water, without much alteration, but if exposed to light and to the open air, and especially to the alternate action of air and water, it soon becomes glutinous, less elastic, and more soluble in alcohol and dilute alkalis than unaltered caoutchouc. This change, which is due to oxidation, takes place more quickly with manufactured caoutchouc than with the less porous natural substance. The chemical nature of the change is shown by the following analyses: A, of natural caoutchouc; B, of

manufactured caoutchouc; C, of the portion of A (11·8 p. c.) which was dissolved out by alcohol, after the caoutchouc had been exposed for nine months to air and light:

	Carbon	Hydrogen	Oxygen		
A . .	85·82	11·11	3·07	=	100
B . .	85·53	12·06	2·41	=	100
C . .	67·23	9·54	23·23	=	100

A similar result was obtained by Spiller (*ibid.* 44) in a waterproof packing-cloth consisting of cotton and dissolved caoutchouc, which had been exposed to the air for six years.

Caoutchouc swells up and dissolves with great facility in melting naphthalene (Kletzinsky, *Zeitschr. f. Chem.* [2] ii. 127).

CAPILLARITY. According to Musculus (*Chem. Centr.* 1864, p. 922; *Jahresb.* 1864, p. 5), many substances, even in small quantity, exert a considerable influence on the capillarity of water, whereas others do not perceptibly alter it. To the class of substances active in this respect belong alcohol, acetic acid, the derivatives of alcohol which are soluble in water, also the biliary acids, and soap; to the inactive class belong mineral acids, most salts, sugar, extractive matters, and albumin. Musculus estimates the force of capillarity by measuring, by means of a simple apparatus, the pressure required to expel the column of liquid from the capillary tube. He recommends capillaritymetry as a delicate analytical method for the detection of substances which are active in the sense above mentioned, and especially for estimating the amount of alcohol or acetic acid in aqueous solutions. The capillarity of water being taken as unity, the following values have been obtained for other liquids, all estimated in the same capillary tube:

	Capillarity
Water	1·000
Alcohol	0·312
Acetic acid	0·393
Water containing 2 p. c. Alcohol	0·904
" 5 p. c. "	0·800
" 2 p. c. Acetic acid	0·950
" 5 p. c. "	0·845

On this principle an alcoholometer called a 'liquometer' has been constructed. Its essential part consists of a graduated capillary tube about 4 inches long, and having its lower end in contact with the liquid to be tested. The point of the tube at which the liquid column finally rests indicates the proportion of alcohol in the liquid. The indications of the instrument are limited to 20 p. c. alcohol; liquids richer in alcohol must previously be diluted with a measured quantity of water. This liquometer is applicable to the testing of pure alcoholic liquids, and probably also of light wines; but not to wines rich in sugar or to beer (*Pharm. J. Trans.* [2] ix. 171; *Jahresb.* 1867, p. 14).

Wilhelmy (*Pogg. Ann.* cxxi. 44; cxxii. 1) has determined by a peculiar process the coefficients of capillarity* of a number of organic substances, and has deduced from the results the following general conclusions respecting the dependence of this physical property upon chemical composition.

1. In substances equal in their proportions of hydrogen and oxygen, the coefficient of capillarity increases with the amount of carbon: *e.g.* alcohol C^2H^6O , and acetone C^3H^6O ; ethyl acetate $C^4H^8O_2$, and methyl-benzoate $C^8H^8O_2$; amylene C^8H^{10} , and xylene C^8H^{10} .

2. In like manner, with equal amounts of hydrogen and carbon, the coefficient of capillarity increases with the amount of oxygen: *e.g.* acetone C^3H^6O , ethyl-formate $C^4H^8O_2$, and lactic acid $C^3H^4O_3$.

* The coefficient of capillarity is the weight of liquid raised by capillary action on an immersed solid body, for the linear unit of the line of contact (1 mm.). This weight, α , is calculated by the equation

$$\alpha = \frac{w - P - \sigma s}{\lambda}$$

in which P denotes the weight in air of the immersed body; σ , the weight which counterpoises the same body when immersed so far that the portion σ of its total volume is within the liquid; λ , the length of the contact-line between the solid body and the liquid; and s , the specific gravity of the liquid.

The above equation gives

$$w = P + \sigma s + \alpha \lambda.$$

Wilhelmy regards this coefficient of capillarity α as an approximate measure of the molecular cohesion of the liquid.

3. It likewise increases with the simultaneous increase of carbon and oxygen: *e.g.* methyl alcohol C^2H^4O , and acetic acid $C^2H^4O^2$; ethyl alcohol C^2H^6O , and lactic acid $C^3H^6O^3$.

4. Increase in the proportion of hydrogen diminishes the coefficient of capillarity: *e.g.* benzoic aldehyde C^7H^6O , and ethyl-amyl ether $C^7H^{10}O$; salicyl $C^7H^6O^2$, and amyl acetate $C^7H^{10}O^2$.

5. By increase of oxygen and diminution of hydrogen it is increased: *e.g.* butyric acid $C^4H^8O^2$, and acetic anhydride $C^4H^6O^3$.

6. The presence of chlorine, bromine, or iodine increases the coefficient of capillarity when the amount of hydrogen is at the same time diminished, and, within certain limits, even when the amount of hydrogen is increased, or that of oxygen diminished: *e.g.* ethyl chloride C^2H^5Cl , and ethylene chloride $C^2H^4Cl^2$; ethyl-amyl ether $C^7H^{10}O$, and benzoyl chloride C^7H^5OCl ; ethyl oxide C^2H^6O ; ethyl chloride C^2H^5Cl , bromide, and iodide.

7. Homologous compounds have equal coefficients of capillarity.

8. Increase of oxygen raises the coefficient of capillarity, even when the substance richer in oxygen differs at the same time by $\pm nCH^2$ from the one which contains less oxygen; this however is true only for compounds of similar character. As examples in which it holds good are adduced: acetic anhydride $C^4H^6O^3$, and ethyl oxalate $C^4H^{10}O^4$; amylene C^6H^{10} , and methyl valerate $C^6H^{12}O^2$; cuminal $C^9H^{10}O$, and methyl benzoate $C^9H^{10}O^2$; cetylene C^4H^2 , and acetic acid $C^2H^4O^2$. As examples of compounds in which the same law does not hold good: salicyl $C^7H^6O^2$, and methyl-salicylic acid $C^8H^8O^3$; cetylene C^4H^2 , and amyl formate $C^6H^{12}O^2$.

9. Isomeric compounds exhibit equal coefficients of capillarity only when they are allied in chemical character.

On *electro-capillary diffusion*, see Becquerel (*Compt. rend.* lxvii. 1081; *Zeitschr. f. Chem.* [2] v. 134).

CAPROIC ACID. $C^6H^{12}O^2 = C^6H^{11}O \cdot H \cdot O = C^6H^{11} \cdot CO^2H$.—This acid occurs, together with butyric and valeric acids, in the flowers of *Satyrium hircinum*, which have an odour of bugs (Chautard, *Bull. Soc. Chim.* [2] ii. 56); and, together with several of its lower homologues, in the sarcocarp of *Ginkgo biloba* (Béchamp, *ibid.*). It has also been found by C. Kraut (*Ann. Ch. Pharm.* ciii. 29), together with butyric acid, in the water of a brook running out of peaty soil.

Caproic acid is formed synthetically:

1. By the action of carbon dioxide on sodium-amyl (produced by treating zinc-amyl with sodium):

(Wanklyn a. Schenk, *Chem. Soc. J.* [2] vi. 31).

2. By treating amyl hydride with carbonyl chloride, whereby caproyl chloride is produced:

converting this chloride into ethyl caproate by the action of boiling alcohol, the ethyl caproate into barium caproate, &c. (Harnitz-Harnitzky, *Bull. Soc. Chim.* [2] iii. 363).

It is also produced in the following reactions:

3. By the action of hydriodic acid upon leucine (amidocaproic acid):

(Hüfner, *Zeitschr. f. Chem.* [2] iv. 391).

4. Together with hexyl alcohol and marsh gas, by the fermentation of ethyl alcohol in contact with syntonin or washed meat, and chalk (Béchamp, *ibid.* 702):

and

5. In small quantity, together with butyric acid, in the fermentation of St. John's bread (the fruit of *Ceratonia siliqua*) and of starch-paste (J. Sticht, *ibid.* p. 220).

6. Together with cœnanthyl and valeric acids and capronitrile, in the oxidation of diamyl by nitric acid (Schorlemmer, *ibid.* 513).

7. By oxidation of octylene hydrate (secondary octyl alcohol) with potassium dibromate and sulphuric acid (P. De Clermont, *ibid.* v. 727).

8. In the dry distillation of wood. After the watery portion of the crude distillate

has been neutralised with soda, and the greater part of the sodium acetate has crystallised out, a mother-liquor is obtained which, after concentration, yields successively the sodium salts of all the fatty acids from formic to caproic (Barre, *ibid.* 445).

Caproic acid prepared by the action of alcoholic potash on amyl cyanide (i. 743) boils at 195° under a barometric pressure of 746 mm. (Rossi, *Ann. Ch. Pharm.* cxxiii. 176).

The primary octylic ether of caproic acid $C^6H^{10}O^2 \cdot C^8H^{17}$ is one of the constituents of the volatile oil of *Heracleum sphondylium*. The acid $C^6H^{12}O^2$, obtained from it, is an oily liquid boiling between 200° and 205° , solidifying at about -10° to a white mass; it appears to be identical with the caproic acid of natural fats, but differs in some respects from that prepared from amyl cyanide, e.g. in the characters of its silver salt (Zincke, *Ann. Ch. Pharm.* clii. 20).

Bromocaproic acid, $C^6H^{11}BrO^2$, produced by heating 2 pts. caproic acid and 3 pts. bromine to 140° – 145° for several hours, is a liquid having a less unpleasant odour than caproic acid itself, and boiling at about 240° . It is converted by potash or moist silver oxide into leucic acid, $C^6H^{12}O^2$, and by ammonia into leucine, $(C^6H^{11}NO^2)$ (Cahours, *Rép. Chim. pure*, iv. 145; *Jahresb.* 1862, p. 250). See also Hüfner (*Zeitschr. f. Chem.* [2] iv. 616).

CAPROIC ALDEHYDE, $C^6H^{10}O = C^6H^{11} \cdot COH$, produced by distilling a mixture of sodium formate and caproate, and purified by separation from its compound with sodium bisulphite, is a liquid having a pungent, but not unpleasant aromatic odour, boiling at 121° (bar. at 743 mm.), slightly soluble in water, miscible with alcohol, ether, and glacial acetic acid. It reduces ammoniacal silver nitrate; is converted by oxidation into caproic acid identical with that obtained from amyl cyanide; and when dissolved in strong acetic acid, and treated with sodium-amalgam, it is converted into primary hexyl alcohol $C^6H^{14}O$, boiling at 150° (Rossi, *loc. cit.*).

CAPRYLAMIDE, $C^8H^{14}O \cdot H^2N$ or $C^8H^{13} \cdot CO^2NH^2$, produced by leaving ethyl caprylate in contact with strong aqueous ammonia for three months, forms large inciporous crystalline laminae, permanent in the air, easily soluble in alcohol and ether, melting at 110° , and boiling without decomposition at a temperature above 200° . When hydrochloric acid gas is passed into its ethereal solution, a solid mass is formed, which redissolves on continuing the passage of the gas, and the ethereal solution when evaporated leaves the crystallised hydrochloride $C^8H^{13}NO \cdot HCl$. *Antimonic chloride* acts violently on caprylamide, but if the mixture be well cooled, no decomposition takes place, the two bodies uniting directly, and forming a compound which crystallises after a few days in large four-sided prisms. *Phosphoric anhydride* converts caprylamide into caprylonitrile, $C^8H^{11}N$ (E. Felletar, *Zeitschr. f. Chem.* [2] iv. 665).

CAPRYLIC ACID. $C^8H^{16}O^2 = C^8H^{15} \cdot CO^2H$.—This acid has been found, together with several of its homologues, in putrid yeast, in the root of *Arnica montana*, and among the products of the oxidation of Chinese wax by nitric acid (*Jahresb.* 1857, pp. 303, 403; 1861, p. 752). It is also produced by oxidising primary octyl alcohol, $C^8H^{17} \cdot CH^2OH$ (from the fruit of *Heracleum sphondylium*), with potassium dichromate and dilute sulphuric acid (Zincke, *Zeitschr. f. Chem.* [2] v. 56). The acid obtained by this last process boils at 230° – 234° , and solidifies at 12° , forming a white mass like spermaceti which melts between 16° and 17° ; it appears, therefore, to be identical with the caprylic acid obtained from butter and from cocoa-nut oil (i. 745). It is slightly soluble in water, and separates therefrom at low temperatures in thin laminae. The *barium salt* $(C^8H^{15}O^2)_2Ba$ separates from a concentrated solution by evaporation or rapid cooling in thin nacreous laminae; by slow cooling in thin flat concentrically grouped needles. The *calcium salt* $(C^8H^{15}O^2)_2Ca \cdot H^2O$ is very much like the barium salt, but somewhat less soluble, and the needles which it forms by slow cooling are thinner, longer, and have a fine silky lustre when dry. The *silver salt* $C^8H^{15}O^2Ag$ is a white curdy precipitate, but slightly sensitive to light or heat, dissolving when boiled with a large quantity of water, but immediately separating in flocks on cooling (Zincke).

CAPRYLONITRILE or **HEPTYL CYANIDE**, $C^8H^{11}N = C^8H^{10} \cdot CN$, obtained by heating ammonium caprylate or caprylamide with phosphoric anhydride, is a clear colourless liquid, having a highly aromatic odour, like that of cinnamon oil, and a sweetish, aromatic, slightly burning taste. Sp. gr. = 0.8201 at 18° . Boiling point 194° – 196° . Very inflammable; burns with a bright fuliginous flame. Mixes with alcohol and ether. By boiling with alcoholic potash it is converted into ammonia and potassium caprylate (Felletar, *Zeitschr. f. Chem.* [2] iv. 666).

396 CAPSULÆSCIC ACID—CARBACETOXYLIC ACID.

CAPSULÆSCIC ACID. $C^{12}H^{12}O^8$.—An acid obtained from the husks of the horse-chestnut. The concentrated alcoholic decoction is left to cool; the liquid expressed from the jelly which then forms is distilled in the water-bath; and the lukewarm aqueous infusion of the residue is precipitated with neutral lead acetate. The portion of the precipitate insoluble in dilute acetic acid, after repeated decomposition with hydrogen sulphide, precipitation with lead acetate, and boiling with alcohol, yields, by evaporation of the liquid filtered from the lead sulphide, colourless crystals of capsulæscic acid. This acid sublimes without decomposition and crystallises unaltered from hot dilute hydrochloric acid. Its aqueous solution is coloured dark greenish-blue by ferric chloride, and its solution in hot potash-ley reacts like an alkaline solution of gallic acid (Rochleder, *Jahresb.* 1866, p. 693).

CARAMEL. When crude caramel obtained by heating sugar to 210° – 220° is dialysed through parchment-paper (iii. 716), carameline and caramelene pass through, whilst caramelin, the component richest in carbon (i. 748), remains on the dialyser. This purified caramel (which may also be prepared from crude caramel by repeatedly precipitating the aqueous solution with alcohol, till the precipitate is no longer plastic, but pulverulent) possesses five times the colouring power of crude caramel. A solution containing 10 p. c. of it is gummy, and coagulates on standing to a jelly perfectly soluble in water, whether hot or cold; its solution dries up in a vacuum to a black shining mass, which when it retains a certain amount of water is still tough and elastic. If this caramel has been completely dried at a comparatively low temperature, it remains soluble in water even after subsequent heating to 120° ; but if its solution be directly evaporated to dryness at 100° , it becomes insoluble both in hot and in cold water. Soluble purified caramel contains 54.59 p. c. carbon, agreeing with the formula $C^{24}H^{30}O^{13}$. A solution of pure caramel is tasteless and neutral; the caramel is precipitated from it by the smallest quantities of mineral acids, alkaline sulphates, sodium chloride and most other salts, and by alcohol, as a brownish-black pulverulent substance insoluble in water; the caramel in the crude product of the roasting of sugar is protected from the action of these bodies by the presence of undecomposed sugar and brown substances of intermediate composition. Insoluble caramel obtained as above swells up to a gelatinous mass in weak potash-solution, and dissolves therein when warmed. If the solution be then dialysed, the proportion of potash in that which remains in the dialyser rapidly diminishes to 9 p. c., and on adding acetic acid, the whole of the potash passes through, and pure caramel remains (Graham, *Chem. Soc. J.* xv. 258).

Caramelene.—According to Gélis (*Rép. Chim. pure*, iv. 410), this substance may be prepared from starch-sugar, and becomes perfectly colourless when treated with animal charcoal. It cannot be reconverted into sugar. When the sugar in the preparation of caramel has not been heated long enough, or to a sufficiently high temperature, the portion of the product soluble in alcohol contains, besides carameline, a considerable quantity of glucosane. The latter is also colourless, and differs from carameline in being reconvertible into sugar by the action of water or dilute acids.

Methods of preparing caramel brown are described by F. Thomson and T. Sherlock (*Chem. News*, xv. 242, 282).

CARAPIN. An uncrystallisable bitter principle obtained from the bark of *Carapa guianensis*. It is nearly related to caill-cedrin (p. 384) and tulucunin (v. 897), and is prepared in a similar manner to those bodies, but is distinguished from the former by its inferior solubility in ether, and from the latter by not being coloured by acids (Caventou, *Jahresb.* 1861, p. 769).

CARBACETOXYLIC ACID. $C^4H^4O^4$ (Wichelhaus, *Ann. Ch. Pharm.* cxlv. 283).—A monobasic acid isomeric with-malonic acid, produced by heating β chloropropionic acid* with excess of silver oxide:

The resulting solution filtered, heated with sodium-amalgam as long as silver chloride is thereby precipitated, and evaporated, yields silver carbacetoxylylate, $C^4H^4AgO^4$, in tufts of steel-grey shining needles, which may be dried at 100° without decomposition. Carbacetoxylic acid, separated from the silver salt by hydrogen sulphide, remains on evaporation as a yellowish, easily soluble syrup, having the odour of the lower fatty acids. The barium salt crystallises in spherical nodules; the lead salt in crusts; the zinc salt in shining scales; the ammonium salt is very deliquescent.

* The modification of this acid produced from lactyl chloride is called α chloropropionic acid; that produced by the action of PCl^5 on glyceric acid, β chloropropionic acid. (See PROPIONIC ACID.)

Carbaceoxylic acid is converted by nascent hydrogen into glyceric acid, $C^3H^4O^4$. Heated in a sealed tube to 200° with aqueous hydriodic acid, it is reduced to pyroracemic acid, $C^3H^4O^3$, with separation of iodine.

CARBACETYLIC ACID. This name is applied to pyroracemic acid by Wichelhaus (*loc. cit.*), who represents it by the constitutional formula $CH^2=CO-COOH$, regarding it as homologous with glyoxalic acid, $H-CO-COOH$. He finds that it is not attacked by phosphorus pentachloride, and therefore does not contain any alcoholic hydrogen, like glycollic acid, lactic acid, &c.

CARBALLYLIC ACID. Syn. with TRICARBALLYLIC ACID (v. 879).

CARBAMIC ACID. $CO^2NH^2 = NH^2.COOH$.—The ammonium salt of this acid, $CO^2.2NH^2 = NH^2.COONH^2$, is produced by the direct combination of gaseous ammonia and carbon dioxide, and by distilling ammonium sulphamate with sodium carbonate (i. 750). It is also contained in commercial carbonate of ammonia. Kolbe a. Basaroff (*Chem. Soc. J.* [2] vi. 194) prepare it by passing carbon dioxide and ammonia gases, both perfectly dry, into cold absolute alcohol, separating the copious crystalline precipitate by filtration from the greater part of the liquid, and heating it with absolute alcohol to 100° or above in a sealed tube; the liquid on cooling deposits the carbamate in large crystalline laminae. Divers (*ibid.* viii. 216) prepares this salt by the following processes, depending partly on the direct combination of CO^2 and NH^2 , partly on the dehydration of the carbonate: *a.* By passing carbon dioxide and ammonia gas into strong aqueous ammonia.—*b.* By digesting the commercial carbonate or any other carbonate of ammonia to $20^\circ-25^\circ$ in a closed vessel for 36 to 40 hours with aqueous ammonia saturated with the gas at a low temperature.—*γ.* By heating commercial carbonate of ammonia with anhydrous potassium carbonate to $50^\circ-80^\circ$ in a retort connected with a wide tube dipping under mercury, the carbamate then subliming in the neck.—*δ.* By distilling in like manner a mixture of commercial carbonate and anhydrous calcium chloride.—*ε.* By very slowly distilling the commercial carbonate, the more remote part of the earlier incrustation then consisting of impure carbamate.—*ζ.* By distilling normal ammonium carbonate at a heat not exceeding 60° .—*η.* By repeatedly dissolving the commercial carbonate at a gentle heat in the same quantity of water, cooling after each addition, and separating the crystals, until normal ammonium carbonate is deposited; then warming the solution; dissolving a fresh quantity of commercial carbonate in it; leaving it to cool and crystallise for a day; separating the crystals; passing ammonia gas; straining (if necessary) the precipitate of normal carbonate produced; renewing or continuing the stream of ammonia gas till the solution (kept cool) is about saturated; and straining off the precipitate of normal carbonate: the solution then exhibits the characters of the carbamate with a little carbonate dissolved in it.—*θ.* By distilling the commercial carbonate with strong spirit, or better, perhaps, with absolute alcohol.

Ammonium carbamate occurs in the form of flocculi; of a more or less crystalline incrustation; of prisms projecting from this incrustation; of crystalline laminae; and of crystals neither tabular nor decidedly elongated or columnar. When exposed to moist air it gives off ammonia and is gradually converted into acid carbonate:

It differs from the carbonates in not melting when heated. When vaporised at any temperature, it is resolved into ammonia and carbon dioxide; but when heated in sealed tubes to $130^\circ-140^\circ$, it is converted into urea, $[CO^2(NH^2)^2 - H^2O = CO^2NH^2]^2$, which is therefore the amide of carbamic acid (Kolbe a. Basaroff). See UREA. It dissolves, with fall of temperature, in about $1\frac{1}{2}$ pt. of water, at first without change, but after a short time it takes up water and is converted into carbamate: $CO^2(NH^2)^2 + H^2O = CO^2(NH^2)^2$.

Ammonium carbamate dissolves in spirit of sp. gr. 0.829 (J. Davy), also in absolute alcohol when heated with it in a sealed tube, and crystallises out on cooling (Kolbe a. Basaroff). It dissolves freely in strong aqueous ammonia, with production of cold. The solution, left to itself for some time, deposits crystals of the normal carbonate; but if cooled to about 0° soon after it is made, it yields the carbamate again in relatively large crystals. Ammonia, therefore, has the power of impeding the hydration of the carbamate; and this appears to be its mode of action in some of the methods above given (*β, η*) for preparing the carbamate from the commercial carbonate (Divers).

The distinguishing reaction between the carbamate and carbonate is that, when added in excess to calcium chloride and ammonia, the carbamate precipitates the

398 CARBANILIC ACID—CARBODIMETHYL-DIETHYL.

calcium very slowly, whereas the carbonate precipitates it immediately. The gelatinous precipitate (calcium carbamate?) produced in solution of ammonium carbamate by excess of calcium chloride can be dissolved by sufficient water almost immediately; the gelatinous carbonate is also sensibly dissolved by water, but not nearly to the same extent as the carbamate (Divers, *Chem. Soc. J.* [2] viii. 363).

Ethyl-carbamate (urethane) is formed, together with ammonium nitrate, by heating urea nitrate with absolute alcohol to 120°–130° (Baute, *Zeitschr. f. Chem.* [2] vi. 90):

Benzylidene-ammonium carbamate is formed as a white solid mass when ammonium carbamate is left in contact with benzoic aldehyde over sulphuric acid:

Heated with water it gives off gas; heated with alcohol it yields hydrobenzamide (E. Mulder, *Zeitschr. f. Chem.* [2] v. 58).

Ammonium Oxy-sulphocarbamate, $\text{CS}(\text{NH}^2)(\text{ONH}^4)$, prepared by passing gaseous carbon oxy-sulphide, COS, into absolute alcohol saturated with ammonia, forms crystals easily soluble in water. Its solution is precipitated by lead acetate, cupric sulphate, and uranic nitrate; by barium chloride only when heated. Hydrochloric acid added to the concentrated aqueous solution decomposes it, with evolution of gas. With *benzoic aldehyde*, the oxy-sulphocarbamate reacts like the carbamate, yielding the compound $\text{CS}(\text{NH}^2)[\text{ON}(\text{C}^6\text{H}^4)^2]$ (Mulder, *loc. cit.*).

CARBANILIC ACID. Roichenbach a. Boilstein (*Bull. Soc. Chim.* [2] ii. 15) have confirmed the result previously arrived at by Gerland, that Chancel's carbanilic or phenyl-carbamic acid, obtained by the action of potash on phenyl-carbamide (i. 752), is identical with amidobenzamide, not with amidodracylamide. (See BENZAMIDE, p. 257.)

CARBANILIDE, or *Diphenyl carbamide*, is formed, together with other products, by heating 1 mol. oxalic acid with 2 mol. aniline, or by the dry distillation of neutral aniline oxalate (Hofmann, *Proc. Roy. Soc.* xv. 335):

Diphenyl-urea, isomeric, if not identical, with carbanilide, is produced by heating 1 pt. urea to 150°–170° with 3 pts. aniline:

This mode of formation of diphenyl-urea is analogous to that of triphenyl-roaniline from aniline and rosaniline (Baeyer, *Ann. Ch. Pharm.* cxxxi. 251):

CARBINOL. The generic name proposed by Kolbe for the monatomic alcohols (p. 62).

CARBINYL. The corresponding term for alcohol-radicles; e.g.,
Dimethyl-carbinol, $\text{C}(\text{CH}^3)^2\text{H}.\text{OH}$.
Dimethyl-carbinyl iodide, $\text{C}(\text{CH}^3)^2\text{H}.\text{I}$.

CARBODIMETHYL-DIETHYL. $\text{C}^4\text{H}^{10} = \text{C} \left\{ \begin{array}{c} (\text{CH}^3)^2 \\ (\text{C}^2\text{H}^5)^2 \end{array} \right\}$ (Friedel a. Lodenburg, *Ann. Ch. Pharm.* cxlii. 310).—A hydrocarbon of the paraffin series, produced by the action of zinc-ethyl on methyl-chloroacetol (i. 27):

To prepare methyl-chloroacetol, acetone is mixed by drops with phosphorus pentachloride, cooled at the commencement of the process, and the mixture is distilled till the distillate dissolves completely in water. This distillate, washed, dried, and several times rectified, yields chloropropylene, $\text{C}^3\text{H}^5\text{Cl}$, between 25° and 35°, and methyl-chloroacetol between 66° and 78°.

CARBODIPHENYL-TRIAMINE—CARBON BROMIDES. 399

To convert this compound into carbodimethyl-diethyl, it is dropped upon zinc-ethyl contained in a flask having an upright condensing tube; and the mixture, after being warmed for some time, is distilled, the portion which goes over below 110° being collected apart. The distillate is then mixed by drops with water in a cooled flask to decompose the excess of zinc-ethyl; the zinc-oxide thereby formed is dissolved in hydrochloric acid; the oil which remains undissolved is dried and subjected to fractional distillation; and the liquid which passes over between 85° and 90° is heated for several days with sodium, to free it from still remaining chlorine. The product thus obtained is pure carbodimethyl-diethyl, boiling between 86° and 87° , having a vapour-density of 3.46 (calc. 3.62), and a sp. gr. in the liquid state of 0.7111 at 0° , and 0.6958 at 20.5° .

CARBODIPHENYL-TRIAMINE. $N^3[C^6(C^6H^5)^3H^3]$.—Syn. with MELANILINE. (See PHENYLAMINES, iv. 461.)

CARBO-DODECANTHYL-TETRAPHOSPHONIUM CHLORIDE.
 $(C^6H^5)_{12}P^4Cl^4$.—Produced, together with other compounds, by the action of carbon tetrachloride on triethylphosphine (Hofmann, *Jahresb.* 1861, p. 448). See PHOSPHORUS BASES.

CARBOHYDROQUINONIC ACID. $C^6H^4O^4$.—This acid, described under DERIVATIVES OF HYDROQUINONE (iii. 214), is produced, with evolution of hydrogen, by heating quinic acid with 4 pts. potassium hydrate (Graebe, *Ann. Ch. Pharm.* cxxxviii. 197):

It decomposes at 200° , giving off pyrocatechin and hydroquinone. The same products, but with a larger proportion of pyrocatechin, are obtained by heating carbohydroquinonic acid with mineral acids (Graebe). The isomeric acid, protocatechuic acid (iv. 738), is resolved at the same temperature into carbon dioxide and pyrocatechin without any admixture of hydroquinone. Carbohydroquinonic acid reduces a neutral silver solution at ordinary temperatures and in the dark; also cupric oxide in alkaline solution; whereas protocatechuic acid reduces silver oxide only in ammoniacal solution, and cupric oxide not at all (Hesse, *Ann. Ch. Pharm.* cxxii. 221).

CARBOMETHYL-TRIAMINE. $C^2H^3N^3 = N^3 \begin{Bmatrix} C^2 \\ CH^2 \\ H^2 \end{Bmatrix}$.—Syn. with METHYL-CRAMINE (iii. 1009).

CARBON. A variety of carbon exhibiting somewhat peculiar properties is found in small quantities at Singhom, near Calcutta, on veins of copper and iron ore traversing clay slate. It is black, with metallic lustre, crystalline structure, and sp. gr. 1.9 (Breithaupt, *Jahresb.* 1859, p. 765).

On the spectrum of carbon, see SPECTRAL ANALYSIS (v. 389).

Carbon is, under certain circumstances, separated from cyanides in the form of graphite. The mother-liquors of the soda manufacture, which are often used for the preparation of caustic soda, are mixed with sodium nitrate, and evaporated down in iron pans for the purpose of oxidising the sulphides and cyanides (chiefly sodium ferrocyanide) contained in them. As soon as the mass has attained a dull red heat, a regular evolution of gas sets in, ferric oxide is deposited, and the surface of the liquid becomes covered with a shining layer of graphite. The separation of the graphite takes place most abundantly when the sodium nitrate is at first added only in quantity sufficient to oxidise the sulphur-compounds, and the further quantity required to decompose the cyanides is added just as the mass begins to exhibit a red heat (Pauli, *Phil. Mag.* [4] xxi. 541).

In connection with the question of the volatility of carbon at high temperatures, Elsner (*J. pr. Chem.* xcix. 257) has observed that when porcelain vessels, &c., are heated in the pottery-furnace on trays made of a mixture of clay and graphite, they become brown-black throughout their mass, and covered with a light grey specular glaze. This result is attributed by Elsner to volatilisation of the carbon. Regnault, on the other hand, ascribes it to the formation of a hydrocarbon (*Jahresb.* 1866, pp. 22, 35).

Respecting the absorptive power of charcoal for gases and vapours, see GASES.

CARBON BROMIDES. The dibromide C^2Br^4 is described in vol. i. p. 764; the tribromide C^3Br^6 , or tetrabromomethylene dibromide $C^2Br^4.Br^2$, in vol. ii. p. 571.

The *tetrabromide*, CBr_4 is produced by the action of bromine, in presence of iodine bromide or antimony tribromide, on carbon bisulphide, bromopichrin, or bromoform. It is a white substance crystallising in shining plates, melting at 91° ; has an ethereal odour like that of the tetrachloride, and a sweetish taste; is almost insoluble in water, but very easily soluble in ether, carbon bisulphide, carbon tetrachloride, chloroform, bromoform, benzol, and American petroleum; also in hot alcohol, from which it separates in the crystalline form on cooling. When heated in alcoholic solution it is decomposed, with formation of aldehyde and hydrobromic acid. The alcoholic solution burns with a pale green flame. The compound is rapidly decomposed by alcoholic potash or soda; thus:

Aqueous potash or soda does not affect it at ordinary temperatures, and only slowly at 100° , but at 150° the action goes on rapidly, the products being sodium bromide, sodium carbonate, and water. When carefully heated it sublimes unchanged, but its vapour when passed through a red-hot tube is for the most part resolved into bromine and carbon, a small quantity of a crystalline substance being however obtained, apparently consisting of the tribromide C^2Br_6 (ii. 571). By water and sodium-amalgam it is reduced, first to bromoform, CHBr_3 , and afterwards to methylene dibromide, CH_2Br_2 (Bolas & Groves, *Chem. Soc. J.* [2] viii. 161).

CARBON CHLORIDES. The *tetrachloride* CCl_4 , heated to 200° in sealed tubes with dry zinc oxide, is converted into carbon oxychloride and carbon dioxide:

When passed, together with carbon dioxide, over pumice heated to 350° , it is converted into carbon oxychloride: $\text{CCl}_4 + \text{CO}_2 = 2\text{COCl}_2$. With carbon monoxide, in like manner, it yields carbon oxychloride and carbon dichloride: $2\text{CCl}_4 + 2\text{CO} = 2\text{COCl}_2 + \text{C}^2\text{Cl}_4$ (Schützenberger, *Compt. rend.* lxvi. 747).

The tetrachloride heated to 100° with sulphuric anhydride gives off carbon oxychloride, and leaves a fuming liquid, which when distilled gives off the excess of tetrachloride at 75° , and at 130° the compound $\text{S}^2\text{O}^3\text{Cl}_2$ identical with that which Rose obtained by the action of sulphuric anhydride on brown chloride of sulphur (v. 535). The reaction is:

When a mixture of sulphuric anhydride and carbon tetrachloride is heated to 100° with benzene, and the product is treated with water, hydrochloric acid, sulphobenzide, and benzene-sulphuric acid are obtained, together with a considerable quantity of benzoic acid (Schützenberger, *ibid.* lxi. 362; *Zeitschr. f. Chem.* [2] v. 631). See Benzoin Acn, p. 306.

The *trichloride* C^2Cl_6 is formed, together with other products, when the vapour of the tetrachloride is passed through a long tube heated to moderate redness. A liquid then condenses in the receiver, coloured yellow by free chlorine and consisting of the trichloride C^2Cl_6 , the dichloride C^2Cl_4 , a little unaltered CCl_4 , and a very small quantity of C^4Cl_8 . On exposing it to light, so that the dichloride may absorb the free chlorine, and distilling till the temperature rises to 150° – 160° , a residue is left in the retort consisting almost wholly of trichloride, which may be completely purified by crystallisation or by distillation with water. The distillate obtained below 160° contains a considerable quantity of dichloride, which may be converted into trichloride by the action of chlorine in sunshine (Bassett, *Chem. News*, xx. 175).

Carbon trichloride is also formed by passing chlorine into butyric acid heated first to 100° , afterwards to the boiling point of the acid: it then collects as a white sublimate in the neck of the retort (A. Naumann, *Ann. Ch. Pharm.* cxix. 120). According to Paterno (*Zeitschr. f. Chem.* [2] v. 246), it appears to be formed by the action of phosphorus pentachloride on acetyl chloride.

The *dichloride*, C^2Cl_4 , unites with nitrogen tetroxide, forming the compound $\text{C}^2\text{Cl}_4(\text{NO}^2)_2$, which may also be regarded as *tetrachlorethylene dinitrylide*, carbon *subtrichloride* or *dinitro-tetrachlorethane*. This compound is formed when the dichloride is heated to 100° – 120° in a sealed tube with liquid nitrogen tetroxide. The product is however somewhat scanty, as a considerable portion suffers further decomposition, resulting in the formation of carbon oxychloride. The compound $\text{C}^2\text{Cl}_4(\text{NO}^2)_2$ is a volatile crystalline compound having very much the aspect of carbon trichloride, and a rather strong odour like that of chloropichrin. It is insoluble in water, easily soluble in ether and hot alcohol, cannot be fused, but decomposes at 140° into C^2Cl_4 and NO^2 .

After drying over sulphuric acid, it is somewhat glutinous, and therefore cannot be pulverised. It would probably be converted by reducing agents into a diamine (Kolbe, *Zeitschr. f. Chem.* [2] v. 430).

Jain's Chloride of Carbon, C^4Cl^4 (i. 768), is identical with hexachlorobenzene, C^6Cl^6 (See BENZENE, p. 267.)

CARBON OXIDES. 1. MONOXIDE or CARBONOUS OXIDE, CO, commonly called *Carbonic oxide*.—This gas is easily obtained pure and in large quantity by passing the gaseous mixture evolved by heating oxalic acid with sulphuric acid, first through a red-hot tube filled with charcoal, then through a mixture of potash and lime-water to absorb the small quantity of carbon dioxide still remaining undecomposed (Chevriér, *Compt. rend.* lxix. 138). It is formed in small quantity when oxygen is absorbed by an alkaline solution of pyrogallie acid, 100 vol. pure oxygen yielding about 3.5 vol. CO. When, however, the oxygen is mixed with excess of nitrogen, as in atmospheric air, the quantity of carbon monoxide thus formed is but small, and scarcely sufficient to affect the result of an eudiometrical determination (Calvert, *Chem. News*, viii. 272; Cloez, *Compt. rend.* lvii. 875; Boussingault, *ibid.* 885).

Carbon monoxide in the dry state is not decomposed by a succession of induction-sparks or by a spiral of iron or platinum wire intensely ignited by the electric current; but over water it is decomposed by the glowing platinum spiral, the carbon monoxide being converted into dioxide and replaced by an equal volume of hydrogen (Buff a. Hofmann, *Chem. Soc. J.* xii. 273).

Respecting the decomposition of carbon monoxide by heat, see CHEMICAL AFFINITY and DISSOCIATION. On the temperature of its flame and the results of its combustion under pressure, see COMBUSTION.

Carbon monoxide passed over heated *sodamide* converts it into sodium cyanide: $NaH^2N + CO = NaCN + H^2O$, ammonia and sodium hydrate being also formed as secondary products by the action of the water on the sodamide (Beilstein a. Geuther, *Ann. Ch. Pharm.* cviii. 88).

With *sodium-ethyl*, carbon monoxide forms propione or diethyl-ketone; thus:

This reaction is general:

(Wanklyn, *Chem. Soc. J.* [2] iv. 13, 326).

With *potassium*, carbon monoxide unites directly, at about 80° , forming the compound K^2CO^2 (iv. 696). Also with *sulphur*, forming carbon oxysulphide, CO^2S (p. 407).

When a mixture of carbon monoxide and *chlorine* is passed over *platinum sponge* heated to 400° , carbon oxychloride is formed, together with a crystallisable compound of carbon monoxide with platonic chloride, $(CO)^2PtCl^4$ (Schützenberger, *Zeitschr. f. Chem.* [2] iv. 321). See PLATINUM.

A mixture of carbon monoxide and carbon *tetrachloride* passed over heated *pumice* yields phosgene and carbon dichloride (p. 400).

For the reaction of carbon monoxide with *blood*, see p. 354.

CARBON DIOXIDE, CARBONIC ANHYDRIDE, or CARBANHYDRIDE, CO^2 , commonly called *Carbonic acid*.—This gas may be liquefied under the ordinary atmospheric pressure by a temperature of -87° , produced by evaporating liquefied ammonia over sulphuric acid in a vacuum. At the same temperature, under a pressure of three or four atmospheres, the carbon dioxide solidifies to a mass which has the transparency of ice, and may be divided, by pressure with a glass rod, into cubic crystals three or four millim. thick; these crystals are unctuous to the touch, and burn severely when pressed between the fingers. Mixed with ether in a crucible, they produce a cold of -81° (Loir a. Drion, *Compt. rend.* lii. 748; *Jahresb.* 1860, p. 42; 1861, p. 109).

Liquid carbon dioxide boils at -78.2° under a pressure of 760 mm. (Regnault, *Jahresb.* 1863, p. 70). Its expansion by change of temperature is exhibited in the following table:

Temperature	Volume
-10°	0.9517
0	1.0000
$+10$	1.0585
20	1.1457

Its sp. gr. at 0° (compared with water at the same temperature) is 0.9470 (Andrieux, *Ann. Ch. Pharm.* cx. 1).

Sup.

D D

The following determinations of its vapour-tension at different temperatures are given by Regnault (*Résumé des Expériences, &c.*; *Jahresb.* 1863, p. 66):

Temp.	Tension in millim. of Mercury.	Temp.	Tension in millim. of Mercury.
-25°	13007.02	+15°	39646.88
-20	15142.44	+20	44716.58
-15	17582.48	+25	50207.32
-10	20340.20	+30	56119.06
-5	23441.34	+35	62447.30
0	26906.60	+40	69184.45
+5	30763.80	+45	76314.60
+10	34998.65		

Gore (*Chem. Soc. J.* xv. 163) has described a method by which small quantities of liquid carbon dioxide may be safely prepared in stout glass tubes closed with gutta-percha stoppers, and solid substances attached to the stoppers submitted to its action. Having in this way examined its action on more than fifty substances, he concludes that it is comparatively an inactive substance, and is not deoxidised by any ordinary reducing agent except the alkali-metals. Its solvent powers are also very limited. It dissolves camphor, iodine sparingly, and a few other substances in small quantity; it does not dissolve any oxygen-salt, and does not reddens extract of litmus. It abstracts the colouring matter of gutta-percha. Caoutchouc left in contact with it for some time, swells up strongly after removal, then slowly contracts again and appears white. The liquid anhydride is a bad conductor of electricity. In its general properties it is somewhat analogous to carbon bisulphide, but has much less power of dissolving fatty bodies.

At the temperature of 0°, gaseous carbon dioxide is reduced to the liquid state under a pressure of thirty-six atmospheres; as the temperature rises, greater pressure is required to effect the liquefaction, and above a certain temperature the gas is no longer liquefied by pressure. The effect of pressure on carbon dioxide at various temperatures has lately been very carefully investigated by Dr. Andrews (*Phil. Trans.* 1869, p. 575; *Chem. Soc. J.* [2] viii. 74; abstr. *Proc. Roy. Soc.* xviii. 42). When this gas is partially liquefied by pressure, and the temperature is gradually raised to about 31°, the surface of demarcation between the liquid and the gas becomes fainter, loses its curvature, and at last disappears, the tube being then filled with a fluid which, from its optical and other properties, appears to be perfectly homogeneous, the phenomena being in fact similar to those observed by Cagniard de la Tour on heating water, alcohol, ether, or petroleum in sealed tubes (*Heat*, iii. 95). The temperature at which carbon dioxide ceases to be liquefied by pressure is designated by Andrews as the 'critical point,' and he finds it to be 30.92°. At temperatures a little above this point, although no liquefaction occurs, a very great change of density is produced by slight alterations of pressure, and the flickering movements above mentioned come conspicuously into view.

At 13.1°, under a pressure of 48.9 atmospheres, the gas, then just on the point of liquefying, is reduced to $\frac{1}{30.5}$ of the volume it occupied under one atmosphere. After liquefaction, the volume of the gas, already reduced to $\frac{1}{27.5}$ of its original volume, continues to diminish as the pressure augments, and at a much greater rate than in ordinary liquids. Similar results were obtained at 21.5°. At 31.1°, or 0.2° above the critical point, the volume of the gas diminished steadily with the pressure, till about 74 atmospheres were attained. After this a rapid fall occurred (but not abrupt, as in the case of liquefaction), and the volume was diminished to one-half by an additional pressure of less than two atmospheres. Under a pressure of 75.4 atmospheres the gas was reduced to $\frac{1}{31}$ of its volume under one atmosphere. Beyond this point it yielded very slowly to pressure. During the stage of rapid contraction there was no evidence at any time of liquefaction having occurred, or of two conditions of matter being present in the tube. At 32.5° and 35.5° the same general results were observed, except that the rapid diminution of volume became less marked as the temperature was higher. The experiments at 35.5° were carried as far as 107 atmospheres, at which pressure the volume of the gas was almost the same as that which it would have occupied if it had been derived directly from liquid carbon dioxide according to the law of the expansion of that body for heat. Lastly, at 48.1°, between the pressures of 62.6 and 109.4 atmospheres, the rapid fall exhibited at lower temperatures almost if not wholly disappears, and the curve representing the changes of volume approximates closely to that of a gas following the law of Mariotte, though the rapid diminution of volume is much greater than if that law held good.

These results are represented graphically by the curves in fig. 10. Equal volumes of air and carbon dioxide, measured at 0° and 760 mm., when compressed at the temperatures marked on each curve, undergo the change of volume indicated by the form of the curve. The figures at the top and bottom indicate the approximate pressures in atmospheres; the volumes of the gas and air are measured upwards from the dotted horizontal line.

FIG. 10.

Under pressures still higher than those above mentioned, carbon dioxide may also be made to pass, without break or interruption, from what is universally regarded as the gaseous to what is in like manner universally regarded as the liquid state of matter. Thus, if a given volume of the gas at 50° or a higher temperature be exposed to a pressure increasing up to 150 atmospheres, its volume will steadily diminish as the pressure increases, and no sudden diminution of volume, without the application of external pressure, will occur at any stage of the process. When the full pressure has been applied, let the gas be allowed to cool down to the ordinary temperature of the atmosphere. During the whole of this operation no breach of continuity will occur. It begins with a gas, and by a series of gradual changes, nowhere presenting any abrupt alteration of volume or sudden evolution of heat, it ends with a liquid. The closest observation indeed fails to discover anywhere indications of a change of condition in the carbon dioxide, or evidence, at any stage of the process, of the compound being in one physical state and part in another. That the gas is changed to a liquid would indeed never have been suspected, did it not show itself to be so changed by entering into ebullition on the removal of the pressure.

From all these results, it may be inferred that the ordinary gaseous and ordinary liquid states are only widely separated forms of the same condition of matter, and may be made to pass into one another by a series of gradations so gentle that the passage shall nowhere present any interruption or breach of continuity. From carbon dioxide as a perfect gas to carbon dioxide as a perfect liquid, the transition may be accomplished by a continuous process, and the gas and liquid are only distant stages of a long series of continuous physical changes. Under certain conditions of temperature and pressure indeed, carbon dioxide finds itself in what may be described as a state of instability, and suddenly passes, with evolution of heat, and without application of additional pressure or change of temperature, to the volume, which by the continuous process can only be reached through a long and circuitous route. In the abrupt change which here occurs, a marked difference is exhibited, while the process is going on, in the optical and other physical properties of the carbon dioxide which has collapsed into the smaller volume, and of the carbon dioxide not yet altered. There is no difficulty here, therefore, in distinguishing between the liquid and the gas. But in other cases the distinction cannot be made; and under many of the conditions above mentioned it would be vain to attempt to assign carbon dioxide to the liquid rather than the gaseous state.

Carbon dioxide, hydrogen chloride, ammonia, common ether, and carbon bisulphide, like carbon dioxide in exhibiting critical points when exposed under

pressure to the required temperatures. Andrews proposes, instead of the present arbitrary distinction between vapours and gases, to confine the term vapour to gaseous bodies below their critical points, and therefore capable of being liquefied by pressure alone, so that gas and liquid may exist in the same vessel in presence of each other.

Reactions.—1. Gaseous carbon dioxide is slowly decomposed by the induction-spark, more quickly by the very high temperature of the electric arc (between iron terminals), into carbon monoxide and oxygen, the latter combining with the iron, and leaving a volume of carbon monoxide equal to the original volume of the gas (Buff a. Hofmann, *Chem. Soc. J.* xii. 282).—2. Respecting its decomposition by heat, see CHEMICAL AFFINITY AND DISSOCIATION.—3. Mixed with carbon tetrachloride and passed over heated pumice, it forms carbon oxychloride: $\text{CO}^2 + \text{CCl}^4 = 2\text{COCl}^2$ (p. 400).—4. Passed over gently heated sodamide, it forms cyanamide and sodium hydrate: $\text{CO}^2 + 2\text{NaNH}^2\text{N} = (\text{CN})\text{H}^2\text{N} + 2\text{NaHO}$ (Beilstein a. Geuther, *Ann. Ch. Pharm.* cviii. 88).

5. With the sodium-compounds of the alcohol radicles $\text{C}^n\text{H}^{2n+1}$, it forms the sodium salts of the next higher fatty acids: e.g.,

(Wanklyn, *Chem. Soc. J.* xi. 103).

6. Potassium immersed for about twenty-four hours in an atmosphere of carbon dioxide standing over lukewarm water, is converted into a mixture of formate and acid carbonate of potassium:

Sodium acts in a similar manner, but appears to produce a smaller proportion of formate (Kolbe a. Schmidt, *Ann. Ch. Pharm.* cxix. 251).

7. Sodium heated with dry sand and exposed to a rapid current of dry carbon dioxide, the paste mixture being well stirred and the temperature ultimately raised to about the boiling point of mercury, is converted into sodium oxalate:

A similar reaction takes place with an alloy of sodium and potassium, or with potassium amalgam, the latter being heated to the boiling point; this last method seems indeed to yield the largest quantity of oxalate (Drechsel, *Zeitschr. f. Chem.* [2] iv. 120).

8. According to J. Kolb (*Compt. rend.* lxi. 862), dry carbon dioxide is not absorbed by the anhydrous oxides or the dry hydrates of the alkali-metals or alkaline-earth metals even after prolonged contact, the presence of water being absolutely necessary to promote the absorption. This statement is, however, somewhat at variance with the well-known fact that carbon dioxide is readily taken up by ignited soda-lime. According to Beketoff (*Jahresb.* 1865, p. 14), carbon dioxide decomposes a solution of calcium acetate under a pressure of 27 or 28 atmospheres, spicular crystals of calcium carbonate being formed in the liquid; on the other hand, it does not decompose a dilute solution of calcium chloride at 45 atmospheres, of barium chloride at 40 atmospheres, or of barium acetate at 30 atmospheres.

Absorption by Water and Saline Solutions.—Khanikoff a. Louguinine (*Ann. Ch. Phys.* [4] xi. 112) have determined the quantities of carbon dioxide absorbed by water under different pressures, and have obtained results not quite in accordance with the law of Dalton a. Henry (ii. 792). In the following table α denotes the volume of carbon dioxide, reduced to 0° and 760 mm., absorbed by 1 vol. water under the pressure P:

P	α	P	α
697.71	0.9441	2188.65	3.1784
809.03	1.1619	2369.02	3.4857
1289.41	1.8647	2554.00	3.7152
1469.95	2.1623	2738.33	4.0031
2002.06	2.9076	3109.51	4.5006

Denoting two of these absorption-coefficients by α^1 and $\alpha^1 + n$, and the corresponding pressures by P^1 and $P^1 + n$, the law of Henry a. Dalton would give $\frac{\alpha^1 + n}{\alpha^1} = \frac{P^1 + n}{P^1}$.

but on calculating the differences of these quotients from the preceding terms of the resulting series exhibit, with increasing pressure,

regular enough to show that the deviation from the law above mentioned cannot be attributed to errors of experiment.

When water is saturated with carbon dioxide under pressure (as in making soda-water), the force with which the gas is retained depends to a considerable extent on the time during which the gas and water have been kept in contact and agitated together. If the agitation be continued merely for an hour or an hour and a half, then, on letting out the water, the excess of carbonic anhydride is immediately disengaged with effervescence throughout the whole mass of the liquid, which becomes creamy; whereas if the gas be left in contact with the water in the closed vessel for 20 to 24 hours, and the liquid be then let out, the carbonic anhydride disengages itself from the water and attaches itself to the sides of the glass. It appears indeed as if after a short contact the carbonic anhydride dissolves in the water as such, but that after prolonged contact it becomes hydrated and dissolves as hydrogen carbonate or carbonic acid, and is then retained more firmly. The dissolution of the carbonic anhydride is greatly accelerated by adding a little common salt to the water, the acceleration being probably due to a reaction between the sodium chloride and carbonic acid, resulting in the formation of acid sodium carbonate and hydrochloric acid. The presence of the latter acid in the resulting solution may in fact be demonstrated by means of ultramarine, which is acted upon by hydrochloric acid, but not by sodium chloride. A solution of lead chloride is acted upon in a similar manner by carbonic acid, a precipitate being gradually formed consisting of carbonate-chloride of lead (Hugo Müller, *Chem. Soc. J.* [2] viii. 37). A solution of ordinary sodium phosphate into which carbonic anhydride is passed is partly decomposed in like manner, with formation of acid phosphate and acid carbonate of sodium. Respecting the law of absorption of carbonic anhydride by aqueous sodium phosphate, see Heidenhain & Meyer, *Ann. Ch. Pharm. Suppl.* ii. 157; *Jahresb.* 1863, p. 92.

CARBON OXYBROMIDE, COBr_2 , is formed when a mixture of bromine-vapour and carbon monoxide, the latter in excess, is exposed to the sun's rays. The mixture becomes nearly colourless, and on bringing it in contact with potash-ley, rapid absorption takes place, the solution containing bromide and carbonate of potassium (J. Schiel, *Ann. Ch. Pharm. Suppl.* ii. 311; *Jahresb.* 1863, p. 156).

CARBON OXYCHLORIDE, COCl_2 . *Carbonyl chloride. Phosgene.*—The following is given by Wilm a. Wischin (*Zeitschr. f. Chem.* [2] iv. 5) as the best method of obtaining considerable quantities of this gas, free from chlorine and containing only a slight excess of carbon monoxide. Into a 10-litre flask of white glass, exposed to sunshine and fitted with a caoutchouc stopper traversed by three tubes, carbon monoxide (prepared from oxalic acid, purified by passing through a mixture of potash and lime, and dried by oil of vitriol) is admitted on one side, and dry chlorine on the other, the two gases being directed on to the bottom of the flask, the carbon monoxide at a slightly more rapid rate than the chlorine, whereby a perfect mixture is effected almost instantaneously. The gaseous mixture is then directed through the third tube to the bottom of a second flask of the same size, the stopper of which is traversed by two tubes, and from this it passes into a third flask fitted up in a similar manner. The gas which passes into the third flask is nearly pure phosgene, quite free from chlorine, and containing only a slight excess of carbon monoxide. By passing it into well-cooled absolute alcohol, it is easy in favourable weather to prepare 2 or 3 pounds of ethyl chlorocarbonate in the course of a day.

On the formation of carbon oxychloride from carbon tetrachloride, see p. 400.

Phosgene is also produced by the oxidation of chloroform with potassium dichromate and sulphuric acid:

a certain quantity of carbon dioxide being formed at the same time by further decomposition. The gas is evolved slowly or quickly accordingly as the mixture is heated in the water-bath or at a higher temperature; in the latter case it also contains free oxygen. To evolve phosgene quite free from oxygen in not too slow a stream, a mixture of 50 pts. potassium dichromate, 400 strong sulphuric acid, and 20 pts. chloroform is exposed to the heat of a water-bath in a flask fitted with an inverted Liebig's condenser, so that the chloroform which distils over may flow back again. The farther end of the condenser is attached a rather large wide U-tube filled with three lumps of metallic antimony, to retain the free chlorine. This tube should be frequently warmed from time to time with the flame of a spirit-lamp, to prevent it getting stopped up by the formation of solid antimonious chloride. The gas evolved contains about 10 p. c. of carbon dioxide and a small

quantity of chloroform-vapour, which cannot be removed by any dry absorbent (Emmerling a. Lengyel, *Ann. Ch. Pharm. Suppl.* vii. 104).

Liquid Phosgene.—The gas prepared by the method just described condenses to a liquid at 0°, or more quickly at the temperature of a mixture of ice and salt. Only a portion of it can however be thus condensed, but the remaining gas may be used for other purposes. 20 grms. chloroform decomposed as above yielded only 4 grms. of rectified liquid phosgene, whereas the theoretical quantity would be 16 grms. Moreover, the liquid phosgene thus obtained always contains chloroform.

A purer and more abundant product may be obtained by evolving the gas by Wilm a. Wischin's method above described. As, however, the presence of an uncondensable gas offers a great obstacle to the liquefaction of the phosgene, it is best to regulate the flow of the two gases, so that the chlorine may be in slight excess instead of the carbon monoxide, this excess of chlorine being removed as above by passing the gas over metallic antimony. From the antimony tube it is passed through a wide U-tube cooled by a freezing mixture, and from this the liquefied phosgene is from time to time quickly poured into a small flask also surrounded by a freezing mixture. Using stoppered bottles of the capacity of 3 or 4 litres, instead of the 10-litre flasks employed by Wilm and Wischin, and with a consumption of 80 litres of carbon monoxide, the quantity of liquid phosgene obtained in the course of a sunny day was about 110 grms.; on a cloudy day, 60 litres carbon monoxide yielded about 50 grms. of liquid phosgene.

Phosgene obtained by the method just described is perfectly pure, whereas that prepared from chloroform cannot be completely freed from the latter, even by repeated fractionation.

Pure phosgene is a limpid very mobile liquid, whose vapours exhibit in the greatest intensity the well-known suffocating odour of phosgene gas. In water it sinks in the form of an oil, and gradually decomposes, with evolution of carbon dioxide. It boils constantly at 8.2° (corr.) under a pressure of 756.4 mm. Vapour-density = 3.505 (calc. = 3.420). Sp. gr. of the liquid = 1.432 at 0°; 1.392 at 18.6°, compared with water at 4° (Emmerling a. Lengyel).

Phosgene gas is gradually absorbed by *zinc-methyl*, forming a white crystalline mass, which is decomposed by water, giving off carbon monoxide (and probably also marsh gas), and a mixture of propylic and butylic alcohols, together with a small quantity of acetic acid (Buttlerow, *Jahresh.* 1863, p. 475).

According to Berthelot (*Zeitschr. f. Chem.* [2] v. 480), phosgene does not act upon ethylene, acetylene, or benzene in the manner described by Harnitzky; the observations of other chemists, however, are in accordance with Harnitzky's results. (See BENZENE, p. 262, and BENZOIC ACID, p. 306.) With *acetone* it produces dichloroacetone (Wroblevsky, *ibid.* iv. 565).

Chlorocarbonic Ethers. Ethyl-chlorocarbonate acts violently on *zinc-methyl*, producing carbon dioxide, ethylene, marsh gas (perhaps also methyl-ethyl), and zinc chloride:

Methyl chlorocarbonate does not act on zinc-methyl under the ordinary atmospheric pressure; and when the mixture is heated to nearly 100°, only partial decomposition takes place, resulting in the formation of methyl carbonate and hydrocarbons (ethylene and its homologues), also carbon dioxide and methylchloride, the latter being produced by a simple splitting up of the methyl chlorocarbonate in presence of the zinc chloride produced. *Plumbotetramethyl* and *mercury-methyl* are likewise only imperfectly decomposed by methyl chlorocarbonate at 100°.

Ethylchlorocarbonate is converted by *zinc* and *sulphuric acid* into ethyl carbonate; by *sodium-amalgam* into alcohol, sodium carbonate, and sodium chloride; by *alcohol* alone at ordinary temperatures, into ethyl carbonate and hydrochloric acid (Buttlerow, *Zeitschr. Ch. Pharm.* 1863, p. 484; *Jahresh.* 1863, p. 474).

Ethyl chlorocarbonate gradually mixed with *potassium phenate* yields potassium chloride and ethyl-phenyl carbonate (Fatianoff, *Zeitschr. Ch. Pharm.* 1864, p. 77):

With *sodium monosulphide* it forms the ethylic ether of dicarbothionic acid, $\text{S}(\text{CO}^2\text{H}^5)^2$ (V. Meyer, *Deut. Chem. Ges. Ber.* 1869, p. 297):

CARBON OXYSULPHIDE. COS.—This compound, discovered by Than (*Ann. Ch. Pharm. Suppl.* v. 326), is produced: 1. By direct combination, when carbon

monoxide mixed with excess of sulphur-vapour is passed through a red-hot porcelain tube. As thus prepared, however, it is always mixed with free carbon monoxide.—
 2. A purer product is obtained by decomposing potassium sulphocyanate with moderately dilute acids. Potassium sulphocyanate is added to a cooled mixture of 5 vol. strong sulphuric acid and 4 vol. water as long as the mass remains liquid, the action being moderated by cooling, or assisted by warming, as may be necessary; and the evolved gas—after passing through three U-tubes, the first containing cotton-wool impregnated with moist mercuric oxide to remove traces of hydrocyanic and formic acids, the second containing fine cuttings of non-vulcanised caoutchouc to absorb carbon bisulphide, and the third containing calcium chloride to absorb water—is collected over mercury. The formation of carbon oxysulphide from sulphocyanic acid is represented by the equation:

which, however, holds good only for a fraction of the mixture, a large portion of the sulphocyanic acid being at the same time resolved into hydrocyanic and persulphocyanic acids, especially when heat is applied (iv. 379) (Than).

3. By heating urea with carbon bisulphide to 110° in a sealed tube, ammonium sulphocyanate being formed at the same time:

On opening the tube, the carbon oxysulphide is given off, together with hydrogen sulphide, from which it may be freed by lead acetate (Ladenburg, *Zeitschr. f. Chem.* [2] v. 253).

4. Together with diethyl-urea, by passing dry hydrogen sulphide into ethyl cyanate (Ladenburg, *ibid.* 345):

5. Thiocetic acid heated to 300° is decomposed, with evolution of a gaseous mixture, three-fourths of which consists of hydrogen sulphide, and one-fourth of carbon oxysulphide, perhaps mixed with a little methyl and marsh gas (Ladenburg, *loc. cit.*).

6. Together with sulphurous oxide, hydrochloric acid, and free sulphur, by heating equivalent quantities of chlorhydrosulphuric acid and carbon bisulphide to 100° for several hours in a sealed tube:

The sulphur is deposited in large yellow crystals; the sulphurous oxide condenses to a liquid; and on opening the tube, this compound is given off as gas, together with hydrochloric acid and carbon oxysulphide, which may be freed from the other two gases by collecting it over water (Dewar & Cranston, *Chem. News*, xx. 174).

7. Together with sulphurous oxide and free sulphur, by gently heating carbon bisulphide with an equivalent quantity of sulphuric oxide (Armstrong, *Zeitschr. f. Chem.* [2] vi. 247).

Carbon oxysulphide is a gas of sp. gr. 2.1046 (calc. 2.0833), and may easily be poured from one vessel to another. It has an aromatic odour like that of some resins, slightly also that of hydrogen sulphide, and a feeble acid reaction than carbon dioxide. At a low red heat it is partly resolved into carbon monoxide and sulphur-vapour; by a fine platinum wire ignited by the electric current, it is slowly but completely decomposed, yielding an equal volume of carbon monoxide. It burns in the air with a faint blue flame, producing carbon dioxide and sulphur dioxide, with $\frac{1}{2}$ vol. oxygen, it forms an explosive mixture burning with a shining bluish-white flame. It is not acted upon by chlorine or fuming nitric acid at ordinary temperatures, and does not form an explosive mixture with nitrogen dioxide (Than).

Water absorbs about its own volume of carbon oxysulphide, acquiring a sweetish and afterwards a pungent taste, and decomposing it after some time. It appears to exist in some sulphur springs and in the sulphurous gases of volcanos. Potash-ley absorbs the gas as completely as carbon dioxide, though less quickly; the solution exhibits the reactions of metallic sulphides, and when treated with acids gives off H^2S and CO^2 :

Baryta and lime water act in a similar manner (Than). It is absorbed by alcoholic potash-solution cooled to a very low temperature, the liquid ultimately solidifying to a crystalline mass of the potassium salt of ethyl-dioxy-sulphocarbonic acid (v. 49):

Neutral or acid solutions of *lead, copper, cadmium, and silver salts* are not precipitated by the gas; but when mixed with excess of ammonia, they yield with it characteristic precipitates of metallic sulphides. *Mercury* is not altered by the dry gas at ordinary temperatures, but at the boiling heat it slowly becomes covered with a film of mercuric sulphide; the moist gas produces this effect at ordinary temperatures. *Sodium* decomposes it even in the cold, and at a low red heat burns in it with explosion, forming a black substance. Finely divided *copper, silver, and iron* decompose it without separation of free sulphur. *Mercuric ethide*, heated to boiling in a stream of the gas, is violently decomposed, yielding metallic mercury and a yellowish liquid (probably ethyl thiopropionate) having an alliaceous odour (Than).

Carbon oxysulphide unites quickly with dry ammonia gas, and is rapidly absorbed by strong aqueous ammonia, forming oxysulphocarbamate: $\text{COS} + 2\text{NH}^3 = \text{CH}^3\text{NSO} \cdot \text{NH}^3$, which when dissolved in water and heated in a sealed tube, is converted into ammonium sulphocyanate: $\text{CH}^3\text{NSO} \cdot \text{NH}^3 - \text{H}_2\text{O} = \text{CHNS} \cdot \text{NH}^3$, and when gently heated with a lead-compound, is converted into urea, $\text{CH}^3\text{NSO} \cdot \text{NH}^3 - \text{H}_2\text{S} = \text{CH}^3\text{N}^2\text{O}$. The reaction with ammonia affords a ready means of distinguishing carbon oxysulphide from the bisulphide, which is but slowly acted upon by ammonia (Berthelot, *Zeitschr. f. Chem.* [2] iv. 415). According to Hofmann (*ibid.* v. 345), the best reagent for separating the two compounds is *triethylphosphine*, which unites immediately with the bisulphide, but has no action on the oxysulphide.

CARBON SELENIDE. CSe^2 .—Formed, but in very small quantity, when moist vapour of carbon tetrachloride is passed over phosphorus selenide. The hydrogen selenide formed by the action of the water on the phosphorus selenide then reacts with the carbon chloride as follows:

It has not been obtained pure, but appears to be a liquid having an intensely pungent and tear-exciting odour, resembling also when diluted that of carbon bisulphide. With alcoholic potash it yields the ethylic ether of selenioxanthic acid, $\text{C}^2\text{H}^4\text{SeO}^2$ (Rathke, *Zeitschr. f. Chem.* [2] v. 722).

CARBON SULPHIDES. I. BISULPHIDE. CS^2 .—This compound is now prepared on a very large scale and applied to a variety of purposes. The several forms of apparatus used for its manufacture are similar in principle to the laboratory apparatus already described (i. 776), differing only in the forms of the retort and condenser, and in the mode of introducing the sulphur. For descriptions and figures see Richardson and Watts's *Chemical Technology*, pt. iii. pp. 124–130. According to Sidot (*Compt. rend.* lxi. 1303), the largest product is obtained at a red heat (not above that temperature). Wager has suggested the production of carbon bisulphide by distilling some of the metallic sulphides with charcoal in closed vessels.

To purify carbon bisulphide obtained as above from free sulphur, hydrogen sulphide, and small quantities of other sulphur-compounds which give it an intensely disgusting odour, it must be rectified and treated with absorbents. Boniéro uses for this purpose a series of water-bath stills, the first containing potash-ley, and the others solutions of lead, copper, iron, &c., to retain the hydrogen-sulphide, &c. (Wagner's *Jahresbericht*, 1860, p. 76). Sidot (*loc. cit.*) first distils it alone, and then agitates it with mercury till the shining surface of the metal is no longer blackened by it. Clossz (*Compt. rend.* lxi. 1356) leaves it in contact for 24 hours, and frequently agitates it, with $\frac{1}{2}$ p. c. of its weight of mercuric chloride, which removes a fetid sulphur-compound; then decants the clear liquid; adds 0.02 of its weight of an inodorous fat; and distils it in the water-bath at a low temperature. The bisulphide purified by either of these processes has an ethereal odour quite different from that of the ordinary commercial product.

Uses.—Carbon bisulphide is now used for a variety of industrial purposes, chiefly on account of its solvent power, e.g. for the vulcanisation of caoutchouc; as a solvent of caoutchouc and gutta-percha; as a substitute for ether in dissolving quinine and other alkaloids; for the extraction of fatty matter from vegetable and animal tissues; for recovering the oils retained by the press-cake of olives and other seeds; for extracting oils and aromatic principles from seeds, spices, &c., and even for extracting the scents of flowers; for these latter purposes it must of course be very pure; also for dissolving bitumen and sulphur from certain rocks in which they exist in too small a proportion to be extracted economically by other processes.

The poisonous properties of carbon bisulphide have been turned to account for the destruction of insects. According to Doyère (*Technologiste*, Aug. 1857, p. 573), grain may be readily freed from insects, if kept in closed receptacles, with a small

addition of the bisulphide (2 grams of the latter to 100 kilo. of the grain). The bisulphide not only kills the insects, but also the larvæ and ova. The odour may be completely removed by merely exposing the grain for a short time to the air.

Lastly, the bisulphide is used in electroplating, a few drops added to the liquid causing the silver to deposit with increased brightness.

For details respecting the industrial applications of the bisulphide, see *Chemical Technology*, pt. iii. pp. 134-141; also *Hofmann's Exhibition Report*, 1862, p. 93.

Reactions.—1. Carbon bisulphide passed through a tube heated to bright redness is partly resolved into its elements, carbon being deposited on the sides of the tube, and sulphur passing off with the undecomposed bisulphide. If the tube be filled with lumps of charcoal, the separated sulphur is reconverted into bisulphide (Berthelot, *Zeitschr. f. Chem.* [2] v. 128; Stein, *ibid.* 512).

2. When carbon bisulphide is exposed to sunshine for some months in sealed tubes, a brown substance is deposited, which after a while greatly interferes with the action of the light. If, however, a small quantity of water be introduced into the tubes, this substance is no longer deposited, and the water takes up a small quantity of formic acid:

On removing the watery layer and the undecomposed bisulphide, a bulky solid substance remains, consisting of carbon sesquisulphide (O. Loew, *ibid.* iv. 622).

3. When a long thin plate of gold or platinum wound into a spiral with tin-foil is immersed in carbon bisulphide, the latter is decomposed, sulphur combining with the tin, and carbon being deposited in small crystals (Lionnet, *Compt. rend.* lxxiii. 213).

4. The action of carbon bisulphide on various metallic salts at a red heat has been studied by W. Müller (*Pogg. Ann.* cxxvii. 404; *Jahresb.* 1866, p. 120). *Potassium chromate* ignited in a current of the vapour yields potassium trisulphide, chromium sesquisulphide, and gaseous products:

Ammonium chromate yields similar products. *Potassium antimonate* is converted into sulphantimonite, according to the equation:

Ammonium antimonate yields an ammonium polysulphide, together with antimonious sulphide. *Potassium manganate* at a strong red heat is converted into potassium trisulphide and manganous sulphide, with evolution of carbon dioxide:

Barium manganate yields similar products. Anhydrous *sodium pyrophosphate* yields sodium metaphosphate and mono-sulphide, together with carbon monoxide and free sulphur:

Sodium metaphosphate is not altered under the same circumstances; but *potassium metaphosphate* is decomposed at a higher temperature, with formation of a sulphide of phosphorus.

5. *Oxamide* heated to 180°-200° in sealed tubes with carbon bisulphide, forms ammonium sulphocyanate, carbon oxysulphide, and carbon monoxide:

The tubes must be opened from time to time to allow the gases to escape. With *acetamide* the reaction is more complex, a combustible gas not absorbed by cuprous chloride, perhaps methyl, being likewise evolved, according to the equation:

If alcohol is added, mercaptan and ethyl bisulphide are also found amongst the products (Ladenburg, *Zeitschr. f. Chem.* [2] v. 478).

6. For the reaction with *sulphuric chlorhydrate* see p. 407.

7. Carbon bisulphide readily dissolves the chlorides, bromides, and iodides of phosphorus, antimony, arsenic, sulphur, and selenium, also hydrogen bisulphide, and mixes with the tetrachlorides of tin and titanium; but the fluorides, chlorides, bromides, iodides, sulphides, and oxides of most metals, and all oxygen salts, are insoluble in it. A solution of phosphorus in carbon bisulphide exerts a reducing action; a solution of bromine or iodine, an oxidising action (Gore, *Phil. Mag.* [2] xxx. 414).

8. Carbon bisulphide may be detected in coal-gas by passing the gas (completely

freed from hydrogen sulphide) over red-hot copper-foil. If any bisulphide is present, the copper acquires an iridescent surface, and its nitric acid solution diluted with water yields after some time a precipitate with barium chloride (A. Vogel, *Zeitschr. f. Chem.* [2] vi. 253).

Hydrate of Carbon Bisulphide.—A hydrate $2\text{CS}^2 \cdot \text{H}^2\text{O}$ is formed in white crystalline scales when moist carbon bisulphide is strongly cooled by rapid evaporation. It decomposes at about -3° , and is therefore as inflammable as the bisulphide itself (Berthelot, *Ann. Ch. Phys.* [3] xlvii. 490; Duclaux, *Bull. Soc. Chim.* [2] viii. 258).

CARBON SESQUISULPHIDE. C^2S^3 .—This compound is formed by digesting recently precipitated hydrogen carbosesisulphide, $\text{H}^2\text{C}^2\text{S}^3$ (*infra*), with strong aqueous ammonia at a gentle heat, and treating the dark red filtered liquid with a current of chlorine. The sesquisulphide is then precipitated, and may be freed from adhering sulphur by means of sodium sulphite, washed with warm water, then with alcohol, and dried. It is also formed when the bisulphide is enclosed, together with water, in sealed tubes and exposed for a long time to the sun's rays (p. 409). It is an amorphous, brown, inodorous powder, insoluble in alcohol, ether, and carbon bisulphide; decomposed into its elements by a heat a little above 200° ; not altered by ammonia, soluble without decomposition in boiling potash-ley. It is oxidised by weak nitric acid, yielding an acid, the barium salt of which is soluble in water, the lead and silver salts sparingly soluble. This acid has perhaps the composition $(\text{C}^2\text{S}^3)^{\frac{1}{2}}\text{H}^2\text{O}^2$ corresponding to oxalic acid (O. Loew, *Zeitschr. f. Chem.* [2] i. 722; ii. 173; iv. 623).

Hydrogen Carbosesisulphide, $\text{C}^2\text{S}^3\text{H}^2$, is produced by agitating carbon bisulphide with pasty sodium-amalgam. On throwing the resulting mass into water, filtering the blood-red solution, passing hydrogen sulphide into it to decompose a mercurial compound, and pouring the liquid into dilute hydrochloric acid, hydrogen sulphide is given off, and a red flocculent substance is precipitated, which when purified by washing with water, dissolution in carbon bisulphide, filtering, and evaporation, has the composition $\text{C}^2\text{S}^3\text{H}^2$. This substance melts at 100° and decomposes at a somewhat higher temperature; it is slightly soluble in alcohol and ether, more freely in carbon bisulphide and in alkaline sulphides.

Hydrogen carbosesisulphide is an acid, and is analogous in composition to glyoxalic acid, $\text{C}^2\text{O}^2\text{H}^2$; it might therefore be called thioglyoxalic acid. Boiled with *baryta*, it forms the salt BaC^2S^3 , which, when treated with hydrochloric acid, reproduces the hydrogen compound. In the same reaction there are formed oxalate, sulphide, and carbomonosulphide of barium, as shown by the equation:

The *sodium salt* is formed, together with sodium sulphide, by heating sodium in a sealed tube with carbon bisulphide to 140° – 150° . The carbosesisulphides of the heavy metals are dark-coloured precipitates. The *copper salt*, which has a black-brown colour, is produced when finely divided copper is digested for several hours in sunshine with carbon bisulphide and water (Loew, *loc. cit.*).

Hydrogen carbosesisulphide is likewise formed by prolonged digestion of phosphorus pentasulphide with acetic acid at 150° in a flask furnished with a condensing tube. The residue left after distillation is washed with water and weak soda-ley, and dissolved in a closed vessel in carbon bisulphide at 120° . The solution when evaporated leaves the compound $\text{C}^2\text{S}^3\text{H}^2$. The portion insoluble in carbon bisulphide is a body which appears to have the composition C^2S ; it dissolves with red colour in hot concentrated sulphuric acid and is attacked by nitric acid. Carbon sulphides containing lower proportions of sulphur are likewise formed by the action of phosphorus pentasulphide on many organic bodies (Loew, *Zeitschr.* [2] iii. 20; *Jahresb.* 1867, p. 157).

The action of sodium-amalgam on carbon bisulphide was first examined by Löwig a. Hermann (*Jahresb.* 1860, p. 397), who obtained compounds of sodium with sulphur and carbon of uncertain composition; afterwards by Guignet (*ibid.* p. 122). Girard (*Compt. rend.* xliii. 396) found that nascent hydrogen evolved by zinc and dilute sulphuric acid converted carbon bisulphide into a crystallised compound, CH^2S , volatile at about 150° , and another substance not examined, hydrogen sulphide being at the same time evolved.

CARBONATES. *Ammonia Carbonates.*—An elaborate examination of those salts has lately been made by Divers (*Chem. Soc. J.* [2] viii. 171 [1870]). The main result of this examination is the discovery of the normal carbonate, and a

confirmation of the conclusions arrived at by Deville (i. 190) respecting the composition of the acid carbonates:

The carbonate of ammonia now found in commerce appears to be a mixture or compound of acid carbonate and carbamate, represented by the formula:

The preparation, physical properties, and chemical reactions of these salts are fully discussed in the memoir above referred to, which also contains a very complete history of the investigations relating to them.

The acid carbonate occurs below the guano of the China Islands, as a saline deposit smelling of ammonia (Phipson, *Chem. Soc. J.* [2] i. 74).

Barium Carbonate.—The precipitated salt dissolves, under a pressure of 4 to 6 atmospheres, in 132.3 pts. of water saturated with carbonic acid, and is afterwards retained in this solution under ordinary atmospheric pressure. The solution when left to evaporate deposits a heavy precipitate consisting of a mixture of amorphous and crystalline barium carbonate; at the boiling heat the whole of the barium is precipitated as crystalline carbonate. The salt appears, therefore, to be insoluble in water (R. Wagner, *J. pr. Chem.* cii. 233; *Jahresb.* 1867, p. 135).

Calcium Carbonate.—A hydrate containing $\text{CO}^2\text{Ca}.6\text{H}^2\text{O}$ is formed on passing carbon dioxide into lime-water or a solution of sugar-lime cooled to between 0° and $+2^\circ$, or by precipitating calcium chloride with sodium carbonate at the same temperature. The precipitate, flocculent at first, soon becomes crystalline, and after washing with ice-water and drying at 0° , contains 20 p. c. water, answering to the formula above given. At 30° it is quickly converted into a semifluid mixture of water and anhydrous carbonate; at 20° this change takes place somewhat more slowly; and at lower temperatures the salt gradually effloresces. Calcium carbonate precipitated at temperatures above 30° is always anhydrous; between 0° and 30° (e.g. at 10° – 20°) precipitates are formed, containing quantities of water (10 to 27 p. c.) varying not only with the temperature, but with the time occupied in the precipitation (J. Pelouze, *Bull. Soc. Chim.* [2] iii. 183). Calcium carbonatechloride, $\text{CaCl}^2.2\text{CaCO}^2 + 6\text{H}^2\text{O}$, was obtained as a sandy crystalline residuum on dissolving in water some crystallised calcium chloride which had been prepared on the large scale for technical purposes. The crystals are decomposed by prolonged contact with water, the chloride dissolving and the carbonate remaining in the form of skeletons, which under the microscope appear like aggregates of amorphous spherical masses. The same double salt is formed when a solution of calcium chloride mixed with ammonia is left exposed to the air, its formation being accelerated by excess of carbonic acid in the air above the liquid.

On the solution of calcium carbonate and dolomite in saturated aqueous carbonic acid, see Cossa (*Zeitschr. anal. Chem.* 1869, 145; *Zeitschr. f. Chem.* [2] vi. 89).

Cupric Carbonate.—By dissolving the precipitated basic carbonate in saturated aqueous carbonic acid under a pressure of 4 to 6 atmospheres, a greenish solution is formed containing 1 pt. of the neutral salt CO^2Cu in 4,690 pts., and depositing an amorphous basic salt when heated to boiling. The portion of the original precipitate not dissolved by the aqueous carbonic acid is a greenish crystalline powder having the composition of malachite (Wagner, *loc. cit.*).

Ferrous Carbonate occurs as an amorphous hydrate, $\text{CO}^2\text{Fe}.2\text{H}^2\text{O}$, in the mines of Pontpéan (Dép. d'Ille-et-Vilaine); white, earthy; but little alterable in the air, and scarcely decomposed by acids at ordinary temperatures (Massieu, *Compt. rend.* lix. 238). Ferrous carbonate (spathic iron) dissolves, under the conditions above specified for the barium salt, in water saturated with carbonic acid, forming a colourless solution which contains 1 pt. in 138 of the normal carbonate, and when heated to boiling deposits a black amorphous precipitate (Wagner).

Indium Carbonate is a white gelatinous precipitate, soluble in ammonium carbonate, reprecipitated on boiling, insoluble in fixed alkaline carbonates. The precipitate formed in indium solutions by alkaline bicarbonates is also soluble in excess of the reagent (Winkler, *J. pr. Chem.* xciv. 1).

Lanthanum carbonate, $2\text{CO}^2\text{La}.5\text{H}^2\text{O}$, precipitated from the sulphate by neutral or acid sodium carbonate, and dried at ordinary temperatures, forms micaceous scales having a silky lustre (Hermann, *ibid.* lxxxiii. 385).

Lead Carbonates.—The basic salt (white lead) is nearly insoluble in saturated aqueous carbonic acid even under pressure; but the carbonate obtained by precipitation with sodium carbonate is perceptibly soluble therein, 1,000 pts. of the solution containing 0.5 pts. of normal lead carbonate (Wagner). On the formation of carbonate-chloride of lead, see p. 405.

Magnesium Carbonates.—According to Merckel (*Jahresh.* 1867, p. 136), normal magnesium carbonate, CO^2Mg , requires for solution at 5° under pressure of several atmospheres of carbonic acid gas, the following quantities of water:

Atmospheres	1	2	3	4	5	6
Parts of water . . .	761	744	134	110.7	110	76

At other temperatures the solubility is in proportion to the quantity of carbon dioxide absorbed by the water.

On the reaction of a mixture of magnesium and calcium chlorides with sodium carbonate, the solubility of the carbonates of calcium and magnesium in solutions of calcium and magnesium salts, and the action of dolomite or gypsum and magnesite in presence of water containing carbonic acid, see T. S. Hunt (*Sill. Am. J.* [2] xlii. 49; *Jahresh.* 1866, 177). On the reaction of basic magnesium carbonate and gypsum with carbonic acid water, see also Gössmann (*Sill. Am. J.* [2] xlii. 217, 368).

Manganous Carbonate.—According to E. Prior (*Zeitschr. anal. Chem.* 1869, 428), the precipitate formed by ammonium carbonate in manganous sulphate has, after drying by pressure, the composition $\text{CO}^2\text{Mn} \cdot \text{H}_2\text{O}$, and gives off half its water over oil of vitriol. The precipitate formed by fixed alkaline carbonates in an atmosphere of hydrogen, and dried out of contact with the air, has also the composition CO^2Mn ; if precipitated in contact with the air, it contains varying quantities of manganoso-manganic oxide.

Carbonates of Potassium and Sodium.—100 pts. water at 10° dissolve 24.4 pts. of CO^2KH and 8.3 pts. of CO^2NaH (G. J. Mulder, *Jahresh.* 1866, p. 87).

The double salt $\text{CO}^2\text{KNa} \cdot 6\text{H}_2\text{O}$, which Marignac obtained by crystallising a solution containing equivalent quantities of the component salts, has been obtained by Stolba (*Bull. Soc. Chim.* [2] iv. 192) in purifying the potash of beet-molasses. The salt is decomposed by recrystallisation, yielding crystals containing larger proportions of sodium carbonate and water, and a mother-liquor richer in potassium carbonate. From a solution containing excess of potassium carbonate, however, the double salt may be crystallised without alteration (see further *Bull. Soc. Chim.* [2] vii. 241; *Jahresh.* 1866, p. 156).

Crystallised *sodio-calcic carbonate*, $(\text{CO}^2)_2\text{CaNa}_2 \cdot 5\text{H}_2\text{O}$ (*Gay-Lussite*), is formed on mixing an excess of a saturated solution of sodium carbonate (sp. gr. 1.185 to 1.200), with a solution of calcium chloride (sp. gr. 1.13 to 1.15); the best proportions are 10 vol. of the former to 1 vol. of the latter. The liquid gelatinous mass at first produced, quickly changes to a sediment composed of well-defined crystals, which are monoclinic like those of the native mineral; when quickly formed, they exhibit the combination ∞P . —P; when more slowly deposited (from somewhat weaker solutions), they are usually larger, and exhibit only the two hemipyramids +P and —P (Fritzsche, *J. pr. Chem.* xciii. 339; *Jahresh.* 1864, p. 190).

Rubidium Carbonate, CO^2Rb^2 (v. 131).

Silver Carbonate, CO^2Ag^2 , separates in crystals from a solution of 1 grm. silver nitrate in 15 grms. water mixed with 1.156 grm. sodium hydrate in 20 pts. water, and then with ammonia added by drops; the liquid first deposits crystallised silver oxide, and afterwards crystals of the carbonate (H. Vogel, *J. pr. Chem.* lxxxvii. 288; *Jahresh.* 1862, p. 228).

Thallium Carbonate, CO^2Tl^2 . — See THALLIUM-SALTS (v. 753).

Thorium Carbonate, $(\text{CO}^2)_2\text{Th}$ (v. 787).

Zinc Carbonate.—By dissolving the precipitated basic salt in saturated aqueous carbonic acid prepared under a pressure of 4 to 6 atmospheres, a solution is formed containing 1 pt. of the neutral carbonate CO^2Zn in 189 pts.; it becomes turbid under ordinary pressure, and deposits amorphous basic salt both by spontaneous evaporation and at the boiling heat (Wagner).

Carbonic Ethers. *Ethyl carbonate*, $\text{CO}^2(\text{C}^2\text{H}_5)_2$, is formed, together with carbon monoxide and alcohol, by the action of sodium ethylate or potassium ethylate on ethyl oxalate. In its formation from the latter by the action of sodium or potassium, it is probable that ethylate of sodium or potassium is first formed, and then reacts as above (Cranston a. Dittmar, *Chem. Soc. J.* [2] vii. 441). See OXALIC ETHERS in this volume.

Ethyl carbonate, saturated with *hydrobromic acid* and heated to 100° , is resolved into ethyl bromide, carbon dioxide, and water (*H. Gal. Compt. rend. lix. 1049*). With sodium it yields sodium-ethylcarbonate, ethyl oxide, and carbon monoxide:

The same products are obtained when ethyl carbonate is heated with sodium ethylate in a sealed tube (Gauthier, *Zeitschr. f. Chem.* [2] iv. 658).

Ethyl-phenyl carbonate, $\text{CO}^{\circ}\left\{\begin{smallmatrix} \text{C}^{\circ}\text{H}^{\circ} \\ \text{C}^{\circ}\text{H}_5 \end{smallmatrix}\right.$, produced by the action of potassium phenate on ethyl chlorocarbonate (p. 406), and separated from the warmed mixture by water, is a transparent, colourless, strongly refracting liquid, having an aromatic odour, resembling also that of phenol, a sp. gr. of 1.117 at 0° , and boiling (though not constantly) at 234° . By boiling with baryta-water, it is resolved into ethyl alcohol, phenol, and carbon dioxide, without formation of salicylic acid (Fatiannoff, *Zeitschr. Ch. Pharm.* 1864, p. 77).

Ethyl orthocarbonate, $\text{CO}^{\circ}(\text{C}^{\circ}\text{H}^{\circ})^3$ or $\text{C}(\text{OC}^{\circ}\text{H}^{\circ})^3$, discovered by Bassett, is described in vol. iv. p. 238.

CARBONAPHTHALIC ACID. Syn. with NAPHTHYL-CARBONIC ACID (*q.v.*).

CARBONUSNIC ACID. $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$.—An acid nearly related to usnic acid, $(\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ})$, existing in *Usnea barbata*, Hoffm., a lichen which grows on cinchona bark. It is extracted by treating the lichen with milk of lime and with alcohol, precipitating the resulting solution of the calcium salt with hydrochloric acid, and recrystallising from ether. It forms sulphur-yellow prisms, insoluble in water, slightly soluble in alcohol, dissolving in 334 pts. ether at 20° . From solution in alkalis or lime-water, it is precipitated by carbonic acid; not coloured by chloride of lime. Melts at 195.4° (usnic acid at 201.8°). When boiled with alcohol or treated with baryta-water in sunshine, it is resolved into carbon dioxide and an acid precipitated by hydrochloric acid and crystallising in prisms; perhaps evernic acid (O. Hesse, *Ann. Ch. Pharm.* cxxxvii. 241).

CARBONYL-DISULPHODIETHYL. $\text{CO}(\text{SC}^{\circ}\text{H}^{\circ})^2$.—A compound isomeric with xanthic ether, produced by the action of strong sulphuric acid on ethyl sulphocyanate (Schmitt u. Glutz, *Zeitschr. f. Chem.* [2] iv. 723). See SULPHOCARBONIC ETHERS.

CARBOPYROLAMIDE. Syn. with DIPYROMUCAMIDE. See PYROMUCIC ACID, AMIDES OF (iv. 765).

CARBOXYL, COOH ; also called *Oxatyl*.—A radicle supposed to enter into the composition of organic acids (p. 38).

CARBOXYLIC ACID. $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$.—An acid formed by oxidation of the hydro-carboxylic acids (iii. 189; iv. 296).

CARBYLAMINES. See CYANIDES, ALCOHOLIC.

CARMENITE. A copper ore approaching nearly in composition to $\text{Cu}^{\circ}\text{S} \cdot \text{CuS}$, occurring, together with red copper ore, malachite, and tile ore, on the island of Carmen, in the Gulf of California. It is massive, imperfectly cleavable, of dark steel-blue colour; hardness 3.5, and sp. gr. 5.29 (Hahn, *Jahresh.* 1865, p. 868).

CARMINE-RED. See the next article.

CARMINIC ACID (i. 804). C. Schaller (*Bull. Soc. Chim.* [2] ii. 414) prepares this acid by precipitating the aqueous extract of cochineal with neutral lead acetate slightly acidulated with acetic acid; decomposing the washed precipitate with sulphuric acid; again precipitating the filtrate with lead acetate, and decomposing the precipitate with sulphuric acid, avoiding an excess; then precipitating a third time, and decomposing this precipitate with hydrogen sulphide. The filtered solution is evaporated to dryness; the residue dissolved in absolute alcohol; the crystalline nodules of carminic acid obtained on leaving this solution to evaporate are freed from a yellow substance by washing with cold water, which dissolves only the carminic acid; and the residue left on evaporating the aqueous solution is recrystallised from absolute alcohol or from ether. Schaller assigns to carminic acid the formula $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$, differing by H°O from that given by Schützenberger, $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$ (i. 804). It is bibasic, forming acid and neutral salts. The neutral sodium salt is obtained by mixing the solutions of the acid and of caustic soda in absolute alcohol, as a precipitate which crystallises from water in nodular groups.

According to Hlasiwetz and Grabowski (*Ann. Ch. Pharm.* cxli. 129), on the other hand, the composition of carminic acid is represented by the formula $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$. With

potash in alcoholic solution it forms a red, afterwards dark violet precipitate, which when washed with alcohol out of contact with the air dries up to a dark violet mass, having when dried at 120°-130° the composition $2C^{11}H^{10}O^7K^2 \cdot H^2O$. The purple-red aqueous solution of this salt is precipitated by the chlorides of barium, strontium, and calcium; the barium-compound dried at 130° consists of $C^{11}H^{10}O^7Ba$.

Carminic acid is a glucoside, and is resolved by boiling with dilute acids into carmine-red and sugar:

To obtain these products of decomposition, the dark violet precipitate formed by lead acetate in a filtered decoction of cochineal, after being carefully washed, is decomposed with dilute sulphuric acid, and the dark red filtrate, completely freed from lead by hydrogen sulphide, is boiled for several hours in a flask having an upright condenser with sulphuric acid (10 c.c. of the concentrated acid to 1 pound of cochineal). The liquid is then mixed with levigated barium carbonate till both the precipitate and the liquid assume a violet colour; the liquid is filtered as quickly as possible; and the filtrate is precipitated with neutral lead acetate. The precipitate (A) contains the carmine-red; the liquid (B), which is mostly reddish, contains the sugar. The solution freed from lead by hydrogen sulphide and cautiously evaporated—best under the air-pump—leaves a honey-yellow syrup, from which alcohol throws down a sugar-barium compound, $(C^6H^{10}O^5)^2Ba$, in white flocks which become gummy in drying. The sugar separated therefrom has the composition $C^6H^{12}O^5$ at 50°, and $C^6H^{12}O^4$ at 100°. It is a honey-yellow, amorphous, hygroscopic mass, having a faint odour of caramel and a bitterish taste; easily reduces cupric oxide in alkaline solution; exhibits Pettenkofer's reaction with bile, even in very small quantity; is nearly insoluble in alcohol, unfermentable and optically inactive.

To separate the carmine-red, the precipitate (A) stirred up with water is treated with dilute hydrochloric acid, till, on adding the acid by drops, the colour of the liquid, which has become scarlet, suffers no further alteration. The filtrate freed from lead by hydrogen sulphide is then evaporated at a gentle heat; the residue is dissolved in cold water; and the solution is perfectly dried over sulphuric acid under the air-pump. Pure carmine-red, $C^{11}H^{12}O^7$, is thus obtained as a dark purple-red shining mass with green reflex, triturable to a very slightly hygroscopic powder, soluble with fine red colour in water and in alcohol, insoluble in ether. When burnt, it leaves a trace of ash, consisting of lime, iron, and phosphoric acid. On mixing the alcoholic solution of carmine-red with an alcoholic solution of potash, a potassium salt $C^{11}H^{10}O^7K^2$ is precipitated, with red colour changing to dark violet. The aqueous solution of this salt gives, with barium chloride, calcium chloride, and zinc sulphate, dark violet precipitates containing respectively $C^{11}H^{10}O^7Ba$, $C^{11}H^{10}O^7Ca$, and $C^{11}H^{10}O^7Zn$. Another zinc compound, $(C^{11}H^{10}O^7)^2Zn$, is deposited on leaving a solution of carmine-red (or carminic acid) in contact with dilute sulphuric acid and excess of zinc, as a pulverulent mass exhibiting a green translucence. A solution of carmine-red boiled with zinc and sulphuric acid, or warmed with sodium-amalgam out of contact with air, becomes almost colourless, yielding easily decomposable products.

Coccinin, $C^{14}H^{12}O^8$, is formed, together with oxalic, succinic, and probably acetic acid, by fusing carmine-red with 3 pts. of potassium hydrate liquefied with a little water (or crude carminic acid with 4 or 5 pts. potash) till a sample of the fused mass dissolves in water with gold-brown colour. By decomposing the aqueous solution of the product with dilute sulphuric acid, filtering to separate a resinous substance, agitating the filtrate with ether, and evaporating the ethereal solution, a crystalline residue is obtained from which water extracts the above-mentioned acids, leaving the coccinin (which is formed only in small quantity) undissolved. The coccinin, when freed by pressure from a brown extractive matter and recrystallised from hot dilute alcohol, forms yellow micaceous laminae having a greenish tinge in the mass, but appearing under the microscope as straw-yellow rectangular tablets, apparently belonging to the rhombic system, and exhibiting the colour-phenomena of polarising crystals.

It is insoluble in water, easily soluble in alcohol, sparingly in ether, very soluble in dilute alkalis. The alkaline solution is yellow at first, but on exposure to the air becomes green, then violet, and at last purple-red; the solution in ammoniacal water soon turns violet when agitated with air; the alcoholic solution is coloured red by ferric chloride. The solution in strong sulphuric acid, which is yellow in the cold, becomes indigo-blue when warmed or on addition of a few grains of manganese dioxide.

CARNAURA—CATASPILITE

With sodium-amalgam, the alcoholic solution immediately deposits black, turns green and then dark blue on exposure to the air, a dark blue amorphous body being at the same time deposited. An ammoniacal compound of coccaine, $C^{10}H^{10}O^3 \cdot NH^3$, is formed on passing ammonia gas over the dried substance; the alcoholic solution gives with lead acetate a yellowish precipitate quickly changing to violet (Hlasiwetz & Grabowski).

CARNAURA WAX. See CANAURA WAX (p. 391).

CARNALLITE, $KCl \cdot MgCl^2 \cdot 6H^2O$, is found in the rock-salt formation of Maman in Persia (Gübel, *J. pr. Chem.* xcvii. 6; *Jahresh.* 1866, p. 912).

CARTHAMIN. According to Malin (*Ann. Ch. Pharm.* cxxvi. 115), this colouring matter, fused with potash till hydrogen is rapidly given off and the aqueous solution of the mass is no longer precipitated by acids, yields paraoxybenzoic acid, together with oxalic acid:

CARVIOLIN. A substance which separates from the concentrated aqueous extract of cauliflower and other species of *Brassica*, in microscopic leaf-like crystals, which on addition of alcohol to the solution, change into granules grouped in hexagonal masses (H. Reinsch, *N. Jahrb. Pharm.* xxvi. 196; xxvii. 197; *Jahresh.* 1866, p. 705; 1867, 767).

CARVOL. $C^{10}H^{10}O$.—Carvol from oil of caraway does not unite with potash, but is converted by it into the isomeric compound carvacrol. When vapour of carvol is passed over heated zinc-dust (metallic zinc, oxide and hydrate), two hydrocarbons are obtained, viz. $C^{10}H^{10}$, boiling, after distillation over sodium, at 173° , and $C^{10}H^{12}$, boiling at 176° – 178° . The hydrocarbon $C^{10}H^{12}$ is oxidised by chromic acid to terephthalic acid, whereas carvone from oil of caraway (i. 809) yields by the same treatment oxalic acid and a resin. This hydrocarbon gives also with fuming sulphuric acid a sulpho-acid identical with that obtained from cymene (Arndt, *Zeitschr. f. Chem.* [2] iv. 730).

CASCARILLINE. A base obtained from cascarilla bark (from *Croton eleuteria*), and allied in its properties to ricinine (Tuson, *Chem. Soc. J.* [2] ii. 195).

CASEIN. See PROTEIDES.

CASSUVIUM POMIFERUM. The kernels of this tree, called *Aqjou* nuts, yield 41·8 p. c. of a sweet pale yellow oil, of sp. gr. 0·916. The pericarp yields 35 p. c. of a white viscid vesicating oil, of sp. gr. 1·014; this oil becomes dark-coloured on exposure to the air; reddens litmus; dyes linen permanently yellow-red; and dissolves in alcohol and ether, leaving a white flocculent substance (J. Lepine, *J. Pharm.* [3] xl. 18).

CASTANEA. See CHESTNUT.

CASTELLITE. A mineral from Guanasevi in Mexico, massive, variegated on the surface, distinctly laminar, and having a sp. gr. of 5·186 to 5·241. Gives by analysis:

S	Cu	Ag	Pb	Zn	Fe
25·65	41·14	4·64	10·04	12·09	6·49 = 100·05,

a composition which may be represented by the formula $(Cu^2; Ag^2)S \cdot 2(Cu; Pb; Zn; Fe)S$ (Rammelsberg, *Jahresh.* 1866, p. 917).

CATASPILITE. A mineral from the Langbans iron mines, in Wermland, Sweden, where it occurs imbedded in grey chlorite. It has the crystalline form of cordierite, and appears to be a product of the alteration of that mineral. Ash-grey, translucent at the thin edges, gradually turning red on exposure to the air. Hardness = 2·5;

SiO^2	Al^2O^3	CaO	MgO	K^2O	Na^2O	Loss by ignition
40·05	28·95	7·43	8·20	6·90	5·25	3·22 to 1·0:

whence the formula $9[2(M^2; M^3)O \cdot SiO^2] + 5(2M^2O^3 \cdot 3SiO^2)$ (Igelström, *Jahresh.* 1867, p. 983).

* With a small quantity of ferric oxide.

CATECHIN (Zwenger, *Ann. Ch. Pharm.*, xxxvii. 320; Neubauer, *ibid.* xcvi. 337; Kraut a. van Delden, *ibid.* cxxviii. 285; Hlasiwetz a. Malin, *ibid.* cxxiv. 118; Schützenberger a. Rack, *Bull. Soc. Chim.* [2] iv. 5).—This substance gives by analysis, in the air-dried state, about 52 p. c. carbon and 6 p. c. hydrogen; dried at 100°, about 61·4 p. c. carbon and 5·0 hydrogen. These numbers agree approximately with the following formulæ, by which catechin dried at 100° has been represented by different chemists:

Zwenger	Neubauer	Hlasiwetz a. Malin	Schützenberger a. Rack		
$C^{20}H^{18}O^8$	$C^{17}H^{18}O^7$	$C^{19}H^{18}O^8$	$C^{19}H^{18}O^4$	$C^{12}H^{12}O^5$	$C^{22}H^{22}O^8$

Kraut a. van Delden also represents catechin dried at 100° by the formula $C^{12}H^{12}O^8$, and the air-dried substance by $C^{12}H^{12}O^8 \cdot 2H^2O$.

Catechin melted with *potassium hydrate* is resolved into protoc catechuic acid and phloroglucin (Hlasiwetz a. Malin):

Kino, which contains catechin, yields by similar treatment 12 p. c. phloroglucin, and is, according to Hlasiwetz, the best material for the preparation of that compound.

Catechin boiled with dilute *sulphuric acid* out of contact with the air, or with alcohol containing *hydrochloric acid*, is converted into a brown amorphous powder called catechuretine, insoluble in water and in alcohol. This substance appears to be formed from catechin by dehydration and [according to the formula of catechin given by Hlasiwetz] its formation may be represented by the equation:

Catechuretine treated with bromine-water is converted into reddish insoluble bromocatechuretine (Kraut a. van Delden). These chemists give for catechuretine the formula $C^{12}H^{10}O^4$ ($= C^{12}H^{12}O^5 - H^2O$), and for bromocatechuretine, $C^{12}H^8Br^4O^4$. According to Sacc (*Compt. rend.* liii. 1102), an aqueous solution of catechu heated to 100° for an hour with sulphuric acid deposits a brown powder insoluble in water, alcohol, ether, and acids (doubtless catechuretine), and the filtered liquid neutralised with calcium carbonate yields, on addition of alcohol, a precipitate consisting of the tartrates of calcium and sodium, and a filtrate which on evaporation leaves a residue of glucose.

Catechin heated to 190° with *benzoyl chloride* yields two brown products, one soluble in alcohol, and having the composition of monobenzoyl-catechin, the other insoluble, derived in like manner from catechuretine. Catechin heated to 100° with water and *phosphorous iodide*, PI^3 , forms a solution which gradually deposits a yellow elastic substance insoluble in water, alcohol, ether, and glacial acetic acid, and agreeing approximately with the formula $C^{22}H^{22}O^8$ [or $C^{19}H^{18}O^7$]. When a solution of catechin in *acetic anhydride* is mixed with pulverised *barium peroxide*, and then with water, a white substance is precipitated, which when freed from baryta by repeated solution in glacial acetic acid and precipitation with water, has the composition $C^{21}H^{18}O^{10}$ [or $C^{18}H^{18}O^9$]. A brown substance of the same or nearly the same composition (called *japonic acid*) is obtained by oxidising catechin with potassium bichromate (Schützenberger a. Rack).

CATECHU, ACIDS OF (J. Loewe, *J. pr. Chem.* cv. 32, 75; *Zeitschr. f. Chem.* [2] v. 538).—1. **CATECHUIC ACID**, $C^{18}H^{14}O^6$. To prepare this acid, pulverised catechu is boiled with water; the solution is left to stand for some days; the crystals which separate are dissolved in water containing acetic acid; the solution is precipitated with lead acetate; and the filtered liquid, after being freed from lead by hydrogen sulphide, is left to crystallise in a dark place. Catechuic acid is thus obtained in concentric groups of white microscopic needles, having the composition $2C^{18}H^{14}O^6 \cdot H^2O$, which give off their water of crystallisation at 100°–160°, and decompose at a higher temperature.

The solution of catechuic acid in alkalis is colourless at first, but soon turns yellow. On addition of acetic acid the colour becomes lighter, and the solution then gives a precipitate with gelatin. Ferric chloride colours the solution of catechuic acid chrome-green, and afterwards forms a brown precipitate. With sodium acetate and ferric chloride an indigo-blue colour is produced. Mercuric chloride produces a white turbidity, soluble in hydrochloric acid; cupric acetate throws down brown flocks. No precipitate is formed by zinc acetate, potassium ferro- or ferri-cyanide, gelatin, alkaloids, or tartar-emetic. Silver nitrate is decomposed, with separation of

metallic silver. Potassium dichromate forms a red-brown precipitate. Solutions of catechuic acid turn brown on exposure to the air, and are then precipitated by gelatin. When boiled with acids, it deposits a brown powder consisting of catechuretine, which, according to Loewe, has the composition $C^{12}H^{12}O^{10}$. The liquid filtered from this precipitate contains catechutannic acid, but no sugar.

2. **CATECHUTANNIC ACID.** $C^{12}H^{14}O^4$.—The aqueous extract of catechu is evaporated; the residue exhausted with alcohol; and the filtered alcoholic solution is freed from lime with sulphuric acid, then treated with lead carbonate, finally purified with hydrogen sulphide, evaporated to a syrup, mixed with water, and evaporated to dryness. The residue is then dissolved in alcohol; the solution mixed with ether, which produces a precipitate; the filtered ethereal solution evaporated; the residue moistened with water; and the resulting aqueous solution filtered from catechuic acid, which crystallises out, and from catechin by repeated agitation with ether, which dissolves the latter. On finally evaporating the solution thus purified, catechutannic acid is obtained as a gummy, easily friable mass, very soluble in water, insoluble in ether, sparingly soluble in a mixture of ether and alcohol. Its aqueous solution gives an immediate precipitate with gelatin, tartar emetic, alkaloids, ferric chloride either alone or mixed with sodium acetate, also with cupric acetate and zinc acetate; it reduces silver nitrate, and forms with potassium dichromate a brown-red precipitate, with mercurous nitrate a white, with platinum chloride a yellow, and with auric chloride a brown precipitate, after a while also metallic gold. Hydrochloric acid added to the solution throws down yellow flocks; sulphuric acid resinifies pulverulent catechutannic acid, but after the latter has absorbed water, forms a yellow powder. The solution of catechutannic acid is coloured brown by caustic alkalis, becomes lighter on addition of acetic acid, and then yields with lead acetate a precipitate which quickly turns brown. The acid dissolves in ammonia, and the solution dries up over sulphuric acid to a varnish, which dissolves in water, is precipitated by acetic acid, but is not altered by gelatin. Catechutannic acid when heated gives off water, and then a yellow liquid which solidifies to small prisms (pyrocatechin?). On boiling the acid with water containing 2 p. c. sulphuric acid, a brown resinous body separates, which when washed with water and dissolved in alcohol leaves on evaporation a gummy mass having the composition $C^{12}H^{12}O^8$. Catechutannic acid is absorbed by animal membranes.

3. The precipitate formed by ether in the alcoholic solution of catechutannic acid contains two compounds, $C^{12}H^{12}O^8$ and $C^{12}H^{14}O^4$, agreeing in their properties with the japonic and rubinic acids described by Svanberg (iii. 442; v. 182).

The portion of the aqueous extract of catechu which is insoluble in alcohol dissolves partially in alcohol containing sulphuric acid; and on removing the sulphuric acid from the solution by lead carbonate, the lead by hydrogen sulphide, and evaporating the filtrate to dryness, a residue is obtained only a part of which dissolves on boiling with water, the remainder being however soluble in alcohol. The residue left on evaporating the alcoholic solution thus obtained has the composition $2C^{12}H^{12}O^8 \cdot H^2O$, and is designated by Loewe as mimotannihydroretin. The aqueous solution when boiled also deposits brown flocks, which are likewise soluble in alcohol, and the resulting alcoholic solution leaves on evaporation a substance called mimotanniretin, having the composition $C^{12}H^{12}O^8$.

Finally, Loewe confirms the observation of Runge, that on agitating an aqueous solution of catechuic acid with ether, and evaporating the ether, a base is obtained in combination with tannic acid.

CATECHURETIN. See CATECHIN, p. 416.

CATHARTIC ACID. $C^{12}H^{12}N^4O^{28}S^7$.—This, according to Dragendorff a. Kubly (*Bull. Soc. Chim.* [2] vii. 356), is the active principle of senna-leaves, in which it exists partly in combination with lime and magnesia. To prepare it, the aqueous extract of the leaves, evaporated to a syrup, is mixed with an equal volume of alcohol, and the liquid, filtered from the mucus and salts thereby separated, is mixed with absolute alcohol as long as a precipitate is formed. The aqueous solution of this precipitate, purified by a second precipitation with alcohol, and freed from albuminous substances by a few drops of hydrochloric acid, yields, on further addition of hydrochloric acid, a precipitate of cathartic acid, which may be purified by precipitation with ether from the alcoholic solution.

Cathartic acid thus obtained is an amorphous substance, brown while moist, black after drying, soluble in alkalis, and precipitable therefrom by acids. It is a glucoside, and is resolved, by boiling with acids in alcoholic solution, into sugar and a yellow-brown powder, insoluble in water and in ether, called cathartogenic acid. Dragendorff a. Kubly represent the decomposition by the following equation:

Sup.

E E

It must be observed, however, that neither cathartic nor cathartogenic acid has yet been obtained sufficiently pure to enable their composition to be determined by analysis: hence the preceding equation is to a great extent conjectural.

The alcoholic liquids obtained in the preparation of cathartic acid contain a reddish-brown substance soluble in ether, and resembling chrysophanic acid; and in the portion insoluble in ether (together with Ludwig's sennepicrin, *q.v.*) a crystallisable saccharine substance, $\text{C}^{21}\text{H}^{40}\text{O}^{18}$ (?), called cathartomannite. This substance is unfermentable, optically dextrogyrate, and does not reduce an alkaline cupric solution, even after several days' contact with dilute sulphuric acid.

CATHARTOGENIC ACID.

CATHARTOMANNITE.

} See the preceding article.

CAVIARE. See Egg.

CEDRELA. The bark of *Cedrela febrifuga*, used in Java as a febrifuge, contains—besides starch, wax, oxalic acid, citric acid, and a non-crystallisable bitter principle—a body, $\text{C}^{10}\text{H}^{10}\text{O}^4$, resembling phlobaphene, and an iron-greening tannin, called cedrela-tannic acid, which appears, from the analysis of its lead-salt, to have the composition $\text{C}^{17}\text{H}^{20}\text{O}^{11}$, analogous to that of cinchona-tannic acid (W. Lindau, *Jahresb.* 1861, p. 768).

CELLULOSE. $\text{nC}^6\text{H}^{10}\text{O}^5$.—This compound, or a modification of it, exists, according to De Luca (*Compt. rend.* lii. 102; lvii. 43), in the skin of the silkworm and of serpents, and according to Béchamp (*ibid.* lxx. 42) in the vibrating corpuscles of the silkworm. These animal substances, boiled with strong potash-ley, yield a non-azotised body insoluble therein, but dissolving in cold strong sulphuric acid, and forming a jelly which by prolonged boiling with water is converted into fermentable sugar.

Cellulose is formed from drowse (a substance obtained by the action of boiling hydrochloric acid on glycodrupose, which constitutes the stony concretions occurring in pears) by boiling with dilute nitric acid:

Also, though in smaller quantity, by similar treatment of glycodrupose itself (J. Erdmann, *Ann. Ch. Pharm.* cxxviii. 1). See GLYCODRUPOSE.

Pure cellulose is easily prepared from the pith of various plants (e.g. *Phytolacca dioica* and *Aralia papyrifera*) by macerating it for eight to fourteen days in a mixture of 1 vol. hydrochloric acid and 9 vol. water, washing the undissolved matter with water, and then with aqueous ammonia (Payen, *Ann. Ch. Phys.* [4] vii. 382; *Zeitschr. f. Chem.* [2] ii. 334). See further Payen (*Compt. rend.* lxiv. 1167; *Jahresb.* 1867, p. 952).

According to E. Mulder (*Scheik. Onderz.* III. deel, tweede stuk, *Onderz.* 146, *Jahresb.* 1863, p. 565), the solution of cellulose in cuprammonia (i. 320) gives with lead acetate a precipitate containing cellulose and lead oxide in varying proportions; by digestion with finely divided lead oxide, the same solution yields the compound $\text{C}^6\text{H}^{10}\text{O}^5 \cdot \text{PbO}$. With potash, soda, baryta, and lime, blue gelatinous precipitates are obtained. Mulder represents the compound of cellulose and cuprammonia by the formula $(\text{C}^6\text{H}^{10}\text{O}^5)_2\text{Cu}(\text{NH})_2\text{O}$, and supposes the blue precipitates just mentioned to have the composition $(\text{C}^6\text{H}^{10}\text{O}^5)_2\text{CuK}^2\text{O}$, $(\text{C}^6\text{H}^{10}\text{O}^5)_2\text{CuBaO}$, &c. Zinc added to a solution of cellulose in cuprammonia precipitates the copper and forms a colourless liquid similar in its chemical properties to the original solution, and quite inactive to polarised light.

Mulder has also observed that when pure (Swedish) filter-paper is heated with water to 200°, a small quantity of glucose is produced.

Acetyl-cellulose.—Cellulose (cotton or Swedish filter-paper) heated to 180° in sealed tubes with six to eight times its weight of acetic anhydride, dissolves to a thick syrup, which when poured into water deposits white flocks of triacetocellulose, $\text{C}^6\text{H}^7(\text{C}^2\text{H}^3\text{O})_3\text{O}^2$. This compound is insoluble in water, alcohol, and ether, soluble in strong acetic acid, and easily saponified by alkalis, with reproduction of cellulose. No more highly acetylated compound is formed, however long the heat may be continued, or however great an excess of acetic anhydride may be employed. Hence cellulose,

$\text{C}_6\text{H}_5\text{O}_3$, appears to be a triatomic alcohol.* Cotton heated to only 150° with 2 mol. acetic anhydride swells up without dissolving, and yields a mixture of mono- and di-acetyl-cellulose, which have not yet been separated (Schützenberger a. Naudin, *Compt. rend.* lxxviii, 814; *Zeitschr. f. Chem.* [2] v. 264).

FULMINOSE.—This name is applied by Blondeau (*Ann. Ch. Phys.* [3] xviii. 462; *Jahresb.* 1863, p. 567) to an isomeric modification of cellulose, which, according to his observations, is produced by boiling gun-cotton with ammonium sulphide; also by the action of concentrated acids, or even of heat alone, on cellulose, and forms the chief constituent of parchment-paper (i. 819). It is not altered by contact with water, acids, or alkalis; in fuming nitric acid it does not dissolve like ordinary paper, but is converted into a nitro-compound. When heated for some time to 100° , it becomes so brittle that it may be pulverised; at 140° it is immediately resolved into water and a porous, very easily combustible charcoal. A piece of calico placed between hot bricks is converted, without alteration of external appearance, into a very friable substance, which burns like tinder. Fulminose decomposes at the same temperature as gun-cotton; it dissolves in a mixture of alcohol and ether, also in acetic acid, and is converted by acetic acid into a gelatinous mass.

CERBERIN. A glucoside existing in solution in the poisonous oil of *Cerbera Odollam*, an East Indian plant, and separating in the crystalline form from the alcoholic solution of the oil (Oudemans, *J. pr. Chem.* xcix. 407).

CERIUM. Atomic weight 92.—Wöhler (*Ann. Ch. Pharm.* cxliv. 251) prepares metallic cerium as follows: The hydrochloric acid solution of crude brown cerium oxide (obtained by igniting the mixed oxalates of cerium, lanthanum, and didymium) was mixed with about an equal weight of potassium chloride and sal-ammoniac, evaporated to dryness, heated as long as sal-ammoniac continued to be given off, and fused. The fused mass (which was perfectly soluble in water) was pulverised, mixed while still warm with small pieces of sodium, thrown into a red-hot earthenware crucible, and after the reaction had commenced, heated till the sodium flame disappeared, but no longer. The cooled mass contained numerous small metallic globules, which were picked out, or separated by lixiviation with cold water. Larger and more numerous globules were obtained by placing the sodium in a single lump on the bottom of the ignited crucible, covered with potassium carbonate, and shaking the pulverised saline mass upon it. The metal thus prepared, which appears to consist mainly of cerium [doubtless containing small quantities of lanthanum and didymium, and perhaps also potassium and sodium] is intermediate in colour between iron and lead, and has a bright lustre on polished surfaces, but requires a blue tarnish on exposure to the air. It is malleable, may be flattened and melted almost like lead, and has a sp. gr. of 5.5 at 12° . Heated to redness before the blowpipe, the fused metal burns with a glimmering light to a brown oxide, and at a stronger heat burns explosively with very brilliant sparks; the pulverised unfused metal takes fire even below 100° . With water it produces a slight disengagement of hydrogen at the boiling heat; hydrochloric acid dissolves it with violent action; strong nitric acid converts it into brown cerium oxide; dilute nitric acid dissolves it readily.

The saline mass which served as matrix to the metallic cerium was accompanied by shining scales of an oxychloride, $\text{CeCl}_3 \cdot 2\text{CeO}$ or $\text{Ce}^*(\text{ClO})_2$.

Preparation of pure Cerium salts.—Bunsen's method (i. 832) has been modified as follows by Czudnowicz (*J. pr. Chem.* lxxx. 16): The mixture of ceroso-ceric, magnesian, lanthanic, and didymic nitrates is cautiously heated to 230° – 300° , with continual agitation, the salts then fusing in their water of crystallisation, and afterwards giving off nitrous vapours. As soon as brown oxide of cerium begins to separate at the bottom of the capsule, the mass is left to cool, and treated first with a large quantity of boiling water, then with water containing nitric oxide, whereby basic ceroso-ceric nitrate is separated, which is to be purified by decantation. The decanted liquids are evaporated to crystallisation, and the crystals are treated as above. In this manner the whole of the cerium present is obtained in the form of basic ceroso-ceric nitrate, which when ignited yields pure ceroso-ceric oxide. See also Holtzmann (*Zeitschr. Ch. Pharm.* 1862, p. 668; *Jahresb.* 1862, p. 130). Popp (*Ann. Ch. Pharm.* cxxxi. 361) mixes the solution of crude cerium oxide with sodium acetate, and passes chlorine gas into it, or treats it with sodium hypochlorite, whereby a precipitate of a hydrated peroxide (CeO_2 , according to Popp) is obtained free from lanthanum and didymium. This is but a slight modification of the original mode of separation given by

* The composition of the nitrated derivatives of cellulose (PYROXYLANS, iv. 777) would seem to show that the true formula of cellulose is $\text{C}^*\text{H}^*\text{O}^*$; if so, the compound above described must be $\text{C}^*\text{H}^*(\text{O}^*\text{H}^*)\text{O}^*$.

Mosander (i. 831). Pattison a. Clark (*Chem. News*, xvi. 259) dissolve the crude oxide of cerium in aqueous chromic acid, evaporate to dryness, and heat the residue to 110° . On subsequently treating it with water, the didymium and lanthanum dissolve, while a pure cerium oxide remains in the form of a yellowish-white powder, which can be rendered soluble only by fusion with potassium bisulphate.

Cerium Carbide.—Produced by heating cerous formate or oxalate in a closed crucible completely filled with it, or better in a glass tube through which a stream of hydrogen is passed. A black-gray powder then remains, which while hot burns like tinder on exposure to the air, but remains unaltered if kept from contact with the air. Hydrochloric acid extracts from it a certain quantity of cerous oxide, leaving the carbide in the form of a dense black powder insoluble in concentrated acids even when heated, and agreeing approximately in composition with the formula CeC^4 (Delafontaine, *Jahresb.* 1865, p. 177).

Cerous Chloride. CeCl^2 .—By digesting ceroso-ceric oxide with hydrochloric acid and hydroferrocyanic acid, colourless crystals of hydrated cerous chloride are obtained having the composition $2\text{CeCl}^2 \cdot 9\text{H}^2\text{O}$ (Lange, *J. pr. Chem.* lxxxii. 129). The *platinochloride* (i. 833) is crystalline and contains $2\text{CeCl}^2 \cdot \text{PtCl}^4 \cdot 8\text{H}^2\text{O}$. The *aurochloride* $3\text{CeCl}^2 \cdot 2\text{AuCl}^3 \cdot 20\text{H}^2\text{O}$ is obtained—by leaving a mixture of the concentrated solutions of cerous chloride and auric chloride for several days over calcium chloride, and recrystallising several times—in yellow, transparent, apparently monoclinic crystals, which deliquesce rapidly in the air, but effloresce over caustic potash, melt in their water of crystallisation at a temperature considerably below 100° , and are soluble in absolute alcohol (Holzmann, *Zeitschr. Ch. Pharm.* 1862, p. 668).

A *chloro-iodide of cerium and zinc* is obtained, as a viscid syrup, or sometimes in crystals, by leaving a mixture of cerous chloride and zinc iodide to stand over quicklime and calcium chloride. The crystals are very soluble in water and in alcohol, and are decomposed by heat (Holzmann, *Jahresb.* 1861, p. 189).

Cerous Iodide. CeI^2 .—Dry ceroso-ceric oxide dissolves easily in aqueous hydriodic acid, with elimination of iodine; and if the free iodine be reconverted into hydriodic acid by a current of hydrogen sulphide, and the solution evaporated in an atmosphere of that gas, a colourless liquid is obtained, which when left over sulphuric acid deposits the iodide in transparent colourless crystals, which deliquesce in the air to a brown liquid (Lange, *J. pr. Chem.* lxxxii. 129).

Oxides.—*Ceroso-ceric oxide*, Ce^2O^4 , is obtained in crystals belonging to the regular system, mostly cubo-octohedrons, by heating cerous chloride with borax for 48 hours in a porcelain furnace, and treating the fused mass with hydrochloric acid. A heavy powder is then left, consisting of transparent colourless crystals of sp. gr. 6.94 at 15° , insoluble in hydrochloric acid, sparingly soluble in sulphuric acid. In one experiment brick-red crystals were obtained having a sp. gr. of 7.09 at 14.5° (Nordenskiöld, *Pogg. Ann.* cxiv. 612).

According to Hermann (*J. pr. Chem.* xcii. 113; *Jahresb.* 1864, p. 193), the oxide produced by calcining cerous oxalate with free access of air, or by igniting ceroso-ceric sulphate with 2 pts. sodium carbonate and lixiviating the residue, consists of ceric oxide Ce^4O^2 ; but this view of its composition is contrary to the results obtained by Rammelsberg, Marignac, Holzmann, and others (i. 834). Hermann further states that an oxide Ce^2O^4 or $2\text{Ce}^2\text{O}^4$. Ce^2O^2 is formed by the calcination of cerous nitrate, or by heating the supposed sesquioxide in oxygen gas. According to Stapf (*J. pr. Chem.* lxxix. 257), the residue obtained by calcining cerous nitrate in an open vessel consists of the dioxide Ce^2O^2 , or perhaps of Ce^2O^2 . According to Popp (*Ann. Ch. Pharm.* cxxxi. 36), the yellow precipitate formed on treating a solution of crude cerium oxide mixed with sodium acetate, with chlorine or hypochlorous acid (p. 419), is a hydrate of the dioxide; this statement however does not appear to be founded on any quantitative determination; moreover, the anhydrous oxide which Popp obtained by calcining the yellow hydrate in the air had a brown colour, indicating the presence of didymium.

Oxygen-salts.—On the sulphates and double nitrates of cerium, see Zschiesche (*J. pr. Chem.* cvii. 65; *Zeitschr. f. Chem.* [2] vi. 41).

Silicide. CeSi .—Ullik (*Zeitschr. f. Chem.* [2] ii. 60; *Jahresb.* 1865, p. 186), by subjecting a mixture of potassium fluoride and cerium fluoride fused in a porcelain crucible to the current of a battery of eight Bunsen's elements, obtained at the negative pole a brown mass mixed with globules of potassium. This mass triturated with water left a powder containing 23.19 p. c. silicon and 76.21 cerium, agreeing with the formula above given. The silicon was derived from the sides of the crucible, which were strongly attacked.

CEROTIC ACID. $C^{32}H^{64}O^2$.—This acid is produced, together with several of its lower homologues, by oxidising paraffin (melting at 66°) with potassium dichromate and sulphuric acid (adding a small quantity of manganese dioxide, which greatly facilitates the oxidation), or with nitric acid of sp. gr. 1.3 diluted with $1\frac{1}{2}$ vol. water. The cerotic acid, purified by repeated crystallisation from alcohol and ether, melted at 78° , and was identical in all its characters with that obtained from Chinese wax (i. 837) (Gill & Mensel, *Chem. Soc. J.* [2] vi. 466). According to Bérard (*Zeitschr. f. Chem.* [2] vi. 465), cerotic acid exists in the free state in carnaüba wax (p. 391), and may be extracted therefrom by alcohol.

CETANE or CETYL HYDRIDE, $C^{32}H^{64}$, is one of the constituents of American petroleum. When separated by fractional distillation it is a colourless liquid boiling at about 280° , and having a vapour-density of 8.078 (calc. 7.96) (Pelouze & Cahours, *Compt. rend.* lvii. 62).

CETENE or CETYLENE. $C^{32}H^{32}$.—Bromine added by drops to cetene under water unites readily with it, forming cetene bromide, $C^{32}H^{32}Br^2$, a yellowish liquid which sinks in water and is decomposed by distillation even in a vacuum. By alcoholic potash it is converted into monobromocetene, $C^{32}H^{30}Br$, a yellowish liquid which floats on water. Cetene also unites with chlorine, but it is difficult to obtain definite compounds. *Cetene diacetate*, $C^{32}H^{32}(C^2H^3O^2)^2$, appears to be formed as a semifluid mass by heating the dibromide to 130° – 140° with silver acetate and glacial acetic acid (Chydenius, *Ann. Ch. Pharm.* cxliii. 267).

Cetene oxychloride or *Chlorohydrate*, $C^{32}H^{30}OCl = C^{32}H^{32}Cl(OH)$, the chlorhydrin of the unknown cetylic glycol, is obtained by agitating a well-cooled solution of hypochlorous acid (of at most 1 p. c., and still mixed with the mercuric oxychloride formed in its preparation) with cetene gradually added, till the acid is all decomposed. The resulting cetylic chlorhydrin is extracted by ether from the mercuric oxide with which it is mixed, and the colourless oil which remains on distilling off the ether, is freed from admixed mercuric chloride by agitation with solution of sal-ammoniac, and from unaltered cetene by prolonged heating to 250° in a stream of carbon dioxide. Pure cetene oxychloride distils at about 300° almost without decomposition; it becomes viscid, but not solid at -15° , and is resolved by potash into potassium chloride and cetene oxide, $C^{32}H^{30}O$, which crystallises in slender microscopic needles, melts at 30° , boils at 300° , and is insoluble in water (Carius, *Ann. Ch. Pharm.* cxvi. 195).

CETINE. $C^{32}H^{30}$ (also called *Cetylene*).—This hydrocarbon, homologous with ethine or acetylene, is produced by distilling monobromocetene, $C^{32}H^{31}Br$, with sodium ethylate or calcium hydrate; also, together with oxalic acid, by heating an ethereal solution of cetene bromide with silver oxalate:

It is a colourless liquid, lighter than water; boils without decomposition at 280° – 285° ; solidifies in a mixture of solid carbon dioxide and ether; becomes liquid again at -25° ; dissolves easily in alcohol and ether. It unites with 2 at. bromine, forming a heavy yellow liquid which is easily decomposed by alcoholic potash, yielding potassium bromide and a dark-coloured liquid containing bromine. This latter, when quite freed from bromine, is a colourless hydrocarbon consisting for the most part of cetene boiling at 275° (Chydenius, *loc. cit.*).

CETYLIC ALCOHOL, $C^{32}H^{64}O$, is formed, together with octane, when sebic acid is heated with caustic baryta. The cetyl alcohol thus obtained melts at 49° , and solidifies again at the same temperature (Schorlemmer, *Proc. Roy. Soc.* xix. 22).

CETYLIC ALDEHYDE. Syn. with PALMITIC ALDEHYDE.

CHELIDONIC ACID. $C^{16}H^{16}O^4$ (i. 847).—The products of decomposition of this acid by heat and by bromine have been studied by J. Wilde (*Ann. Ch. Pharm.* cxvii. 164; *Jahresb.* 1863, p. 388). At 150° it gives off water, in addition to that which is expelled at 100° ; at 220° it softens, turns black, gives off carbon dioxide, and yields a crystalline sublimate melting at 55° . The aqueous solution of the residue leaves on evaporation a crystalline acid, to which Wilde assigns the formula $C^{16}H^{16}O^{14}$, its silver salt giving by analysis numbers approximating to the formula $C^{16}H^{12}Ag^2O^{14}$; but it is very improbable that an acid containing only 7 at. carbon and 4 at. hydrogen should be transformed by heat into another containing 16 at. C and 14 at. H. On treating an aqueous pulp of chelidonic acid with excess of bromine, and distilling the product with water, a heavy oil passes over, and a watery residue is left, together with an oil heavier than water. This latter solidifies on cooling to a crystalline mass, having the composition and properties of penta-bromacetone, CH^3Br^5O .

The watery liquid above this oil contains oxalic acid; and the oily distillate consists of bromoform. If this last compound be regarded as a secondary product, the action of bromine on chelidonic acid may be represented by the equation

Monoargentic chelidonate, $C^2H^3AgO^6.H^2O$, obtained by recrystallising the diargentic salt (i. 849) from very dilute nitric acid, forms white needles which give off their water at 140° – 150° (Wildo).

CHEMICAL ACTION. Researches on the laws of connection between the conditions of a chemical change and its amount have been made by Harcourt and Esson (*Proc. Roy. Soc.* xiv. 470; xv. 262; *Chem. Soc. J.* [2] v. 460). One of the reactions studied was that between *hydrogen dioxide* and *hydriodic acid* (or between a mixture of sodium or barium dioxide, hydrochloric acid, and potassium iodide). The progress of the reaction was observed by determining the intervals of time which elapsed between the successive appearances of the yellow coloration (or blue if starch was added) after the iodine, separated according to the equation

had been recombined (reconverted into hydriodic acid) by addition of a small quantity of sodium hyposulphite. The solution of this salt was added by drops, and always in equal measures; and the amount of hyposulphite in such a measure, and the quantity of peroxide used, were accurately estimated. In this manner data were obtained for determining the quantity of hydrogen dioxide present in the mixture at the time t of a particular coloration, and the quantity y' still present at the time t' of the next coloration, whence the quantity $y - y'$ of dioxide decomposed in the interval $t - t'$ was determined. The observed results are given in the following table:

Amount of dioxide	Time from the beginning	Chemical change in each interval	Intervals
20.95	0.00		
19.95	4.57	1	4.57
18.95	9.37	1	4.80
17.95	14.5	1	5.13
16.95	19.87	1	5.37
15.95	25.57	1	5.70
14.95	31.68	1	6.11
13.95	38.20	1	6.52
12.95	45.23	1	7.03
11.95	52.82	1	7.59
10.95	61.12	1	8.30
9.95	70.15	1	9.03
8.95	80.08	1	9.93
7.95	91.27	1	11.19
6.95	103.88	1	12.61
5.95	118.50	1	14.62
4.95	135.85	1	17.35
3.95	157.00	1	21.15
2.95	181.53	1	27.53
1.95	223.45	1	38.92
0.95	291.13	1	66.73

The general conclusion deducible from these experiments is that the amount of change at any moment varies directly with the quantity of dioxide present in the solution; in accordance with this law, the quantities of dioxide at the end of a series of times taken in arithmetical progression are themselves in geometrical progression, and the curve which represents the relation between these times and quantities is a logarithmic curve.

These results are corroborated by experiments on the reaction between permanganates and oxalic acid in presence of sulphuric acid, the ultimate result of which is represented by the equation:

The observations were made by varying successively the quantities of sulphuric

acid, permanganate, and oxalic acid, while the quantities of the other substances present remained constant.

The influence of the relative quantities of the reacting substances on the final result of a chemical action has been studied by Chiżyński (*Ann. Ch. Pharm. Suppl.* iv. 226; *Phil. Mag.* [4] xxxii. 388; *Jahresh.* 1866, 12) in the case of the action of phosphoric acid on mixed solutions of lime and magnesia. Solutions of calcium chloride and magnesium chloride were mixed with quantities of phosphoric acid sufficient only for partial precipitation, and with ammonia, and the proportion of the bases in the precipitate was determined. The composition of this precipitate, which invariably contained both lime and magnesia, was found to be nearly independent of the quantity of water used for dilution, and of the quantity of ammonia present, but to vary with the ratio between the calcium and magnesium salts, and with the proportion of both to the phosphoric acid. The results are given in the following table; 1 cub. cent. of the calcium chloride solution contained 28.5 milligr. lime; 1 c.c. of the magnesium chloride solution contained 21 milligr. magnesia; 1 c.c. of the phosphoric acid solution contained 72.3 milligr. phosphoric anhydride. The absolute quantity of phosphoric acid was in all the experiments 5 c.c.

Experimental liquid in c.c.		Contents of precipitate in		To 1 mol. P ² O ⁵ the precipitate contained mols. of		($\frac{1}{x}$)	(z)

These numbers lead to the following conclusions: When the two chlorides are mixed in equivalent proportions, the lime passes into the precipitate in greater equivalent proportion than the magnesia, and this proportion increases as the total quantity of the chlorides used is greater. When the quantity of calcium chloride is increased, that of the magnesium chloride remaining constant, the quantity of lime in the precipitate increases, while that of the magnesia diminishes; the contrary takes place when the quantity of calcium chloride remains constant, and that of the magnesium chloride increases; these variations in the composition of the precipitate are not sudden, but steady and gradual. With a large excess of calcium chloride the composition of the precipitate approximates to the formula $4RO.P^2O^5$; with excess of magnesium chloride to the formula $2RO.P^2O^5$, probably because the salt $Ca^{+}P^{+}O^{+}$ is produced in the former case, and $(NH^{+})MgPO^{+}$ in the latter. It appears from this that the affinity of lime for phosphoric acid is greater than that of magnesia. On the other hand, from 2.5 to 3 mol. magnesium chloride, $(MgCl^2)$, exert towards 1 mol. phosphoric acid the same action as 1.5 mol. calcium chloride, $(CaCl^2)$, inasmuch as with these proportions in the solution, the two bases combine with the phosphoric acid in nearly equivalent proportions. The chemical action of a body is therefore a function of its chemical affinity and of its mass conjointly,

increasing as the product of these magnitudes increases, though not in exact proportion thereto. Moreover, when the quantities of two bodies increase in equal proportion compared with a third for which they both have affinity, the chemical action of the body with the greater affinity increases more quickly, and that of the body with the smaller affinity decreases more quickly than might be expected according to their relative masses. The action of calcium chloride on phosphoric acid is always greater, and that of magnesium chloride is always less than they should be according to Berthollet's law of the action of masses (i. 860). To estimate the amount of chemical action according to quantity, it is necessary to multiply the chemical mass (the number of equivalents) with a *coefficient of affinity*, which varies with the mass, and, according to the preceding experiments, is, for calcium chloride, greater than unity ($\frac{1}{x}$ of $x < 1$), and for magnesium chloride less than unity (x).

Generalising this result, Chiżyński modifies Berthollet's law of the action of masses as follows: *Chemical actions* (W, W') *are proportional to the products of the chemical masses* (M, M') *and their coefficients of affinity*, ($\frac{1}{x}; x$), or:

$$W : W' = M \frac{1}{x} : M'x.$$

He calculated the coefficients of affinity for calcium chloride and magnesium chloride, taking account of the disturbing influence arising from the presence of sal-ammoniac and ammonia in the solutions, on the assumption that, with the smallest possible and equal chemical masses, their actions are proportional to these masses, and therefore equal; and finds that with equal increase of the chemical masses, the coefficient enters as a factor in the one case directly, in the other inversely, as appears from the values in the last column of the table, which agree nearly with the actual results of experiment. Equal masses of calcium chloride and magnesium chloride appear therefore to possess coefficients of affinity equal in magnitude, but opposite in direction. Chiżyński regards it as probable that the same law with regard to equal chemical masses of unequal chemical energy is universally applicable.

That reciprocal decomposition does not always take place between mixed salts as required by Berthollet's law, is shown by the following experiment of Bettendorff (*Zeitschr. f. Chem.* [2] ii. 641; *Jahresb.* 1866, 10). A solution of ferric acetate when examined by the spectroscope absorbs part of the spectrum (in the red and green, and especially in the violet), but does not exhibit any bands. If, however, a tube filled with vapour of nitrogen tetroxide be interposed between this solution and the source of light, bands make their appearance in numbers increasing with the strength of the solution. A very dilute solution of ferric chloride, either alone or mixed with ferric acetate, makes no alteration in the absorption spectrum of the latter, or in that of nitrogen tetroxide; the same is the case with potassium acetate. Now a solution of ferric acetate (containing from 0.0044 to 0.0350 grm. of the neutral salt in 26 c.c.), after addition of an equivalent quantity of potassium chloride, affects the spectrum of nitrogen tetroxide in exactly the same manner as an equally diluted solution of pure ferric acetate; and, moreover, a solution of ferric chloride mixed with an equivalent quantity of potassium acetate affects the said spectrum in exactly the same manner as an equally diluted solution of the entire quantity of ferric acetate corresponding to the ferric chloride; hence it must be inferred that potassium chloride and ferric acetate do not decompose one another, and that the reaction between potassium acetate and ferric chloride gives rise, not to four salts, but only to two—namely, potassium chloride and ferric acetate. For this reaction, therefore, Berthollet's law does not hold good.

Experiments on the degree of neutralisation of acids by different bases, and the modifications produced therein by the presence of neutral salts, have been made by Löwenthal & Leussen (*J. pr. Chem.* lxxxv. 241, 401; *Jahresb.* 1863, 120).

Influence of Pressure on Chemical Action.

When a body is decomposed by heat in a confined space, and one or more of the separated elements (ultimate or proximate) is gaseous, the decomposition goes on until the liberated gas or vapour has attained a certain tension greater or less according to the temperature. So long as this temperature remains constant no further decomposition takes place, neither do any portions of the separated elements recombine; but if the temperature be raised, decomposition recommences and goes on till the liberated gas or vapour has attained a certain higher tension, also definite for that particular temperature; if on the other hand the temperature be lowered,

recomposition takes place, until the tension of the remaining gas is reduced to that which corresponds to the lower temperature. These phenomena, which are closely analogous to those exhibited in the vaporisation of liquids (iii. 81), have been especially studied by Deville (*Compt. rend.* xlv. 857; lvi. 195, 322; lx. 317, 884; *Jahresh.* 1857, 58; 1863, 27; 1865, 59, 63; *Leçons sur la Dissociation*, Paris, 1864) and Debray (*Compt. rend.* lxiv. 603; lxvi. 194; *Jahresh.* 1867, 85; 1868, 76). Deville designates decomposition under these conditions by the term 'Dissociation'; but the utility of this new word is by no means obvious.

1. When calcium carbonate is heated in an iron tube from which the air has been exhausted by means of a mercury-pump, no decomposition takes place at 300°, and a scarcely perceptible decomposition at 440°; but at 800° (in vapour of cadmium) it becomes very perceptible, and goes on till the tension of the evolved carbon dioxide becomes equivalent to 85 millimetres of mercury; there it stops so long as the temperature remains constant; but on raising the temperature to 1040° (in vapour of zinc) more carbon dioxide is evolved until a tension equivalent to about 520 mm. is attained. If the tension be reduced by working the pump, it is soon restored to its former value by a fresh evolution of carbon dioxide. If, on the other hand, the apparatus be allowed to cool, the carbon dioxide is gradually reabsorbed by the quicklime, and a vacuum is re-established in the apparatus.

2. Similar phenomena are exhibited in the *efflorescence of hydrated salts*. When such a salt is enclosed in a sealed and exhausted glass tube, also containing a small mercurial pressure-gauge, and heated to a constant temperature in a water-bath, the tension of the vapour emitted by it in the closed space is found to increase with the temperature, and to be constant for each particular temperature. As the temperature falls the tension diminishes, in consequence of the reabsorption of a portion of the aqueous vapour.

The efflorescence or hydration of a salt exposed to the open air is determined by similar conditions. For as the pressure of the air has no perceptible influence on the tension of vapours which form in it, a salt will effloresce when the tension of its vapour is greater than that of the aqueous vapour in the atmosphere at the existing temperature; on the other hand, an effloresced salt will take up water from the air, if the tension of the vapour in the atmosphere is greater than that of the vapour which the effloresced salt emits at the same temperature.

In the decomposition of calcium carbonate by heat, the maximum tension of the evolved gas corresponding to each particular temperature is quite independent of the proportion of the compound already decomposed; and the same is the case in some instances of the efflorescence of salts, but not in all. Take for example the common diacid phosphate $\text{Na}^2\text{HPO}_4 + 12\text{H}_2\text{O}$. The tension of the vapour emitted by this salt is at first independent of its state of efflorescence. Thus a salt containing all its water (62.8 p. c.) and an effloresced salt containing only 53 to 51 p. c., emit vapours of exactly the same tension at any given temperature; but when the quantity of water is reduced to 50 p. c., corresponding to the hydrate $\text{Na}^2\text{HPO}_4 + 7\text{H}_2\text{O}$ (which is obtained by crystallising the salt below 31°), the tension of its vapour is much less. On comparing the tensions of the vapour emitted by a salt containing 49.5 p. c. water with that emitted by the salt containing $12\text{H}_2\text{O}$, the following differences have been observed:

Temperature	Na^2HPO_4 with 7 to 12 aq.		Na^2HPO_4 with rather less than 7 aq.	
	mm.		mm.	
12.3°	7.4	.	4.8	.
16.3	9.9	.	6.9	.
20.7	14.1	.	9.4	.
24.9	18.2	.	12.9	.
31.5	30.2	.	21.3	.
36.4 (melting point)	39.5	.	30.5	.
40.0	50.0	.	41.2	.

Hence it appears that, in its first phase of decomposition, ordinary sodium phosphate behaves like a compound of water with the hepta-hydrated salt. This compound decomposes just like calcium carbonate, emitting aqueous vapour whose tension is constant for a given temperature, whatever may be the proportion of water and hepta-hydrated phosphate existing in the effloresced salt; but when this first phase is terminated, and the quantity of water in the residue is reduced to 7 molecules, this hepta-hydrated salt likewise gives off aqueous vapour, but of lower tension for a given temperature. The difference between the decomposition of hydrated salts by heat,

and that of calcium carbonate, consists therefore in this, that there are no compounds intermediate between calcium oxide and calcium carbonate, as there are between an anhydrous salt and its highest hydrate. A careful study of the vapour-tensions of hydrated salts would afford the means of determining the several hydrates which the same salt is capable of forming (Debray).

3. Similar phenomena are exhibited by certain compounds of ammonia with metallic chlorides. The compound $\text{AgCl} \cdot 3\text{NH}_3$, formed by exposing well-dried silver chloride to ammonia gas at 0° , possesses sufficient tension at ordinary temperatures to render it possible to remove half the ammonia by exhaustion with the air-pump, so as to convert the compound into $2\text{AgCl} \cdot 3\text{NH}_3$. The tension of the latter at 68° is 760 mm.; that of the compound $\text{AgCl} \cdot 3\text{NH}_3$ at 20° is 800 mm.; at these temperatures therefore the compounds in question cannot be formed under the ordinary atmospheric pressure. Both of them when heated in a Faraday's tube yield liquid ammonia; if the cooled arm of the tube has a temperature of about 13.5° , the compound $\text{AgCl} \cdot 3\text{NH}_3$ must be heated to 56° , the compound $2\text{AgCl} \cdot 3\text{NH}_3$ to 103° , at which it melts. Iodide and cyanide of silver take up but small quantities of ammonia, forming compounds which behave in a similar manner to the ammoniacal compounds of silver chloride (Isambert, *Compt. rend.* lxvi. 1259; *Jahresh.* 1868, 182).

Calcium chloride forms with ammonia the compounds $\text{CaCl}_2 \cdot 2\text{NH}_3$; $\text{CaCl}_2 \cdot 4\text{NH}_3$; $\text{CaCl}_2 \cdot 8\text{NH}_3$. The two latter at given temperatures give off ammonia of constant tension, this tension increasing, as in the preceding case, as the temperature rises. When half the ammonia has been expelled from the compound $\text{CaCl}_2 \cdot 8\text{NH}_3$, the tension suddenly falls to that which corresponds to the compound $\text{CaCl}_2 \cdot 4\text{NH}_3$. The compound $\text{CaCl}_2 \cdot 2\text{NH}_3$ is decomposed with difficulty, and only at high temperatures. Similar relations are exhibited by the compounds $\text{CaI}_2 \cdot 6\text{NH}_3$; $\text{ZnCl}_2 \cdot 6\text{NH}_3$; and $\text{MgCl}_2 \cdot 6\text{NH}_3$, the two latter being converted by heat into $\text{ZnCl}_2 \cdot 4\text{NH}_3$ and $\text{MgCl}_2 \cdot 4\text{NH}_3$ respectively; also by the mercurous compound $\text{Hg}_2\text{Cl}_2 \cdot 2\text{NH}_3$ (Isambert).

4. We have next to consider decompositions in which the decomposed body, as well as one at least of its constituents, is gaseous. In these cases it is not possible to obtain an exact measurement of the maximum tension corresponding to the temperature; nevertheless the decomposition is found to take place according to the same general law, ceasing as soon as the liberated gases have attained a certain tension, which is greater as the temperature is higher.

It has long been known that chemical combination between any two bodies capable of uniting directly takes place only at and above a certain temperature, and that the combination is broken up at a higher temperature; but it is only in later years that we have become acquainted with the fact that bodies like water begin to decompose at temperatures considerably below that which they produce in the act of combining, and therefore that their combination at that temperature is never complete. Grove showed some years ago that water is resolved into its elements in contact with intensely ignited platinum. This reaction has been more closely studied by Deville, who finds that when vapour of water is passed through a heated platinum tube, decomposition commences at 960° – 1000° (about the melting point of silver), but proceeds only to a limited extent; on raising the temperature to 1200° , further decomposition takes place, but again only to a limited amount, ceasing in fact as soon as the liberated oxygen and hydrogen have attained a certain higher tension. The quantity of these gases actually collected in this experiment is however very small, the greater portion of them recombining as they pass through the cooler part of the apparatus, till the tension of the remainder is reduced to that which corresponds to the lower temperature. In Grove's experiment, the heated platinum first becomes surrounded with an atmosphere of aqueous vapour, part of which is then resolved into oxygen and hydrogen; but these gases as they rise to the surface are cooled by the water, and therefore recombine as above. The recombination of the mixed gases is not however quite complete, because they are surrounded by a considerable excess of aqueous vapour, which interferes with their combustion. (See next page.)

The recombination of the gases may be prevented to a greater extent by means of an apparatus consisting of a wide tube of glazed earthenware, through the axis of which passes a narrower tube of porous earthenware, the two being tightly fitted by perforated corks provided with gas-delivery tubes, and the whole strongly heated by a furnace. Vapour of water is passed through the inner tube, carbon dioxide through the annular space between the two, and the gases, after passing through the heated tubes, are received over caustic potash-solution. The vapour of water is then decomposed by the heat as before; but the hydrogen, according to the laws of diffusion, passes through the porous earthenware into the surrounding atmosphere of carbon dioxide, being thus separated from the oxygen, which remains in the

inner tube, and becomes mixed with carbon dioxide passing through the porous septum in the opposite direction to the hydrogen. As these gases pass through the alkaline water, the carbon dioxide is absorbed, and a mixture of hydrogen and oxygen collects in the receiver. A gramme of water passed in the state of vapour through such an apparatus yields about a cubic centimetre of detonating gas (Denville).

A small quantity of water is likewise decomposed when a stream of carbon dioxide saturated with aqueous vapour is passed through an intensely heated porcelain tube filled with fragments of porcelain. The gaseous mixture, collected over potash, exhibited in two experiments the following composition :

Oxygen	46.1	46.8
Hydrogen	35.4	31.9
Carbon monoxide	12.0	10.7
Nitrogen	6.5	10.6
						100.0	100.0

The carbon monoxide arises from the reducing action of the hydrogen on the carbon dioxide; the nitrogen is an accidental admixture. The quantity of detonating gas obtained in this experiment is only about a fourth of that in the preceding, because the separated oxygen and hydrogen remain in contact during the cooling of the mixture; their complete recombination is however prevented by diffusion through a large quantity of neutral gas, just as the detonation of a mixture of the same or other combustible gases by the electric spark is prevented by the presence of a large excess of either of them, or of any indifferent gas. In like manner, in Grove's original experiment of the decomposition of water by incandescent platinum, the complete recombination of the gases is prevented by their diffusion through a considerable quantity of aqueous vapour.

The decomposition of water at comparatively low temperatures may also be effected by passing its vapour over melted silver, hydrogen being then set free, and the oxygen being absorbed by the silver, which then acquires the property of spitting. In this experiment, first made by Regnault, the water is not decomposed by the superior affinity of the silver for oxygen, for silver does not oxidise at that temperature; but the decomposition of the water, as in the former cases, is a direct effect of heat, and the oxygen thereby liberated does not combine with the silver, but is simply absorbed by it. That such is the case, Deville has shown by substituting litharge for the silver. When vapour of water is passed over litharge contained in a platinum boat, placed within a porcelain tube and heated to 1200°-1300°, the litharge remaining in the boat after the experiment is found to have absorbed oxygen, which has subsequently escaped from it by spitting, and part of the litharge carried over in fine particles by the vapour has been reduced to metallic lead, forming a black ring at that part of the tube where the heat, though rather high, was not great enough to melt the litharge. These results show that part of the aqueous vapour had been resolved into oxygen and hydrogen.

5. Carbon dioxide passed through a porcelain tube filled with fragments of porcelain, and heated in a furnace to 1200°-1300°, is partly resolved into carbon monoxide and free oxygen. In one experiment the gaseous mixture received over potash was found to consist of 30 p. c. oxygen, 62.3 carbon monoxide, and 7.7 nitrogen.

6. When carbon monoxide is passed through an intensely heated porcelain tube in the axis of which is fixed a narrow tube of silvered brass, and a stream of water cooled to 10° is passed through the metal tube during the whole of the experiment, the surface of this tube becomes coated at its lower part with a black layer of carbon. The particles of the carbon monoxide in contact with the lower part of the porcelain become strongly heated, and consequently expand and rise, striking against the lower surface of the metal tube; at the same time they are decomposed, and their carbon is deposited on the cold surface of the metal; if the tube were not kept cool, the carbon thus set free would recombine with the oxygen.

7. Sulphurous oxide may be decomposed in a precisely similar manner, the metal tube, however, having a thicker coating of silver than in the preceding case. The sulphurous oxide is resolved into oxygen and sulphur, the latter uniting with the silver (sulphurous oxide itself does not attack silver even at 300°), while the oxygen combines with another portion of sulphurous oxide, converting it into sulphuric oxide or anhydride, which is deposited in white flocks on the cooled surface.

8. When dry Hydrochloric acid gas is passed through the same apparatus, the surface of the metal tube having been previously slightly amalgamated, decomposition takes place to a small extent at about 1800°, a small quantity of hydrogen gas being

given off, and small quantities of mercurous chloride and silver chloride being formed on the surface of the metal tube.

Carbon dioxide, sulphur dioxide, and hydrochloric acid gases are decomposed by a stream of induction-sparks nearly in the same way as by heat in the apparatus just described. In fact the decomposing action of the electric spark appears to be due merely to the great heat which it evolves. The particles in the immediate neighbourhood of the spark, and these alone, become intensely heated and are decomposed, the separated elements being immediately diffused through a large mass of the undecomposed gas and thereby cooled—as by the cold metal tube in the experiments above described—below the temperature at which they can recombine.

On the decomposition of *hydriodic acid* by heat, see IODINE; on that of *cyanuric acid*, see CYANIC ACID.

The influence of pressure on chemical decomposition is seen in other reactions besides those which are brought about by heat. Babinet in 1828 (*Ann. Ch. Phys.* [2] xxxvii. 183) found that zinc and dilute sulphuric acid cease to give off hydrogen when the pressure of this gas amounts to thirteen atmospheres at 10°, or to thirty-three atmospheres at 25°. Faraday had previously observed that under these circumstances the evolution of gas is not arrested, but only retarded (*New Quarterly Journal of Science*, iii. 474); and the same result appears to follow from the experiments of L. Gmelin.

Lothar Meyer (*Pogg. Ann.* civ. 189; *Phil. Mag.* [4] xvi. 160) found, by experiments in which, as in those of Gmelin, zinc and sulphuric acid were enclosed together in sealed glass tubes, that, with acid of the most various strengths, even in presence of large quantities of metallic sulphates, and likewise when citric and acetic acids were used, the pressure of the eliminated hydrogen very greatly exceeded the limits assigned by Babinet (amounting to sixty-six atmospheres at 0°). Nevertheless, the chemical action under these circumstances appeared to reach a limit, inasmuch as the liquid, after remaining in the tube for several months, even in contact with excess of zinc, still exhibited a very strong acid reaction. According to Favre (*Compt. rend.* li. 827), the decomposition of dilute sulphuric acid by zinc still goes on under a pressure of eighty-six atmospheres, but at a slower rate.

Similar observations have been made by Cailletet (*Compt. rend.* lxxviii. 395; *Zeitschr. f. Chem.* [2] v. 190) on the action of hydrochloric acid upon zinc. A plate of zinc which, when acted upon by hydrochloric acid in the open air, exhibited after a certain time a loss of weight denoted by 10, suffered, under precisely similar circumstances, excepting that the materials were exposed to a pressure of 60 atmospheres, a loss of only 4.7, and under 120 atmospheres only 0.1. In like manner the quantities of calcium carbonate dissolved by nitric acid in the same time under a pressure of 150 atmospheres, and in the open air, were found to be as 1 to 11.09. A similar retardation of chemical action under pressure takes place in many other instances. The electrolysis of water is retarded under pressure. The action of sodium-amalgam on water in sealed glass tubes is entirely or almost entirely arrested as soon as the evolved hydrogen has attained a certain tension. Chemical action thus retarded by pressure may be accelerated again by rise of temperature. The quantities of gas evolved by the action of dilute sulphuric acid on a plate of zinc in a sealed tube at 0° and at 50° were to one another as 1 to 2.8. Under diminished pressure the preceding reactions go on with increased rapidity, the quantity of metal dissolved in an acid in a given time being greater in a vacuum than under ordinary pressure. With aluminium in hydrochloric acid the ratio is 1 : 1.68; with zinc in sulphuric acid 1 : 1.53; with calcium carbonate in nitric acid, 1 : 2.51.

From the preceding results Cailletet concludes that, under a certain pressure, substances which ordinarily react on one another become actually indifferent. Berthelot, on the other hand (*Zeitschr. f. Chem.* [2] v. 191), maintains that the action of acids upon metals under the circumstances above described is not completely arrested, but only retarded, the retardation arising partly from the formation of a film of saturated solution at the surface of the metal, partly from the adhesion of hydrogen to its surface. Under increased pressure, the gas-bubbles become smaller and move less freely, and consequently the agitation of the liquid, which under ordinary atmospheric pressure is caused by these gas-bubbles and facilitates the transport of fresh acid to the surface of the metal, is greatly impeded: hence the retardation. To these observations Cailletet replies (*ibid.* 368) that he has kept zinc and sulphuric acid for twelve days in sealed tubes, which were continually agitated by a mechanical arrangement, and that on opening the tubes the acid was found to be still unsaturated, and capable again of acting on the zinc under ordinary pressure.

In all the reactions above noticed, the elimination of a gas is an essential condition of the change, and this being prevented, the action is retarded. On the other hand,

there are numerous reactions which are greatly promoted by increased pressure—those, namely, which depend on the solution of gases in liquids, or on the prolonged contact of substances which under ordinary pressure would be volatilised by heat. Bickeloff has shown (*Compt. rend.* xlviii. 442; *Zeitschr. f. Chem.* 1865, 376; *Jahresb.* 1859, 66; 1865, 13) that solutions of silver nitrate and sulphate, and an ammoniacal solution of silver chloride, are reduced by hydrogen in sealed tubes, though under the ordinary atmospheric pressure, little or no reduction takes place; dilute solutions of silver sulphate are reduced under lower pressures than concentrated solutions. A solution of calcium acetate is decomposed by carbon dioxide under a pressure of twenty-seven to twenty-eight atmospheres, calcium carbonate being precipitated in microscopic spherical groups of pointed crystals; under fourteen atmospheres no precipitation takes place. Carbon dioxide does not decompose a neutral solution of calcium chloride under a pressure of forty-five atmospheres, or of barium chloride at forty, or of barium acetate at thirty atmospheres.

Theories of Chemical Action and Chemical Affinity, and of the Constitution of Chemical Compounds, have been proposed by:

CHENEVIXITE. A ferruginous cupric arsenate from Cornwall, occurring in quartz-rock, as a dark green compact mass, of sp. gr. 3.93 (nearly), and hardness 4.5. Gives by analysis 32.20 p.c. As_2O_5 , 2.30 P_2O_5 , 31.70 CuO , 25.10 Fe_2O_3 , 0.34 CaO , and 8.66 water (= 100.30) (Pisani, *Bull. Soc. Chim.* [2] vi. 30).

CHENOPODINE. $\text{C}_6\text{H}_{13}\text{NO}_4$.—A base existing in white goosefoot (*Chenopodium album*), and produced in small quantity in the putrefaction of yeast and of vegetable juices. It is prepared by heating the recently expressed juice of the young plant, to free it from albumin, then evaporating to a thin syrup, treating the extract with hot alcohol, and again evaporating the alcoholic solution. The chenopodine, which gradually separates in grains, is pressed, washed with ether, and then dissolved in alcohol of 80 p.c., from which it separates in the pure state on cooling. It is a white, granular, tasteless, and inodorous powder, appearing under the microscope as a mass of spherules made up of concentric needles, and when moistened with amyl alcohol or linseed-oil varnish, exhibiting a dark cross in polarised light. It dissolves in 3 to 4 pts. of hot and about 11 pts. of cold water; in 77 pts. of boiling and 200 pts. of cold alcohol. At 200° it begins to sublime in snow-white crystals, and at 225° sublimes completely, becomes liquid, and begins to boil, giving off an extremely pungent repulsive odour. Melting sodium hydrate converts it, with evolution of ammonia, into a peculiar acid. On adding bromine to the alcoholic solution, a red powder separates after a while, and the red solution deposits large cubic crystals of *chenopodine hydrobromide*. The *hydrochloride* likewise crystallises in cubes, and forms a yellow precipitate with platinum chloride. The *sulphate* and *nitrate* crystallise in rhombic needles (H. Reinsch, *N. Jahrb. Pharm.* xx. 268; xxi. 132; xxvii. 193; *Jahresb.* 1863, p. 613; 1867, p. 631; also *Wittstein's Vierteljahrsschrift*, xvii. 37; *Zeitschr. f. Chem.* [2] iv. 670).

CHIASTOLITE occurs near Lancaster in Massachusetts, in large elongated nodules an inch thick, and exhibiting a well-marked crucial structure in the interior. Sp. gr. 2.923. Composition 41.95 SiO_2 , 48.60 Al_2O_3 , 9.30 Fe_2O_3 , 0.41 CaO (= 100.26) (Peterson, *Jahresb.* 1860, p. 925).

CHILDRENITE. This mineral occurs, with amblygonite, at Hebron in Maine (U.S.), forming small hair-brown crystals essentially similar in form to those found

at Tavistock in Devonshire (i. 869), but distinguished by the occurrence of the face αP , and prismatically elongated in the direction of the brachydiagonal. Combination $\alpha P.P.2P\infty.\infty P\infty$ (G. J. Brush, *Sill. Am. J.* [2] xxxvi. 257. J. P. Cooke, *ibid.* 258).

CHIMAPHYLLIN. A yellow crystalline substance obtained from *Pyrola* (or *Chimaphylla umbellata* (iv. 760).

CHINOLINE. C^9H^7N .—This base, like aniline (iv. 429, 475), unites with metallic salts, forming compounds represented by the general formula $C^9H^7N.MX$, where M denotes a metal (univalent), and X an acid radicle. These compounds are mostly crystallisable, slightly soluble in cold water, decomposed by the prolonged action of boiling water, and turn slightly yellow when exposed to sunlight. The *zinc-compound* $(C^9H^7N)^2.ZnCl^2$ crystallises from a hot solution in small prisms, apparently monoclinic. The *mercury-compound* $(C^9H^7N)^2.Hg(NO^3)^2$ is a white precipitate nearly insoluble in pure water, but crystallisable from very dilute nitric acid. By decomposing the corresponding acetate with various salts of the alkali-metals, the more easily decomposable compounds of chinoline with other mercury salts may be prepared. A compound of chinoline with *mercuric cyanide*, $(C^9H^7N)^2.Hg(Cy)^2$, crystallises from water in long shining prisms. Chinoline unites in like manner with stannic chloride, bismuth chloride, antimonious chloride, and arsenious chloride; but the resulting compounds are less stable than the corresponding salts of aniline. Acids decompose the compounds of chinoline with metallic salts (except the mercury-compound), giving rise to crystallisable double salts, of which the following are examples:

Antimony salt	$SbCl^3.C^9H^7NCl$
Zinc salt	$ZnCl^2.2C^9H^7NCl$
Stannic salt	$SnCl^4.2C^9H^7NCl$
Bismuth salt	$BiCl^3.3C^9H^7NCl$

(H. Schiff, *Ann. Ch. Pharm.* cxxxi. 112; *Jahresb.* 1863, p. 429).

Tribromochinoline, $C^9H^4Br^3N$, is produced by the action of bromine-vapour on chinoline, and crystallises from alcohol in colourless silky needles, which melt at $173^\circ-175^\circ$, and volatilise without residue at a higher temperature. Insoluble in water, sparingly soluble in cold, easily in hot alcohol, easily also in strong hydrochloric or sulphuric acid, and precipitated therefrom by water. When fused with potash it exhibits the same colours as chinoline. A compound intermediate between tri- and tetra-bromochinoline is formed by the action of bromine on chinoline-sulphuric acid (Lubavin, *Z. itschr. f. Chem.* [2] v. 690).

Chinoline-sulphuric acid, $C^9H^7N.SO^3H$, formed by heating chinoline for several days with fuming sulphuric acid, separates from hot water in large anhydrous crystals, easily soluble in alcohol, insoluble in ether. The *barium salt* $(C^9H^7N.SO^3)^2Ba$ is sparingly soluble in water and separates on evaporation in warty crusts. The *silver salt* crystallises in sparingly soluble needles. The acid fused with potash gives off vapours of chinoline and leaves a black amorphous mass (Lubavin).

CHINOLINE-BLUE or CYANINE. The blue dye known in commerce by these names, which was discovered by C. Gr. Williams (i. 873), and is prepared on the large scale by Müller in Basel, has been investigated chemically by Nadler a. Merz (*J. pr. Chem.* c. 129, *Jahresb.* 1867, p. 512). It is an amyl-chinoline derivative having the composition $C^{22}H^{33}IN^2$, whereas the similarly named compound from the works of Ménier in Paris, examined by Hofmann, is an amyl-lepidine derivative, $C^{20}H^{31}IN^2$ (iii. 573).

Chinoline-iodocyanine, or more shortly *Iodocyanine*, $C^{22}H^{33}IN^2$, forms, accordingly as it is recrystallised by spontaneous evaporation or by cooling of very concentrated alcoholic solutions, cantharides-green prisms and scales, or crystalline grains of a brass-yellow to bronze-yellow colour, differing from one another by their amount of water. It is very slightly soluble in cold water and in ether; very soluble, with deep dark blue colour, in hot alcohol; and melts at 100° , with loss of water, to a bronze-coloured liquid which solidifies to a crystalline mass on cooling. Its formation by the action of potash on amylchinoline iodide (i. 873) is represented by the equation:

The colourless solution of chinoline-iodocyanine in hydrochloric acid deposits on evaporation colourless scales of the hydrochloride $C^{22}H^{33}IN^2.2HCl$, which in the

exsiccator gradually crumble to a yellow powder; at 100° this salt gradually gives off half its hydrochloric acid, leaving the bronze-coloured salt $C^{26}H^{23}IN^2 \cdot HCl$, sparingly soluble in water, easily in alcohol.

Chinoline-cyanine, or more shortly *Cyanine*, $C^{26}H^{23}N^2O$ or $C^{26}H^{23}(OH)N^2$, is obtained, together with resinous substances, by treating the iodine-compound with recently precipitated silver oxide, or with potash in alcoholic solution, as a viscid, uncrystallisable mass.

Chlorocyanine, $C^{26}H^{23}ClN^2$, is obtained by mixing the solution of cyanine in hydrochloric acid with ammonia, or by decomposing an acetic acid solution of sulphatocyanine (*infra*) with barium chloride, and saturating the filtrate with ammonia; or by digesting an alcoholic solution of iodiccyanine with silver chloride. It forms brown flocks easily soluble in hot water and in alcohol, and separates from the former in a coherent cake of long blue prisms, from the latter by spontaneous evaporation, in cantharides-green shining needles, or in dark green prisms and tables. In the air-dried state it contains $4H^2O$ (14.2 p. c.). It dissolves without colour in acids, forming salts resembling those of iodo-cyanine.

Nitratocyanine, $C^{26}H^{23}(NO^3)N^2$, is obtained by precipitating an alcoholic solution of iodiccyanine containing a little nitric acid, with silver nitrate, supersaturating the filtrate (freed from silver by cautious addition of hydrochloric acid) with excess of ammonia, and distilling off the alcohol. The residual resinous mass, which solidifies in the crystalline form, is purified by recrystallisation from very weak spirit. Nitratocyanine crystallises with 1 mol. (3.76 p. c.) water in bronze-coloured highly lustrous rhombic needles and prisms, sparingly soluble in ether and in cold water, more easily and with splendid blue colour in hot water and alcohol. The solution of nitratocyanine in hydrochloric acid deposits by evaporation over quicklime, long transparent prisms of the compound $C^{26}H^{23}N^2O^3 \cdot 2HCl$, which when heated above 65°, gives off HCl , and is converted into the blue salt $C^{26}H^{23}N^2O^3 \cdot HCl$. Nitratocyanine heated with ammonium sulphide yields, together with other products, a slightly basic compound, dissolving with red colour in ether, and separating therefrom in shining yellowish-red monoclinic crystals, whose analysis leads to the formula $C^{26}H^{23}N^2SO^2$.

Sulphatocyanine, $C^{26}H^{23}(SO^4)N^2 \cdot 4H^2O$, is formed, with evolution of iodine and sulphurous oxide, on heating iodiccyanine with excess of strong sulphuric acid:

On diluting the acid solution with water and adding ammonia, the sulphatocyanine is precipitated in bulky red-brown flocks, and separates from a hot aqueous solution, like chlorocyanine, in a mass of long blue needles, resembling a blood-clot.

Cyanine-platinochloride, $C^{26}H^{23}N^2Cl^2 \cdot PtCl^4$ or $C^{26}H^{23}(ClN^2 \cdot HCl) \cdot PtCl^4$, is formed as a yellow hydrated precipitate on adding platinum chloride to the hydrochloric acid solution of a cyanine salt.

Iodiccyanine and its analogues may be regarded as diamines (sulphatocyanine as a tetramine), represented by the following formulæ:

These diamines form mono-acid and bi-acid salts, the latter being colourless, and converted at a moderate heat into the mono-acid salts, which are coloured like the bases themselves. Even silk decomposes the colourless solutions of the bi-acid salts, setting acid free and acquiring a deep blue dye. Chinoline-blue, which appears of an equally beautiful lilac tint by lamplight, is unable to withstand the action of sunlight.

CHINOLINE, HOMOLOGUES OF. Bases obtained, together with chinoline, by distilling cinchonine or quinine with potassium hydrate. Chinoline and lepidine may be partly separated by fractional distillation, and afterwards more completely by fractional crystallisation of their platinum salts (i. 869); but for separating the bases of higher boiling point, the latter method is alone available. The higher portion of the crude distillate (boiling above 270°), freed from pyrrol and other impurities by heating its hydrochloric solution with a little nitric acid, and filtered to separate a resinous mass, gives with platinum chloride yellow precipitates, the first

of which contain the bases of highest molecular weight. The names and formulae of the known bases of the series are given in the following table :

Chinoline,	C^8H^7N .	Pentahioline,	$C^{12}H^{13}N$.
Lepidine,	$C^{10}H^9N$.	Isoline,	$C^{14}H^{17}N$.
Dispoline,	$C^{11}H^{11}N$.	Ettidine,	$C^{15}H^{19}N$.
Tetrahioline,	$C^{12}H^{12}N$.	Validine,	$C^{14}H^{21}N$.

Dispoline is contained in the fraction boiling between 282° and 304° , and forms a beautiful orange-coloured platinum salt. By the action of sodium on these bases a substance is obtained which dyes silk a splendid orange-red (C. Gr. Williams, *Laboratory*, i. 109).

CHLORACETENE. Syn. with chlorethylidene. See ETHYLLIDENE.

CHLORAL. $C^2HCl^3O = CCl^3.CO.H$.—Produced by heating trichloroacetal with sulphuric acid to 150° (Paterno, *Zeitschr. f. Chem.* [2] iv. 733).

Chloral is converted by strong sulphuric acid into insoluble chloral, or metachloral, $C^2H^3Cl^3O^2$, which is afterwards resolved into chloralide and chloroform, or the products of decomposition of the latter, hydrochloric acid and carbon dichloride (Städeler, *Ann. Ch. Pharm.* cvi. 253):

Chloral or metachloral distilled with strong nitric acid, or a mixture of nitric and sulphuric acid, yields chloropicrin, $CCl^3.NO^2$ (Kekulé, *ibid.* 144).

Chloral mixed with an alcoholic solution of sodium ethylate, is converted into chloroform and ethyl formate. The reaction however takes place wholly between chloroform and alcohol; thus:

The same reaction is produced by alcoholic potash, but not by alcohol alone, although great heat is produced on mixing the two liquids. Besides the chief products above mentioned, there are also formed sodium formate, ethyl oxide, and a small quantity of a liquid having a higher boiling point, probably Kay's tribasic formic ether (Kekulé, *Ann. Ch. Pharm.* cxix. 187).

When chloral is mixed with phosphorus pentachloride, added by small portions, the mixture being gently warmed each time, ultimately boiled for some hours, and then mixed with water, an oil separates out, which when distilled yields pentachlorodimethyl or pentachlorethane, C^2HCl^5 or $CCl^3.CHCl^2$:

The same compound appears to have been obtained, though not pure, by Regnault, by the action of chlorine in sunshine on ethyl chloride and ethylene chloride (i. 533, 573) (Paterno, *Zeitschr. f. Chem.* [2] v. 245).

Chloral hydrate introduced under the skin is converted, on coming in contact with the alkali in the blood, into chloroform and formic acid:

The physiological action of chloroform thus generated within the circulation is different from that which it exerts when inhaled, producing deep sleep, but not insensibility to pain. The chloroform and formic acid are ultimately converted into chloride and formate of sodium (Liebreich; Personne, *Compt. rend.* Nov. 8, 1869).

The preparation of chloral hydrate has lately been the subject of considerable attention, but all the methods given are merely modifications of that already described (i. 881). Müller a. Paul pass a current of dry and pure chlorine into pure absolute alcohol for about 70 hours, till the contents of the flask are converted into a white crystalline mass (*Deut. Chem. Ges. Berlin*. No. 16, 1859). See also Thomsen (*Zeitschr. f. Chem.* [2] vi. 156; Roussin, *ibid.* 96; Personne, *Compt. rend.* Dec. 27, 1869). According to Thomsen, chloral hydrate boils at 116° under a pressure of 755 mm., and solidifies at 40.2° . According to Müller a. Paul, it is readily sublimable, and may be thus obtained as a snow-white crystalline powder.
